Identification of the primary cancer site has important implications for prognosis, treatment planning, and salvage surgery. TORS provides an

opportunity to identify small primary cancers in lingual tonsillar tissue that were only recognized if they were identified in random BOT biopsies performed during panendoscopy. While the advent of TORS creates an opportunity to optimize oncologic therapy and potentially reduce side effects by directing therapy to the primary cancer site and also opening the door for de-escalated treatments for HPV positive cancers, it must be remembered that chemoradiation protocols are also effective in treating HNSCCUP. The role of the head and neck surgeon in management of HNSCCUP is not only to assess patients for surgical options but also provide balanced evidence-based alternatives to the patient, especially as evidence and surgical experiences for management of the oropharynx are rapidly changing with increasing experience and technological advances.

Review Questions

1. p16 positivity within the lymph node fine-needle aspiration biopsy can also occur from a non-oropharyngeal primary site.

   a. **True**

   b. False

2. The transoral surgery base of the tongue resection has been shown to detect which percentage of tumors that have failed the traditional workup?

   a. 25%

   b. 50%

   c. 75%

   d. **90%**

3. What are some advantages to identifying the primary tumor site?

   a. Improved oncologic outcomes

   b. Decreased long-term dysphagia

c. Focused radiation

d. **All of the above**

Sentinel Lymph Node Biopsy

Mathew Geltzeiler, and Robert L. Ferris

Introduction

Sentinel lymph node biopsy (SLNB) is primarily used in the head and neck for malignant melanoma and squamous cell carcinoma (SCC) of the oral cavity. The technique is employed to help the surgeon understand the pathologic status of a clinically N0 neck. Multiple prospective randomized trials for melanoma have failed to demonstrate a survival benefit for elective neck dissection in the N0 patient.[1-3] Similarly, no clear survival benefit exists for patients with SCC. Nevertheless, cervical metastasis remains the most important prognostic factor in patients with cancer of the head and neck. As the thickness of the primary cancer increases, so does the risk for cervical metastasis. Traditionally, patients with primary lesions felt to have a more than 20% risk of nodal metastasis would undergo an elective neck dissection. Lesions of lower risk could employ a "watchful waiting" approach. In this lower risk group, SLNB provides a minimally invasive technique to help surgeons better understand the status of the neck while sparing these patients the morbidity of an elective neck dissection. If the SLNB reveals lymph node metastasis, a selective neck dissection is subsequently performed clearing the neck levels at greatest risk for metastasis.[4]

The most important randomized control trial examining malignant melanoma was the 2006 Multicenter Selective Lymphadenectomy Trial (MSLT-1), which was updated again in 2014. MSLT-1 failed to establish a survival benefit for intermediate-risk patients stratified to observation versus SLNB with immediate lymphadenectomy for positive nodes.[2,3] This lack of survival benefit emphasizes the point that the purpose of the SLNB is to deliver prognostic information, provide regional control, and guide additional therapy. From this perspective, SLNB is extremely effective since the most important prognostic factor in survival from

melanoma is the status of the sentinel node, and SLNB has a negative predictive value of 96%.[5]

Similar to melanoma, neck dissection for oral cavity SCC (OCSCCa) has no proven survival benefit. SLNB is useful when the indication to perform elective neck dissection is unclear. The largest study concerning this group is the American College of Surgeons Oncology Group (ACOSOG) study from 2010 which also revealed a negative predictive value of 94% to 96% for T1 to T2 lesions after examining 106 SLNBs.[6] Of note, lesions less than 6 mm were excluded.

The use of SLNB is also being examined in other cutaneous malignancies (i.e., SCC and Merkel cell carcinoma) in addition to other sites in the upper aerodigestive tract (i.e., nasopharynx, oropharynx, and larynx). At this point, the evidence supporting these techniques is still being collected. Similarly, SLNB is being used to determine whether a cancer approaching the midline has unilateral or bilateral drainage pathways to help inform the extent of the neck dissection. Some investigators are also studying SLNB's utility in predicting lymphatic drainage in patients with recurrent cancer. These are areas of active research. We will therefore focus on primary malignant melanoma and oral cavity SCC for the remainder of the chapter.

Key Operative Learning Points

1. SLNB should only be offered to patients who have a clinically N0 neck with malignant melanoma of the head and neck stage 1b or greater.

2. SLNB can also be used for patients who have OCSCCa with T1 to T2 lesions who are clinically N0.

3. SLNB provides prognostic information and determines the need for additional neck dissection and potentially adjuvant therapy.

4. SLNB has approximately 96% negative predictive value in both melanoma and oral cavity SCC.

5. Patients who undergo subsequent neck dissection for a positive SLNB have no benefit in overall survival but benefit from reduced regional recurrence.

6. Sentinel lymph nodes are removed until the remaining count on the

gamma probe has reduced 90% from the original value.

7. Thinner sectioning of the sentinel lymph node (SLN) and immunohistochemical testing for cancer markers differentiate this technique from routine lymph node evaluation. Immunohistochemistry (IHC) for S-100 and melan-A (MART-1) are used for melanoma and cytokeratin used for SCCa.

8. Patients should be counseled on the possible need to undergo two operations.

9. Optimal injection requires a comfortable patient, especially for oral cavity lesions.

10. Avoid injection of local anesthetic in the immediate vicinity of the tumor.

11. Accurate injection of radiocolloid into the dermal lymphatics is crucial.

12. Avoid "shine through" artifact by properly injecting the primary tumor, resecting the primary tumor first, and creating adequate exposure to direct the gamma probe at the lymph nodes but away from the primary site.

Preoperative PERIOD

History

1. All patients with cancer of the head and neck should undergo a complete history and physical examination.

2. Patients with malignant melanoma will typically describe a cutaneous lesion that is changing in size, shape, or color. The lesion can also be pruritic, while at later stages it may bleed and become painful. A history of sun exposure, sunburns, prior skin biopsies, prior skin cancers, occupation, and family history also should be sought.

3. Patients with OCSCCa will typically report a lesion in the mouth that has persisted or is slowly growing over time. The lesion can become painful and cause bleeding. A history of dysarthria, dysphagia, odynophagia, ill-fitting dentures, and weight loss should be sought.

Importantly, tobacco (smoking and chewing) and alcohol use should be discussed.

Physical Examination

1. Primary malignant melanoma should be evaluated for the "ABCDE" checklist. Lesions of concern are **a**symmetric, have **b**order irregularity, **c**olor variation, and a **d**iameter of greater than 6 mm, and be **e**volving over time.

2. Patients with malignant melanoma require a full body cutaneous examination searching for second primary lesions. Great care must be taken when examining the patient's scalp as hair can make identifying additional lesions difficult.

3. The pinna should be carefully examined along with palpation of the parotid gland and neck.

4. Evaluation of facial nerve function is important for primary cancers at risk of draining to the parotid lymph node basin.

5. For OCSCCa, complete evaluation of the upper aerodigestive tract mucosa is imperative, including flexible fiberoptic laryngoscopy, as many patients will be at risk for second primary lesions given the high incidence of smoking and alcohol use in this patient population.

6. Palpation of the primary lesion can give a sense of the depth of the cancer. For a lesion of the tongue, one should assess mobility. Additionally, attention should be paid to the function of the mental, lingual, and hypoglossal nerves.

7. Oral opening should also be assessed, as trismus is not only indicative of invasion into the pterygoid muscles but also makes performing injection of the radiotracer into the primary difficult.

8. All patients should have their neck palpated to search for cervical lymph node metastasis.

Imaging

1. Patients with malignant melanoma and SCC of the head and neck will

undergo a computed tomography (CT) scan of the neck with contrast to evaluate for cervical lymph node metastasis. The CT scan will also give information on the degree of invasion for larger primary cancers.

2. The metastatic evaluation for malignant melanoma and SCC is dictated by the stage of the primary tumor. Patients who are candidates for SLNB are clinically N0. Stage 1 patients do not require any chest imaging. Stage 2 and 3 patients should undergo optional chest imaging.

3. Chest radiograph is preferred for melanoma, and chest CT scan should be considered with OCSCCa patients with a prior history of smoking. Lastly, patients who have stage 3 melanoma can get an optional lactate dehydrogenase level.

4. Lymphoscintigraphy during the SLNB procedure will be discussed below.

Indications

1. For malignant melanoma, SLNB has proven to be the most sensitive and specific tool for identification of occult cervical metastasis with a negative predictive value of approximately 96%.[5]

2. SLNB is currently recommended for all patients with melanoma with a primary tumor that is >1 mm thick and a clinically N0 neck.

3. The National Comprehensive Cancer Network (NCCN) additionally recommends offering SLNB to stage 1b patients (≤1 mm thick with ulceration or mitotic rate ≥1 per mm^2).[7]

4. The NCCN notes that one can consider a SLNB in T1a patients (tumor <1 mm without ulceration and low mitotic rate) with other negative prognostic factors like young age, angiolymphatic invasion, or deep positive margins.[7]

5. For OCSCCa, the indications are slightly less clear. Traditionally, most cancers of the oral cavity would warrant an elective neck dissection. Patients with only superficially invasive lesions might have their neck observed.

6. The ideal lesion for SLNB is a T1 to T2 with intermediate thickness (2–4 mm). Cancers with invasion into deeper structures are better served with

elective neck dissection.

Contraindications

1. SLNB is only offered to patients who are clinically N0. Therefore, the presence of clinically positive lymphadenopathy is an absolute contraindication to the procedure.

2. OCSCCa with advanced-stage primary cancer (T3 to T4 lesions) carries a high enough risk of occult lymph node metastasis that elective neck dissection is more appropriate than SLNB. Additionally, the patient should have adequate oral opening, and the cancer should be in a location that is easily accessible for injection of the radiotracer.

Preoperative Preparation

1. Clinical staging should be completed, and indications for the procedure must be validated prior to the surgery.

2. Preoperative check must be made to ensure that the required instrumentation is available prior to surgery, especially ensuring coordination with the nuclear medicine team.

Operative Period

Anesthesia

1. SLNB can be performed under monitored anesthesia care (MAC) or general anesthesia.

2. Patients with OCSCCa are better served with general anesthesia, as resection of the primary is easier with the patient intubated.

Perioperative Antibiotic Prophylaxis

1. Antibiotic protocols vary by institution. SLNB is a clean procedure; therefore antibiotic prophylaxis is not required. At our institution, skin flora is routinely covered with Cefazolin.

Positioning

1. The patient is positioned supine with a horizontally oriented shoulder roll.

Monitoring

1. The surgeon can consider the use of facial nerve monitoring for lesions in the parotid gland. We do not routinely use facial nerve monitoring when performing SLNB.

Instruments and Equipment to Have Available

1. Handheld gamma probe

2. Technetium 99 (^{99}T)

3. Methylene blue

Key Anatomic Landmarks

1. Understanding the natural flow of lymph throughout the head and neck is critical for planning surgical interventions.[8] The location of the primary cancer dictates the cervical nodal basins at greatest risk for metastasis. While these relationships are not directly involved with performing an SLNB, they do help surgeons predict the location of the sentinel node and inform the extent of the therapeutic neck dissection, if necessary.

2. The surgeon can draw an imaginary coronal plane through the external auditory canal. For primary cancers of the facial skin, ear, and scalp, lesions arising anterior to this plane typically drain through the parotid lymph nodes then down to jugular lymphatic chain.

3. More inferiorly and anteriorly located lesions (i.e., the chin) can drain through the facial and submandibular lymph nodes, avoiding the parotid.

4. Lesions posterior to this coronal plan will drain to the postauricular, occipital, and posterior triangle lymphatics.

5. Surgeons should be comfortable performing the resection and reconstruction of cutaneous lesions in anatomically high-risk areas (i.e., near the lips and eyelids).

6. For OCSCCa, the lymphatics at greatest risk are the facial, submental, and submandibular lymph nodes, which then drain to the jugular chain.

7. Understanding the surgical anatomy of the parotid and neck is critical to avoiding morbidity when performing SLNB. Approximately 25% to 30% of head and neck melanomas drain through the parotid bed.[9]

8. When sentinel lymph nodes are detected in the parotid, the surgeon can safely remove the nodes without performing a superficial parotidectomy because these nodes typically lie within the superficial lobe of the gland.[10] However, the surgeon should always be aware of the proximity of the facial nerve and be prepared to perform a superficial parotidectomy if necessary.

9. Facial nerve monitoring can be considered as an adjunct tool in this setting.

10. For sentinel nodes that are present in the neck, great care must be taken to preserve the spinal accessory nerve as well as the other critical neurovascular structures typically saved in a selective neck dissection.

Prerequisite Skills

1. Surgeons should be experienced in performing the resection and reconstruction of cutaneous lesions in anatomically high-risk areas (i.e., near the lips and eyelids).

2. Surgeons should be experienced in performing superficial parotidectomy with preservation of the facial nerve, if required.

3. Surgeons should be experienced in performing the selective neck dissection if the sentinel node is found to be positive.

Operative Risks

1. SLNB is a safe procedure with a complication rate of less than 1%.

2. Injury to the facial nerve and spinal accessory nerve are both potential risks of the procedure depending on the location of the sentinel node.

3. Morbidity from the resection of the primary tumor is also an important consideration. As mentioned previously, the surgeon should feel comfortable with resection and reconstruction of the primary tumor site.

Surgical Technique

1. Effective collaboration with nuclear medicine physicians is essential in performing effective SLNB.

2. Prior to the operating room, the patient is brought to the nuclear medicine suite, and the primary tumor site is injected with radiotracer.

3. Lymphoscintigraphy is subsequently performed, and the first node to which the tracer flows is defined as the sentinel lymph node. This site is marked on the patient's skin.

4. Lymphoscintigraphy can also be fused with a CT scan for increased spatial localization.

5. The injection typically takes place the morning of the procedure but can also be done the night prior. The ideal time delay is not defined, but we prefer to perform the operation within 4 hours of the injection.

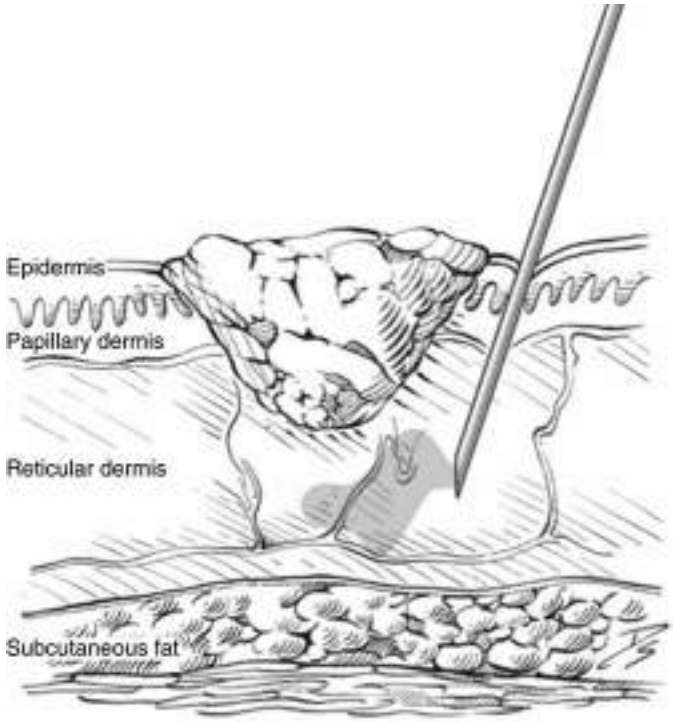

FIG. 62.1 Proper depth and location for injection of radiocolloid (^{99}T) and methylene blue. Taken with permission from Cohen J and Clayman G, Atlas of Head & Neck Surgery, Elsevier; Phila, PA 2011.

6. ^{99}T is the only available radiocolloid in the United States, but others can be obtained in Europe. ^{99}T is available in filtered and unfiltered forms. The unfiltered form is preferred, as it does not flow downstream as quickly. While this decreases the likelihood of finding multiple sentinel nodes, it does result in increased "shine through" artifact, which is when residual tracer at the primary site interferes with readings around the nodal basin. "Shine through" artifact is a more pronounced concern with oral cavity lesions than melanoma.

7. The operating room staff is exposed to a minimal amount of radiation during these cases. The dose is sufficiently low to not require any special precautions; however, team members, especially those who may be pregnant, should be notified.

8. Injection of the radiotracer is performed at the primary site in an awake patient. The use of anesthesia with endoscopic guidance is only required for pharyngeal, laryngeal, and sinonasal tumors, which are still under investigation.

9. A narrow needle (25 g) is used to inject 4 to 5 mL of ^{99}T with a

circumferential or four-quadrant technique into the underlying dermis for melanoma (Fig. 62.1).

10. Oral cavity cancers should be injected along their leading mucosal edge and within the cancer itself (Fig. 62.2).

11. It is important in either case not to inject into the subcutaneous or submucosal spaces as these do not accurately map the sentinel node and can lead to excessive "shine through" artifact.

12. The patient can be given mild sedation or regional anesthesia for oral cavity cancers, but one should avoid directly injecting the area of the tumor with epinephrine containing local anesthetic as this may affect the lymphatic drainage.

13. If the primary cancer has already been resected, the remaining scar can be injected with good results shown in melanoma.

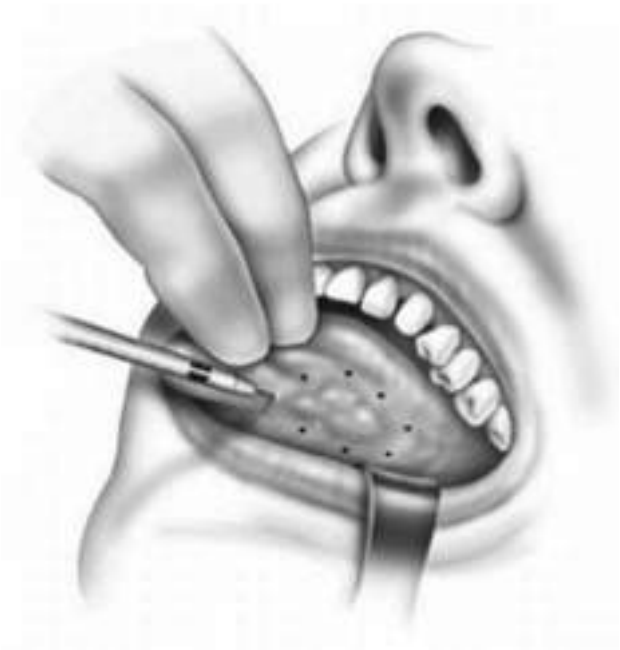

FIG. 62.2 An example of proper injection technique of radiocolloid for a cancer of the oral cavity. Taken with permission (permission yet to be requested) from Myers and Ferris, Master Technique in Otolaryngology—Head and Neck Surgery, vol 1. Thyroid, Parathyroid, Salivary Glands, Paranasal Sinuses and Nasopharynx, Wolters Kluwer Health-Lippincott Williams & Wilkins; Phila, PA 2014.

14. The sentinel node is then mapped with lymphoscintigraphy plus or minus CT scan as previously described.

15. The patient is then taken to the operating room and positioned with the head of the bed rotated 90 degrees away from the operative side. A horizontally oriented shoulder roll is placed, and the sentinel node position is confirmed with the gamma probe.

16. Excision of the primary site should include adequate margins based upon the depth of the cancer for melanoma and T-stage for OCSCCa.

17. The incision for the SLNB should be planned with consideration of the subsequent neck dissection, if required (Fig. 62.3).

18. Methylene blue is then injected in a similar manner to the ^{99}T as already described. Typically 0.2 to 0.5 mL is injected into the dermal lymphatics, which produces a characteristic bluish infiltrate. The purpose of the methylene blue is to color the sentinel node and make intraoperative identification easier.

19. Methylene blue is preferred to isosulfan blue due to the approximately 1% incidence of anaphylaxis with isosulfan.

20. The patient is then prepped and draped.

21. The primary cancer is excised first. Performing this step first gives the methylene additional time to flow to the sentinel node and removes residual ^{99}T at the primary site to help with confounding "shine through." Oral cavity cancers can be sent for frozen section determination of margin status. This step is usually skipped in melanoma.

22. The sentinel lymph node dissection is then performed. Exposure to the site will vary depending on the location of the node. As mentioned earlier, sentinel nodes located within the parotid gland can be removed safely without performing a formal superficial parotidectomy.

23. The gamma probe sensor is directional in nature, so adequate exposure should allow for placement of the probe directed at the sentinel node, yet away from the primary site. The methylene blue can help visually identify the sentinel node and can also illuminate small lymphatics, which can be followed to the sentinel node.

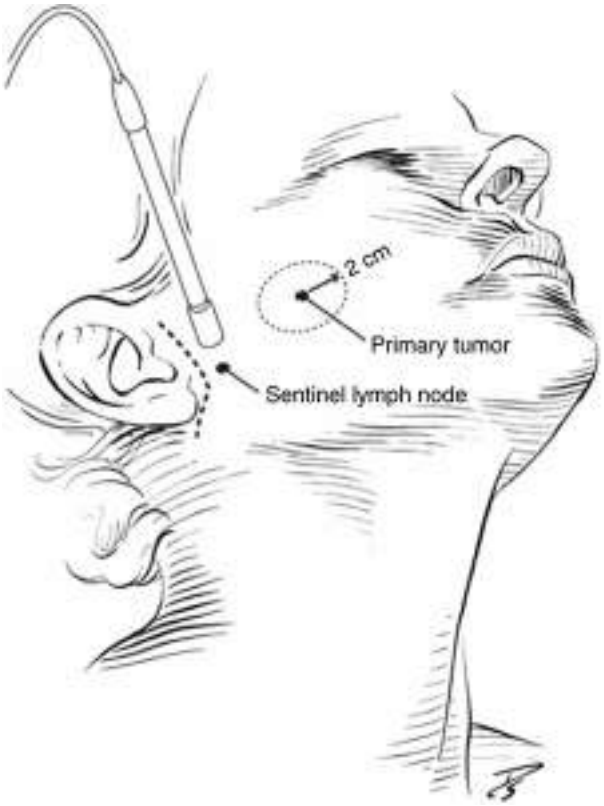

FIG. 62.3 An example of a primary cancer site with planned incision for sentinel lymph biopsy. Taken with permission (permission yet to be requested) from Cohen J and Clayman G, Atlas of Head & Neck Surgery, Elsevier; 2011.

24. Once the sentinel lymph node is identified, a 10-second count on the gamma probe is performed and recorded (Fig. 62.4A). The node is then removed, and the count is repeated on the specimen node itself. Lastly, a count is performed within the remaining lymphatic bed (Fig. 62.4B).

25. If a single sentinel node is removed, there should be no more than 10% residual activity within the nodal bed. Any more than 10% means that the node removed was not the only sentinel node or the patient has multiple sentinel nodes. In either case, additional nodes should be removed until a 90% reduction from the original maximum count is reached.

26. It is not uncommon to have multiple sentinel lymph nodes present in cancers in the head and neck. If the surgeon is unable to reduce the residual activity to 10%, judgment must be used to determine when to stop. We typically do not remove more than 4 sentinel nodes.

27. The wound is then closed in layers.

28. After removal, the specimen is sent to pathology and specifically labeled as "sentinel lymph nodes." Proper labeling is important, as the pathology team will perform finer sectioning of the nodes than typically performed with a standard neck dissection. Serial sectioning, usually 150 to 200 μm, is utilized with hematoxylin and eosin (H&E) staining in addition to IHC for S-100 and MART-1 for melanoma.

29. Frozen section is not used in melanoma.

30. With OCSCCa, frozen section of the node can be useful because the selective neck dissection can be performed immediately. However, the sensitivity of frozen section for SCC is only 60%.[6]

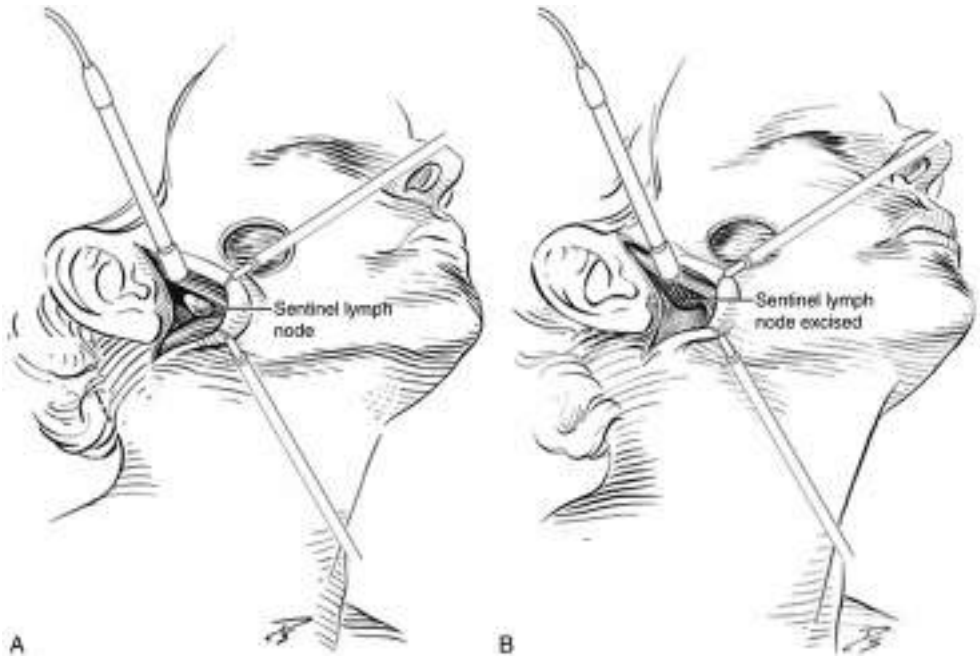

FIG. 62.4 **A,** Identification of sentinel lymph node with gamma probe and, **B,** measurement of residual activity after sentinel lymph node removal. Taken with permission (permission yet to be requested) from Cohen J and Clayman G, Atlas of Head & Neck Surgery, Elsevier; Phila, PA 2011.

Common Errors in Technique

1. Injection of the ^{99}T and methylene blue should be into the subdermal

plexus, which is the location of the lymphatics, and not deeper in the subcutaneous tissue. Oral cavity cancers should be injected along their leading mucosal edge and within the cancer itself.

2. "Shine through" artifact is when radiation from the primary injection is inadvertently detected by pointing the gamma probe toward the primary when searching for a sentinel node in the neck. This problem is most commonly encountered when looking for level 1 A sentinel nodes for a primary cancer of the floor of mouth. "Shine through" artifact can be minimized by properly injecting the primary cancer, resecting the primary cancer first and creating adequate exposure to direct the gamma probe at the lymph nodes but away from the primary site.

3. No more than four sentinel lymph nodes need to be removed even if a 90% reduction of background activity has not been achieved.

Postoperative Period

Postoperative Management

1. Routine postoperative care can be performed as similar to excisional lymph node biopsy.

2. Drains typically are not required unless a neck dissection is performed.

Complications

1. Complications for SLNB are rare.

2. As noted previously, there is less than 1% incidence of injury to the facial and spinal accessory nerves.

Alternative Management Plan

1. For malignant melanoma, the SLNB has become the standard of care, and indications for SLNB are covered in the *Indications* section above. For lower risk patients, the neck can be observed. For higher risk patients, an elective neck dissection can be performed.

2. For OCSCCa, the ideal cancer for SLNB is a T1 to T2 with intermediate thickness (2–4 mm mm). A small superficially invasive cancer can be managed with resection alone with no neck dissection as long as the patient is clinically N0. T2 and larger cancers all require management of the neck with either an SLNB or neck dissection. Given that OCSCCa is typically managed surgically, elective neck radiation is generally not indicated.

Discussion

Evidence-Based Medicine Question

Does performing SLNB improve overall survival for patients with malignant melanoma and SCC of the oral cavity?

There is no clear survival benefit that has been established for performing SLNB for malignant melanoma or OCSCCa. Additionally, no survival benefit exists when performing a neck dissection in an elective or therapeutic manner in either of the disease processes. The purpose of the SLNB is to provide prognostic information and help to guide additional therapy and reduce regional recurrence.

Editorial Comment

SLNB addresses a decision-making process with respect to elective neck dissection in early stage melanoma and OCSCCa. Although evidence does not point to improvement in overall survival, as we have mentioned, SLNB provides valuable prognostic information that can guide further treatment and reduce regional recurrences, both of which bring value to overall patient care. A recent article in NEJM by DCruz AK et al. (2015) reports improved overall and disease-free survival in patients undergoing elective versus therapeutic neck dissection for early-stage (T1 to T2) oral cancer. Future research will further elaborate when we, as head and neck surgeons, must be aggressive surgically in the management of the neck and also develop criteria for avoiding neck dissections and avoiding unnecessary morbidity to the patient.

Access the review questions and additional source list online at http://www.expertconsult.com

Review Questions

1. Which of the following patients would be a candidate for a sentinel lymph node biopsy (SLNB)?

   a. 1.6-mm thick melanoma with a single palpable cervical lymph node

   b. 0.5-mm thick melanoma with negative surgical margins

   c. **1.1-mm thick melanoma without angiolymphatic invasion**

   d. T3N0 oral cavity squamous cell carcinoma (SCC) with trismus

2. Before removal of the first sentinel lymph node, the activity in the field is 6400. After removal of the node, what level of residual activity would signify the end of the procedure?

   a. **500**

   b. 700

   c. 1000

   d. 3200

3. A patient is scheduled for an SLNB at noon. When should the primary cancer be injected with Technetium 99 (^{99}T)?

   a. Within 3 days of the procedure

   b. **At 8 a.m. that morning**

   c. Immediately prior to going into the OR

   d. Just prior to resection of the primary tumor

4. A patient is scheduled for an SLNB at noon. When should the primary tumor be injected with methylene blue?

   a. Within 3 days of the procedure

   b. At 8 a.m. that morning

   c. Immediately prior to going to the OR

   d. **Just prior to resection of the primary tumor**

5. The proper site of injection of the radiocolloid for malignant melanoma is

   a. Within the epidermis

   b. Within the dermis

   c. Within the subcutaneous fat

   d. **Into the primary lesion itself**

Superselective Neck Dissection

Brian J. Boyce, and David M. Cognetti

Introduction

The nodal status of the neck remains one of the most important prognostic factors for overall survival in patients with cancer of the head and neck. The lymphatic drainage of the neck is organized into anatomic compartments (Fig. 63.1). The type of neck dissection depends on the nodal levels removed and the extent of nonlymphatic structures preserved (Table 63.1). Over the past century, the surgical approach to regional nodal metastases has continued to evolve in an effort to lessen morbidity while preserving locoregional control and survival rates. The radical neck dissection for a clinically positive neck was described by Crile more than 100 years ago and included removal of the sternocleidomastoid (SCM) muscle, spinal accessory nerve (SAN), internal jugular vein (IJV), submandibular gland, and sensory rootlets, in addition to the lymphatic bearing fibroadipose tissue. In the 1950s Suarez found success using an approach that preserved at least one of the nonlymphatic tissue-bearing structures that would come to be known as the modified radical neck dissection, which would be popular throughout the 1950s and 1960s. In both of these procedures, the lymph node levels I–V were removed, but the postoperative morbidity was decreased with the modified radical neck dissection. In the 1960s and 1970s, Ballantyne advocated for the removal of only the nodal compartments at highest risk while leaving some nodal stations undissected and preserving all nonlymphatic structures. This type of dissection would be known as the selective neck dissection and has many variations, including the supraomohyoid and the lateral neck dissection. The concept of selective neck dissections was further popularized by the work of Lindberg and then by Shah, which showed that regional spread occurs in an orderly and predictable fashion. Many studies have shown

that selective neck dissection has decreased the morbidity with surgical treatment of the neck, while preserving oncologic safety in both the N0 and N+ neck.

Recently there has been an interest in more precisely targeting nodal levels at risk and further minimizing potential complications by using the superselective neck dissection (SSND). This technique is defined by dissection of only one or two contiguous nodal stations and preservation of all nonlymphatic bearing tissue. In this chapter we will discuss the indications, technique, and rationale for SSND.

Key Operative Learning Points

- SSND is the removal of one or two contiguous neck levels while preserving all nonlymphatic structures.
- SSND is appropriate for N0 necks by examination and imaging, salvage neck dissections with a single concerning node, and indeterminate lateral nodes in papillary thyroid cancer (PTC).
- SSND performed for oral cavity primaries and N0 neck should include levels I and II.
- SSND performed for laryngeal primaries and N0 neck should include levels II and III.
- The goal of SSND is to minimize morbidity while maintaining regional control and survival rates.

Preoperative Period

History

- All patients with cancer of the head and neck should have a complete basic history regarding the mass in the neck, including onset, duration, location, pain, severity, and progression.
- All patients should be questioned about dyspnea, dysphagia, weight loss (how much over specific time period), hemoptysis, dysphonia, and otalgia.

- All patients should be asked about previous cancer of the head and neck. If yes, how were they treated? Surgery? Radiation? Chemotherapy? Combination of modalities?
- A full social history should be included regarding their occupation use of tobacco and alcohol, illicit drugs, and exposure to carcinogens or radiation.
- The patient should have a good social support system and be motivated to proceed with SSND. Reliability is an important factor as well, since close surveillance and follow-up are warranted.
- All patients should have a detailed family history performed with an emphasis on malignancies of the head and neck/thyroid.

Past Medical History

- The history regarding bleeding and coagulation disorders must include a history of bleeding or bruising easily. Ask about a family history of bleeding easily or a history of hemophilia or von Willebrand's disease.
- Ask if there is a history of reactions to general anesthesia or malignant hyperthermia.
- Ask about a history of previous neck surgery (cervical spine fusion, thyroid surgery, previous neck dissection or open biopsies, carotid endarterectomy).
- Review the list of medications.
  - Any anticoagulants other than aspirin should be held in the perioperative period.
  - All herbal and over the counter (OTC) vitamins should be held perioperatively.
- Ask all patients about risk factors for poor wound healing (chronic steroid use, hypothyroidism, connective tissue disorders).

Physical Examination

- Overall appearance of the patient: Cachectic? Dehydrated? Well-nourished?

- Primary site: Note the location of the primary cancer and whether it extends to areas that include bilateral lymphatic drainage (midline lesions such as the base of the tongue, floor of the mouth, or supraglottis). It is important to estimate the thickness of the cancer, since this has been shown to correlate with occult cervical metastases.
  - In patients who have been previously treated for the cancer, evaluate for complete response, and biopsy any suspicious areas (leukoplakia, erythema, or ulcerations).
- Evaluate all mucosal surfaces of the oral cavity, oropharynx, larynx, and hypopharynx to rule out synchronous lesions.

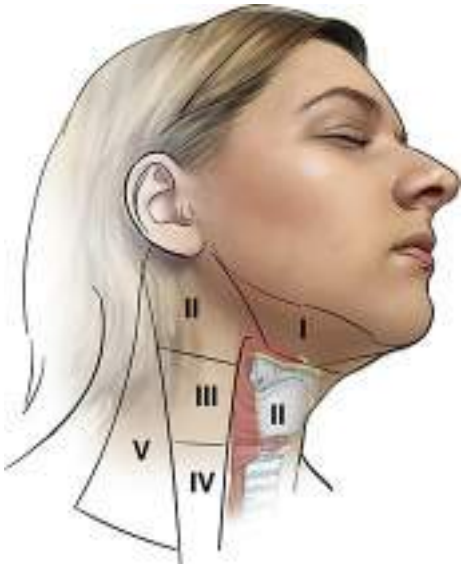

FIG. 63.1 Nodal compartments in the neck.

TABLE 63.1

Classic Definitions of Neck Dissections

Radical neck dissection	Removal of nodal compartments I–V, IJV, SCM, and CN XI
Extended radical neck dissection	Removal of nodal compartments I–V, IJV, SCM, CNXI, and a nonlymphatic structure (nerve, vessel, muscle, skin, etc.)
Modified radical neck dissection	Removal of nodal compartments I–V and preservation of at one of the following: IJV, SCM, or CN XI
Selective neck dissection	Removal of lymphatic bearing tissue only, leaving at least 1 nodal compartment undissected
Superselective neck dissection	Removal of one or two contiguous nodal compartments and preserving all nonlymphatic tissue

IJV, Internal jugular vein; *SCM,* sternocleidomastoid.

- Perform laryngoscopy to search for any mucosal lesions and vocal fold mobility.
- Neck: Palpate for any appreciable lymphadenopathy and note the level. Is the mass freely mobile or adherent to the skin or underlying structures?
  - Evaluate mobility, including flexion and extension. Look for scars or evidence of previous surgery.
  - In patients who have previously undergone radiotherapy to the neck, note the pliability and firmness of the tissue.
- It is important to note baseline function, especially in patients who have been previously treated.
  - Shoulder mobility, normal protrusion of the tongue, facial nerve movement, and vocal fold mobility

Imaging

- With an overall 30% rate of occult lymph node metastases in squamous cell carcinoma (SCCa) of the head and neck, physical examination of the neck should be augmented with imaging.
- The best imaging modality to detect nodal disease not appreciated on physical examination is controversial. While the sensitivity, specificity, and predictive values vary depending on the institution, we suggest that any of the modalities listed here are excellent options either in the pretreatment or posttreatment setting.
  - Ultrasound
  - Computed tomography (CT) scan with contrast
  - Magnetic resonance imaging (MRI) with gadolinium
  - Positron emission tomography - Computed tomography (PET-CT)

Indications

- There are currently two clinical situations where SSND is considered:

- Patients whose primary cancer is in the larynx or oral cavity and an N0 neck by examination and imaging
- Patients who have been previously treated with either surgery or radiotherapy and have a persistent neck mass

- Another proposed indication is an SSND for pathologically indeterminate lateral neck nodes but clinically suspicious for patients with malignancy. These are typically patients who have nodes that are suspicious on ultrasound or CT, but the fine-needle biopsy was indeterminate or unable to be performed due to the location of the lymph node.

Contraindications

- Poor surgical candidate based on the patient's medical status or comorbidities
- Patients with distant metastatic cancer
- In patients undergoing primary treatment, known cervical lymph node metastases are a contraindication to SSND. These patients will have a high risk of having nodal metastasis extending beyond one or two levels.
- Any evidence of extracapsular extension that would require sacrifice of nonlymphatic tissue

Preoperative Preparation

- All imaging should be reviewed prior to surgery. Any previous biopsies or pathology slides should be reviewed in house. We recommend a second review at the end of the case but before closing to ensure that no other suspicious areas were missed initially.

Operative Period

Anesthesia

- General endotracheal anesthesia with the endotracheal tube taped to the side opposite the neck dissection
- Paralysis should be avoided so that the surgeon can stimulate nerves once identified and be alerted by movement if dissecting near a nerve.

Positioning

- Supine with a shoulder roll or inflatable pillow for cervical extension. Exercise caution in patients with fusions or overextension in elderly patients.
- We prefer that the table be turned 180 degrees away to allow freedom of movement around the patient's head and neck.

Preoperative Antibiotic

- The use of preoperative antibiotics in clean cases such as neck dissections is controversial. It is also important to note that many patients with cancer of the head and neck have risk factors for surgical site infections (age, poor nutrition, diabetes mellitus, tobacco and alcohol use, recent hospitalization, and previous treatment with radiation and chemotherapy).
- The World Health Organization advocates preoperative antibiotic prophylaxis in all cases.
- The American Society of Health System Pharmacists recommends against the routine use of antibiotics in clean cases without mucosal contamination.
- We routinely use a single dose of Ancef (cefazolin) before incision and discontinue it in the postoperative period, given the risk factors listed previously in patients with cancer of the head and neck and the low risk of a single preoperative antibiotic dose. Clindamycin is an alternative choice in patients with an allergy to beta-lactam antibiotics.

Monitoring

- Nerve monitoring is not used routinely. A handheld probe is used to

confirm identification and function of nerves. The use of continuous neuromonitoring is controversial, but typically monitored nerves include the spinal accessory and marginal mandibular branch of the facial nerve. There is some predictive value of postoperative function to neuromonitoring CN XI based on amplitude and latency changes. However, these nerves should be at low risk during an SSND.

Instruments and Equipment to Have Available

- Standard neck dissection set
- Handheld nerve stimulator
- Many surgeons use energy devices to seal and cut vessels using ultrasonic or bipolar energy.

Key Anatomic Landmarks

- Platysma: This is the first muscle that is visualized after performing the initial incision on the neck. It is divided, and sub-platysmal flaps are elevated superiorly and inferiorly.
- External jugular vein (EJV): Located inferior to the great auricular nerve as it courses over the superior third of the SCM. EJV can have several communications to the facial, deep facial, and retromandibular veins.
- Great auricular nerve: Located just above the EJV and is the sensory nerve to the earlobe, and the skin around the inferior aspect of the auricle
- Marginal mandibular nerve: Branch of the facial nerve that innervates the depressor anguli oris, depressor labii inferiorus, and mentalis. It can be routinely identified coursing over the facial vessels at the mandibular notch or 1 cm anterior and 1 cm inferior to the angle of the mandible.
- The fibroadipose tissue containing lymphatic structures and nodes is located between the fascia of the SCM laterally, carotid sheath

medially, and deep layer of the deep cervical fascia.

- Posterior belly of the digastric muscle: This separates level IB from IIA. It is safe to dissect on the inferior border of this muscle. The facial vein runs superficial to the digastric, so care must be taken not to damage this structure as it crosses. The spinal accessory and hypoglossal nerves run deep to the digastrics and should be safe while dissecting on the superficial surface of the muscle.
- Omohyoid: Strap muscle that originates from the scapula and inserts on the hyoid bone and depresses the larynx, and it defines the border of level III and IV. Dissecting on the superficial surface of this muscle protects the contents of the carotid sheath.
- Hyoid bone: Horseshoe-shaped structure in the upper neck that divides level II and III. Consists of the body, lesser cornu, and greater cornu.
- Hypoglossal nerve: Innervates the muscles of the tongue except for the palatoglossus. It can be found immediately anterior to the IJV in level IIA or inferior to the posterior belly of the digastric coursing under the ranine veins.
- SAN: Motor nerve to the SCM and trapezius muscles. It has a variable relationship to the IJV and can course over (96%), under (3%), or through (1%) the IJV. It can be found high in level IIA as it crosses the IJV, at its insertion in the SCM around the tendon, about 1 cm above Erb's point or about two finger breadths above the lateral clavicle as it enters the trapezius. It divides level IIA from IIB.

Prerequisite Skills

- Experience with radical neck dissection, modified radical neck dissection, and selective neck dissection techniques

Operative Risks

- The risks of this procedure are similar to those in any neck dissection. The risks should be minimized due to the limited dissection area, but thorough anatomic knowledge of the neck is essential.

- Poor wound healing (especially radiated patients), hematoma, infection, scarring, shoulder dysfunction, chyle leak, marginal mandibular nerve weakness, damage to major vessels including stroke, voice problems and swallowing difficulty, phrenic nerve damage resulting in paralyzed diaphragm, numbness, and Horner's syndrome

Surgical Techniques

- This description provides a technique that can be applied to all levels of the neck that are indicated for SSND.
- For lesions that have bilateral lymphatic drainage (supraglottis, floor of the mouth), bilateral SSND should be performed.
- An incision should be planned in an existing transverse skin crease if possible. We recommend injection into the skin crease with 1% lidocaine and 1:100,000 parts epinephrine prior to incision. Given the limited dissection area, a smaller incision can be made.
- The incision is carried down through the subcutaneous tissue until the platysma is identified. It should be divided and subplatysmal flaps elevated circumferentially. Care should be exercised to elevate these flaps immediately deep to the platysma to avoid damaging superficial structures such as the marginal mandibular nerve superiorly over the mandible. This is especially true in thinner patients who have little fibroadipose tissue present.
- Identify and preserve the EJV and great auricular nerve when elevating subplatysmal flaps.
- For oral cavity primary SSCa, dissection of level I is necessary. The first maneuver should be to identify the marginal mandibular nerve. It can be found in a 1 × 1-cm area at the mandibular notch or approximately 1 cm and anterior and inferior to the angle of the mandible. The nerve must be dissected free and swept superiorly over the mandible to protect it during further dissection.
  - Dissection then proceeds along the inferior aspect of the mandible to displace the submandibular gland and fibroadipose contents inferiorly. The facial artery and vein must be controlled and ligated

at this step.

- Dissect inferiorly along the anterior and posterior belly of the digastric. The facial vein must again be identified and controlled along the posterior belly of the digastric.
- Begin by reflecting the fibroadipose tissue laterally off the mylohyoid. Here the nerve to the mylohyoid and submental vessels are encountered and can be ligated. The submental vessels can retract and cause bothersome bleeding, so pre-emptive control is important. Once the mylohyoid is free, retract it medially using an Army-Navy retractor.
- The loose areolar tissue around the submandibular gland can be pushed away with blunt dissection until the specimen is pedicled on the submandibular ganglion and submandibular duct. The facial artery can be ligated as it emerges from behind the posterior belly of the digastric.
- The submandibular ganglion is divided to preserve the lingual nerve, and the duct is ligated as close to the floor of mouth as possible, which mobilizes the specimen.
- Level IA can be quickly dissected off of the mylohyoid centrally between the two anterior bellies of the digastric.

- Dissect along the anterior border of the SCM while reflecting the muscle laterally and fibroadipose contents medially. The SAN should be identified and preserved as it enters the SCM. Care should be exercised in avoiding the branch of the SAN to the trapezius, as this branch can leave CN XI before it enters the SCM (Fig. 63.2). The SAN should be traced in a superomedial direction until it intersects the IJV under the posterior belly of the digastric. Retraction of the posterior belly superiorly aids in this dissection. We do not routinely advocate the dissection of level IIB in N0 necks, given the low incidence of isolated disease in the absence of level IIA metastases. This also reduces potential injury to CN XI and postoperative morbidity.
- Once the posterior edge of the SCM is reached, change the angle of dissection and begin moving in a medial direction.
- Identify the cervical sensory rootlets and elevate the fibroadipose tissue off of these nerves, keeping them intact. Do not dissect deep to the

omohyoid muscle into level IV in salvage neck dissections for oral cavity/laryngeal primaries with N0 necks. This minimizes the risk of damage to the transverse cervical vessels, thoracic duct, and phrenic nerve. When dissecting level IV for indeterminate lateral lymphadenopathy in PTC, dissection should proceed over the deep cervical fascia to protect the phrenic nerve. The transverse cervical artery and vein will be visualized as well, and small branches off them to the nodal packet should be controlled. When dissecting medially in level IV, the fibroadipose contents should be clamped and ligated to prevent a chyle leak.

FIG. 63.2 Right superselective neck dissection with complete isolation of the spinal accessory nerve and no fibroadipose tissue remaining lateral to the internal jugular vein.

- As the specimen is dissected medially the carotid sheath is encountered. It is important to recognize this landmark and not to continue dissection behind the carotid artery, which puts the sympathetic chain at risk.
- We use a 15-blade scalpel to dissect the contents off of the IJV, carotid artery, and vagus nerve. Care should be taken in controlling small vessels off the IJV, which can result in significant bleeding if cut. Attempts to preserve the ansa cervicalis are encouraged but not mandatory. The jugular vein should be nearly circumferentially free

after this portion of the dissection.

- Medial to the IJV dissection proceeds over the descendens hypoglossi to remove the remainder of level III to the sternohyoid. In level IIA, the hypoglossal nerve should be identified, and the fibroadipose contents superficial to it should be removed (Fig. 63.3**).**
- A drain is placed after a Valsalva is performed and hemostasis is achieved.
- A layered closure of the platysma and skin is performed

Common Errors in Technique

- Not choosing the correct patient for this procedure
- Not recognizing suspicious lymph node metastases on imaging
- Not removing involved lymph nodes in a salvage neck dissection
- If concerning nodes or lymphatic tissue are encountered, the SSND should be abandoned, and a traditional selective neck dissection should be performed with the levels based off of the primary site location.

Postoperative Period

Postoperative Management

- Clear liquids initially progressing to a regular diet as tolerated is recommended.
- Postoperative antibiotics are not indicated.

FIG. 63.3 Example of superselective neck dissection completely clearing the level IIA and III nodal groups. The hypoglossal nerve is seen coursing over the external carotid artery without any remaining fibroadipose tissue left in this area.

- Given the limited area of dissection, a surgical drain is typically not needed, but this is at the surgeon's discretion.
- May discharge the patient from the hospital the same day. If a drain is placed, it can usually be removed the following morning.

Complications

- Complications typical of any neck dissection: infection, poor healing, hematoma, seroma, numbness, nerve/vessel injury but theoretically minimized due to the limited extent of neck dissection

Alternative Management Plan

- May require radical or modified radical neck dissection depending on intraoperative findings

Discussion

Evidence-Based Medicine Question

What is the evidence for performing an SSND for patients with an N0 neck, salvage setting, and indeterminate lateral nodes in papillary thyroid carcinoma (PTC)?

The rationale for performing an SSND in these two situations is based off of research evaluating nodal levels at the highest risk for metastases from these primary sites. This concept is based off the idea that nodal metastases follow an orderly and predictable pattern based on the primary site. In the oral cavity, the work by Woolgar describes the pattern of nodal metastases as an "inverted cone" with the majority of metastatic nodes present in levels I and II.[1] She reported a gradual reduction in the volume and extent of lymph node metastases at progressively higher nodal compartments but does note a 10% risk of skip metastases from cancer of the tongue to level IV. This is an important point to consider, because they would not be removed in an SSND of levels I and II. Another study evaluated skip metastases in primary cancer of the oral tongue and showed a 3.8% and 1.9% risk of isolated nodal disease in levels III and IV, respectively. In laryngeal carcinoma, the majority of nodal disease will be present in levels II and III. This was demonstrated in a large study of 402 patients that revealed that levels II and III were the first compartments involved in every patient.[2] They also demonstrated occult isolated metastases occurred to level IV in only 3% of cases. Other studies have confirmed this finding as well.

Another indication for SSND is in patients who have been treated with primary nonoperative management and have persistent, suspicious adenopathy in one nodal compartment. In a study that included 240 patients who underwent salvage neck dissection after chemoradiotherapy, SSND was performed in 8% of patients.[3] The regional control rate was significantly superior for SSND when compared with patients that underwent Radical neck dissection (RND) or Modified radical neck dissection (MRND), but there was no significant difference in survival between the groups. In another study that included two institutions, 35 SSNDs were performed in the salvage setting, and there were no regional recurrences over a median follow-up of 33 months.[4]

Lastly, there is controversy regarding the optimal way in which to treat suspicious lymph nodes in the lateral neck of patients with PTC. These are nodes that are concerning on imaging but are in difficult locations

and cannot undergo FNA. According to the ATA guidelines, lateral neck dissection should be performed in cases of pathologically confirmed metastatic carcinoma. Performing an SSND of levels III and IV is an option and can be performed through the existing thyroidectomy incision. This prevents overtreating with a lateral neck dissection for nodes that might be negative and also prevents potentially having to perform a second surgery for nodes that were initially positive. In a study of 35 patients, SSND was performed for indeterminate nodes, and 38% had metastatic cancer in the pathologic specimen.[5] The oncologic outcomes of the SSND patients were compared with patients with known lateral neck disease who underwent formal lateral neck dissection. The patients who had SSND had significantly better recurrence-free survival than the patients with known N1b neck metastasis who had a lateral neck dissection.

In an effort to reduce the morbidity of surgical treatment of the neck, neck dissections have been progressively more targeted. In the SSND, we remove only the nodal compartments with the highest probability of harboring disease but risk missing disease in adjacent compartments. When limiting our dissection, we must weigh the potential advantages of the SSND against the risks of an SSND. When performed by a proficient surgeon, the SSND has a minimal postoperative morbidity. More studies and randomized controlled trials are needed to show the benefit of SSND while preserving oncologic safety.

Editorial Comment

SSND is a sophisticated option for management of neck metastasis with select indications. Pros and cons must be weighed carefully, and the surgeons must look beyond clinical indications for the procedure and also consider patient factors such as patient reliability and social support that may impact timely follow-up and consequently identification of recurrent cancer. The authors provide a comprehensive overview of the technique and a balanced perspective of how SSND fits into the paradigm for management of neck metastasis.

Review Questions

1. What is not a current indication for SSND?

   a. T2N0 oral tongue SCCa

   b. T1N0 supraglottic SCCa

   c. **T1N1 floor of mouth SCCa**

   d. Residual adenopathy in level II after CRT

2. What is an example of a SSND?

   a. Removal of levels II, III, and IJV

   b. **Removal of levels III and IV**

   c. Removal of levels I, II, and III

   d. Removal of levels II and IV

3. All of the following are potential benefits of SSND, except

   a. Less operative time

   b. **Improved survival**

   c. Less postoperative morbidity

   d. Smaller incisions

4. If you encounter a clinically suspicious node with ECS during SSND, what should you do?

   a. Continue with SSND.

   b. Close and offer radiation to the patient.

   c. Remove the single node and close the incision.

   d. **Adjust to MRND to include the tissue involved in the ECS.**

Selective Neck Dissection

Karen Pitman

Introduction

Selective neck dissection (SND) is distinguished by the preservation of lymph node groups and nonlymphatic structures that are removed during radical neck dissection. SND is a generic term that applies to a group of procedures named according to the levels of the neck in which the lymph nodes are removed. SNDs evolved as surgeons developed an understanding of the predictable lymphatic drainage patterns in head and neck cancer and sought opportunities to optimize the patient's postoperative function. The primary indication for SND is management of the clinically negative neck when the risk of occult metastases is greater than 15% to 20% and the primary tumor is treated surgically. Selective procedures are used for elective treatment of the neck in primary cancers of mucosal sites of the head and neck, malignancies of the thyroid, salivary glands, and skin.[1]

Guidelines for naming neck dissections were developed by a committee with representatives from the American Head and Neck Society and the American Academy of Otolaryngology–Head and Neck Surgery.[2] The committee also recommended the use of levels and sublevels designated by Roman numerals I–VII to describe the location of lymph nodes in the neck. The naming convention is accepted by surgeons worldwide and facilitates communication and reporting of results. This system names the procedure according to the levels/sublevels that are removed.[3]

The most common SNDs are:

1. SND I–III, known as supraomohyoid neck dissection, SND I–IV, or extended supraomohyoid, typically used for treatment of oral cavity cancer

2. SND II–IV or lateral neck dissection for squamous cell carcinoma (SCC) of the oropharynx, hypopharynx, and larynx

3. SND II–V or posterolateral neck dissection for cutaneous malignancies posterior to the coronal planes through the external auditory canal (EAC) (e.g., posterior pinna and scalp). The suboccipital and retroauricular lymph node groups are included in the dissection.

4. SND VI or central compartment neck dissection, for thyroid cancer and cancers of the glottis and subglottis, piriform sinus, cervical esophagus, and trachea.

Key Operative Learning Points

- Occult or micrometastases are not detectable on physical examination or radiographic imaging.
- SNDs are used for pathologic staging of the clinically negative neck.
- Pathologic findings guide decision making for adjuvant therapy.
- Learn both clinical and radiographic borders for the levels of the neck.
- Understand the lymphatic drainage patterns and lymph node groups at risk for occult metastasis according to site and stage of the primary cancer.
- Be familiar with the surgical anatomy of the neck.
- SNDs are also used for N1 and limited N2 cancers.[4,5]

Preoperative Period

History

- Complete patient history with attention to symptoms of the primary cancer
- No specific symptoms for occult lymph nodes

Physical Examination

- Complete examination of the head and neck to assess the extent of primary cancer
- Accuracy of neck examination is dependent on patient habitus.
- Assess location and mobility of palpable neck nodes.
- Rule out synchronous second primary cancer.

Imaging

- CT or MRI of the neck and primary cancer within 30 to 60 days prior to surgery to assess local extent of primary tumor and the status of cervical lymph nodes
- Radiographic criteria for suspicious lymph nodes: size, shape, irregular enhancement, groups of lymph nodes
- Imaging not sensitive or specific enough to detect lymph node metastasis less than 1 cm
- Ultrasound-guided fine-needle aspiration biopsy of suspicious lymph nodes if results will impact the treatment plan

Indications for Selective Neck Dissection

- Clinically N0 neck and risk of occult metastases greater than 15% to 20%
- Transcervical approach to the primary cancer
- Access the neck for vascular anastomosis/free flap reconstruction
- Clinically N1 neck with metastases in the first echelon level[4,5]
- Low-volume clinical N2 neck without fixation of surrounding soft tissue invasion[4,5]
- Limited neck metastasis following radiation or chemoradiation
- Indications for specific levels by primary site:
  - Ia: Cancer of the lower lip, anterior tongue, and anterior mandibular alveolar ridge

- Ib: Oral cavity, anterior nasal cavity, skin of the midface, and submandibular gland

  IIa/IIb: Oral cavity, nasal cavity, nasopharynx, oropharynx, hypopharynx, and larynx. Level IIb has a very low (<5%) incidence of occult adenopathy and is usually not dissected in elective neck dissection. Removal of IIb is included when SND is performed for clinically positive neck metastasis.[6-9]

- III: Oral cavity, nasopharynx, oropharynx, hypopharynx, and larynx[6,7]
- IV: Larynx, hypopharynx, thyroid, and cervical esophagus
- V: Nasopharynx, oropharynx, skin of the posterior scalp and neck
- VI: Thyroid, glottis/subglottis, hypopharynx, and cervical esophagus

Contraindications

- Poor surgical candidate
- Nonsurgical treatment of primary cancer
- Unresectable primary cancer
- Fixed cervical lymph adenopathy
- Distant metastases

Preoperative Preparation

- Appropriate assessment of surgical risk from medical standpoint
- Plan for reconstruction of primary site defect if applicable.

Operative Period

Anesthesia

- General endotracheal anesthesia
- Avoid muscle paralysis to assist with identification of important

nerves. Once at-risk nerves are identified, the patient can be paralyzed at the surgeon's discretion.

- Communicate during the case when anticipated significant blood loss and any change in the patient's condition is encountered.
- Presurgical discussion with anesthesia team about duration of procedure, anticipated blood loss, nerve monitoring, and other intraoperative concerns

Positioning

- Turn table 90 to 180 degrees to facilitate surgeon and assistant's access to the head and neck, especially with bilateral neck dissections.
- Patient position—Supine with head turned away from side of surgery
- Shoulder roll—Moderate shoulder roll for neck extension; avoid hyperextension to prevent postoperative neck pain

Perioperative Antibiotic Prophylaxis

- Guided by surgical approach to the primary cancer
- Not required for isolated neck dissection

Monitoring

- Not routinely used for isolated neck dissection

Instruments and Equipment to Have Available

- Standard neck dissection set
- Vascular suture for inadvertent internal jugular venotomy or other bleeding
- Nerve hooks and/or loops
- Headlight and loupes

- Bipolar, monopolar, and harmonic scalpel

Key Anatomic Landmarks

- External during surgical marking
  - Osseous: Lower border and angle of mandible, mastoid tip, clavicle, and hyoid bone
  - Non-osseous: sternocleidomastoid (SCM) muscle, external jugular vein, and carotid sheath
- Superficial and deep layers of the deep cervical fascia—SND removes the lymphoareolar tissue between these two layers
- Erb's point—Landmark for location of spinal accessory nerve at posterior border of SCM
- Cervical plexus—Motor and sensory branches
- Phrenic nerve
- SCM, anterior and posterior belly of digastric, sternohyoid, and omohyoid muscles
- Level I—Facial artery and vein, marginal mandibular nerve, lingual and hypoglossal nerves
- Spinal accessory nerve
- Carotid artery, jugular vein, vagus nerve
- Thoracic duct—Location, tributaries, and course
- Cervical sympathetic trunk—Ascending preganglionic sympathetic fibers; deep and medial to the carotid artery with multiple ganglia. Injury results in ipsilateral Horner's syndrome.

Surgical Landmarks for the *Levels of the Neck*

- Ia: Submental lymph nodes—Triangle overlying the anterior belly of digastric muscles, from the mandible to the hyoid

- Ib: Submandibular lymph nodes—Triangle bounded by mandible, anterior belly of digastric muscle and stylohyoid muscle, along with the posterior belly of the digastric muscle; includes the submandibular gland, the preglandular, prevascular, retrovascular, retroglandular, intracapsular, and deep submandibular lymph node groups
- IIa/IIb: Upper jugular lymph nodes—Area from the skull base to the hyoid bone, bounded anteriorly by the lateral border stylohyoid muscle; extends to the posterior border of the sternocleidomastoid muscle. A vertical plane formed by CN XI divides IIa from IIb.[9]
- III: Middle jugular lymph nodes—Inferior border of the hyoid bone to inferior border of cricoid cartilage, bounded anteriorly by the lateral border sternohyoid muscle; extends to the posterior border of the sternocleidomastoid muscle
- IV: Lower jugular lymph nodes—Lower border of the cricoid cartilage to the clavicle. Anterior extent is the lateral border of sternohyoid muscle; extends to the posterior border of sternocleidomastoid muscle
- Va/Vb: Posterior triangle lymph nodes—Superior border is intersection of sternocleidomastoid trapezius muscles, triangle formed by anterior border of trapezius, clavicle inferiorly, and posterior border of SCM. A horizontal plane extending from the inferior border of the cricoid cartilage divides level Va cranially from Vb caudally. Level Va includes the spinal accessory lymph node group, and Vb are the supraclavicular and transverse cervical lymph nodes.
- VI: Central compartment lymph nodes, including the prelaryngeal, pretracheal, and paratracheal lymph nodes. Surgical boundaries are the hyoid bone superiorly and medial border of carotid sheath bilaterally to the suprasternal notch inferiorly.
- Other lymph node groups: Groups of nodes located outside these levels are named by anatomic location:
  - Superior mediastinum: Suprasternal notch to innominate arteries, lateral boundary-carotid sheath, includes the anterosuperior mediastinum, and tracheoesophageal grooves
  - Retropharyngeal
  - Periparotid

- Postauricular lymph nodes—on and behind the mastoid process
- Occipital lymph nodes

Prerequisite Skills

- Basic surgical skills
- Familiar with the anatomy of the neck

Operative Risks

- Shoulder dysfunction, shoulder pain, capsulitis
- Chyle leak
- Infection
- Edema of the neck and face
- Sialocele
- Wound healing problems/flap necrosis in post radiation neck
- Hematoma
- Hypocalcemia for bilateral central compartment
- Nerve damage
- Vocal cord paralysis
- Skin and ear numbness
- Dysphagia
- Marginal mandibular nerve weakness/paralysis
- Dysarthria, tongue weakness, tongue numbness
- Horner's syndrome
- Paralysis of the diaphragm

Surgical Technique

- Neck dissections are defined by the levels that are removed, and the surgical steps for each level are described individually here. The sequence of events for every neck dissection will be different, depending on surgeon preference, the location of palpable lymph nodes, and the plan for excision of the primary cancer. General principles for all neck dissections are to define the superficial borders of the dissection and work from the superficial to deep structures to ensure adequate exposure of critical structures.
- Planning the incision—Depends on levels being removed and surgeon's preference. A transverse incision placed in a skin crease or standard utility incision affords good exposure for most SNDs.
- Incise the skin along the entire length of the planned incision. Identify the platysma prior to incising it, as the posterior border provides a reliable landmark for the external jugular vein and great auricular nerve.
- Incise platysma and elevate subplatysmal flaps. Keep the plane of dissection just deep to the platysma; this is an avascular plane that facilitates preservation of the external jugular vein, great auricular nerve, and the superficial layer of the deep cervical fascia (e.g., the fascia overlying the SCM). In areas where the platysma is dehiscent, flap elevation is continued in a subcutaneous plane of the dissection that is best defined by the surgeon.
- The extent of flap elevation depends on the levels of the neck that will be removed.
  - Level I: Inferior border of the mandible. Staying in the avascular plane just deep to the platysma will minimize the risk of injury to the marginal mandibular nerve.
  - Level II: Posterior belly of the digastric muscle
  - Level III: Inferior belly of omohyoid muscle
  - Level IV: Clavicle
  - Level V: Anterior edge of the trapezius muscle and clavicle
  - Level VI: Sternal notch, anterior border of SCM, hyoid bone
- Expose the most superficial boundaries of the neck dissection according to levels removed:

- Level Ia—Lateral border of contralateral anterior belly digastric, mentum, and hyoid
- Level Ib—Lower border of mandible, anterior and posterior digastric, facial artery and vein at their junction with the lower border of the mandible
- Levels II–III—Posterior belly of digastric, lateral border of sternohyoid, and SCM from behind the angle of the mandible to the posterior omohyoid muscle
- Levels II–IV—Posterior belly of the digastric, lateral border of sternohyoid, SCM from behind the angle of the mandible to the clavicle, and the clavicle anterior to the insertion of SCM
- Level V—Mastoid tip, anterior border of trapezius, clavicle, and posterior border SCM

Level I Dissection

- Level Ia—Submental triangle: Dissect the fibrofatty tissue overlying the anterior bellies of the digastric muscles, from the mentum to the hyoid bone; includes lymphatic tissue between and deep to the anterior digastrics
- Complete dissection of level Ib includes the investing fascia of the submandibular gland and requires identification, dissection, and protection of the marginal mandibular nerve (Fig. 64.1).[10] The course of the nerve in relation to the inferior border of the mandible is variable, and identification is facilitated by opening the investing fascia in the vicinity of the angle of the mandible, where it exits the tail of the parotid. Once the nerve is skeletonized and placed above the inferior border of the mandible, the fascia of the gland is separated from the inferior border of the mandible, and the facial artery and vein are ligated. Level I contents are retracted inferiorly and posteriorly while dissecting the lymphatic tissue from the anterior belly of the digastric and mylohyoid to expose the lateral border of the mylohyoid. After ligating the blood supply to the mylohyoid, an angled retractor is used to retract the lateral border anteriorly to expose the lingual and hypoglossal nerves, submandibular ganglion, and duct and cross the hyoglossus muscle. The ganglion and the duct are ligated and

transected while visualizing the lingual nerve and, once accomplished, will allow inferior retraction of the specimen and improved exposure of the hypoglossal nerve inferior and deep to the submandibular duct. Both the lingual and hypoglossal nerves are identified prior to ligating the submandibular duct as anteriorly as possible to ensure removal of the accessory gland tissue along the duct.

Level II–III and II–IV Dissection

- Elevate the investing fascia of the SCM along the entire anterior border preserving the great auricular nerve. Ligating the external jugular vein is not required but may be performed to improve exposure to level IIb. If the external jugular vein is ligated, consideration is given to reconstruction needs, and it should be ligated high along the anterior border of the SCM so sufficient length remains for anastomosis. As the fascia is developed, retract the SCM posteriorly to clear fascia off the deep surface of the muscle (Fig. 64.2).
- Identify CN XI as it enters the SCM. Avoid vigorous traction or trauma to the nerve. The transverse process of the atlas is a palpable landmark for the lateral border of the jugular in proximity of XI if anatomy obscures immediate visual identification.
- Skeletonize the inferior border of the posterior belly of the digastric muscle and retract superiorly to expose CN XI as it crosses the jugular vein.
- Expose the lateral border of the jugular vein at the superior extent of the dissection, which will be defined by whether IIb is included in the dissection. For IIa, the superior extent of dissection is inferior to the intersection with CN XI. If level IIb is included in the dissection, retract the posterior belly of the digastric/stylohyoid muscle complex superiorly and the SCM posteriorly with angled retractors. Then skeletonize CN XI from the lateral border of IJ to its entrance into the SCM (Fig. 64.3). Expose the lateral border of the jugular vein, and gently retract XI inferiorly to fully expose level IIb. Bovie cautery can be used to clear the fibroadipose tissue from the muscular floor in the superolateral corner of IIb but as the dissection nears CN XI and the jugular vein changes to a dissector and bipolar cautery or Ligasure are used instead. Sweep IIb contents under CN XI and continue in

continuity with level IIa.

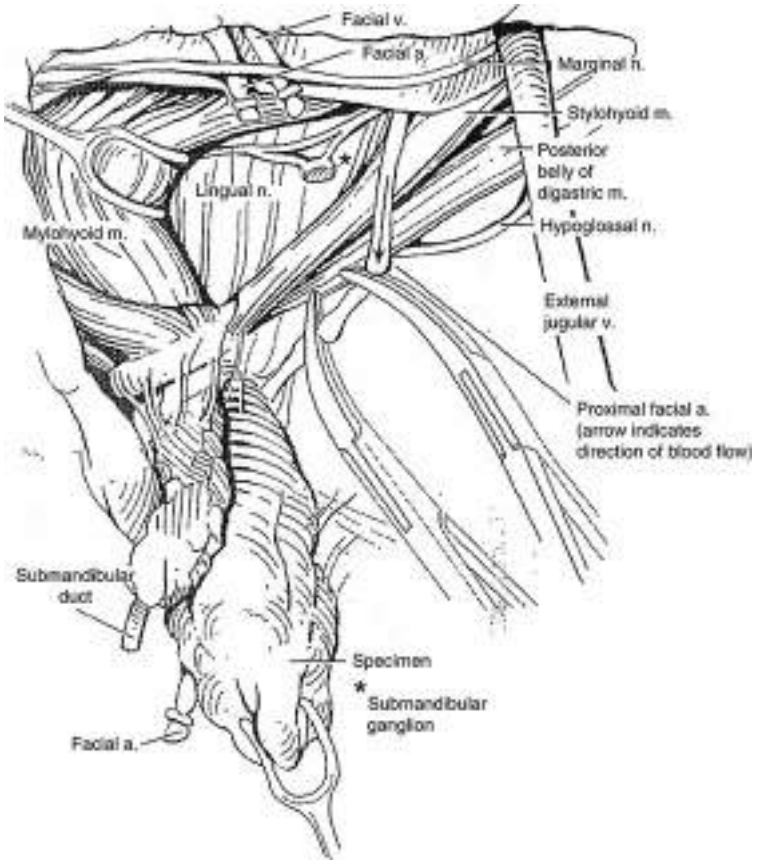

FIG. 64.1 Level Ib lymph node dissection. From Cohen JI, Clayman GL: Atlas of Head and Neck Surgery. 2012 [9781416033684, Fig. 19.6], Elsevier, with permission.

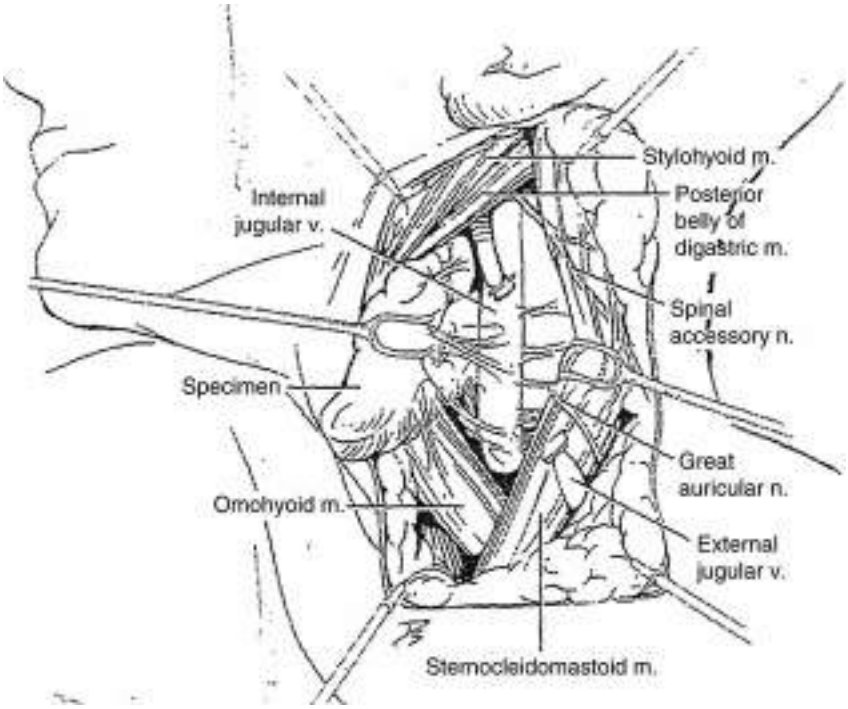

FIG. 64.2 Level II and III lymph node dissection. From Cohen JI, Clayman GL: Atlas of Head and Neck Surgery. 2012 [9781416033684, Fig. 19.7], Elsevier, with permission.

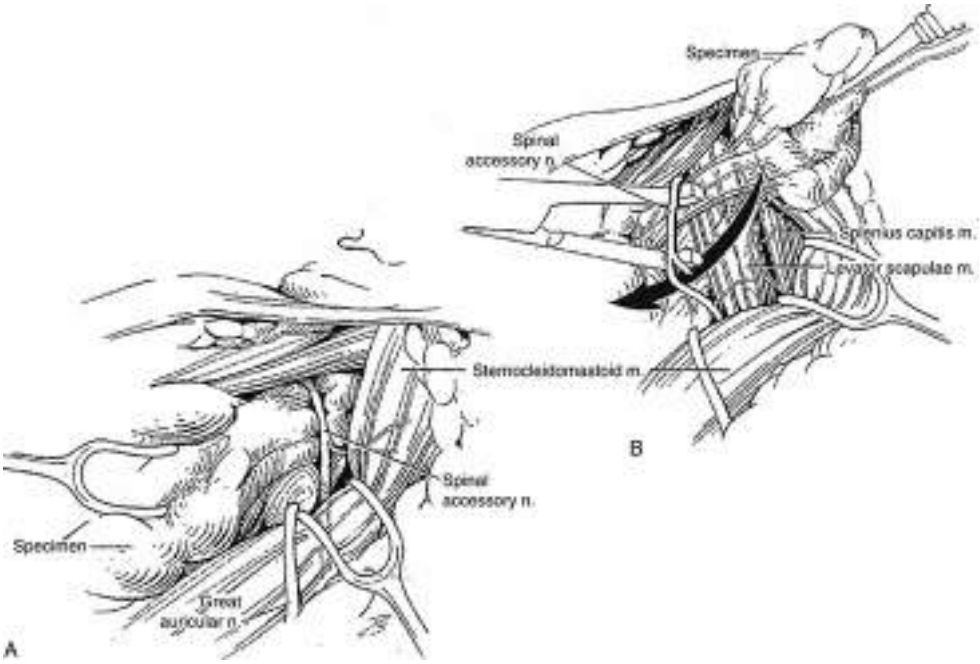

FIG. 64.3 Level IIb lymph node dissection. **A,** Level IIb as identified. **B,** Fibroadipose tissue in Level IIb dissected free of spinal accessory nerve and the muscular

floor. From Cohen JI, Clayman GL: Atlas of Head and Neck Surgery. 2012 [9781416033684, Fig. 19.8], Elsevier, with permission.

- The posterior border of the SCM and cutaneous branches of the cervical plexus are the lateral extent of II–IV dissection. While retracting the SCM posteriorly, define the floor of the neck by incising the fibroadipose tissue deep to the SCM to expose the muscular floor while the assistant provides countertraction of the specimen anteriorly using a surgical sponge. This will expose the deep cervical fascia overlying the scalene and levator scapulae muscles.
- Division of the posterior omohyoid muscle facilitates complete exposure of level III and removal of the jugulo-omohyoid lymph node. This LN group should be removed in both level III and IV dissections (Fig. 64.4).
- The deep cervical fascia is left intact on the deep muscles of the neck. This protects the phrenic nerve and brachial plexus. The cervical rootlets are also preserved in SNP. The plane of dissection continues anteriorly in the plane superficial to the deep layer of cervical fascia from the posterior border of the SCM to the carotid sheath. The transverse cervical artery and vein are superficial to the fascia and can be preserved.
- Prior to dissection of the carotid sheath, identify the inferior most extent of the level III/IV dissection. To prevent inadvertent torsion of the internal jugular vein (IJV) here, identify the lateral border of the IJV, and open the carotid sheath by using a dissector to expose the lateral border of the IJV. Then clamp and tie the lymphatic tissue lateral to this point for about 2 to 3 cm toward the SCM. Since this is the location of the thoracic duct and its tributaries, the use of Bovie cautery alone for this maneuver is avoided.
- The superior and inferior borders of the carotid sheath dissection are clearly defined by exposing them; the neck contents are retracted anteriorly by the assistant to provide a broad plane of dissection along the entire length of the internal jugular vein. The carotid sheath is incised sharply, while the assistant provides anterior retraction, and the surgeon holds countertraction, both adjusting position as the internal jugular vein is exposed by the surgeon. Tributaries to the IJV are ligated as they are encountered. Traction and countertraction, and

a sharp #10 blade, ensure complete clearance of the jugular chain lymph nodes of levels II, III, and IV.

- After dissection of the jugular vein the contents are freed from the lateral border of the sternohyoid muscle. If the omohyoid muscle was divided, the superior belly is in the specimen and is separated from the hyoid completing removal of the specimen.

Level V Dissection

- Expose boundaries of dissection: posterior edge of SCM, clavicle, and anterior border of the trapezius muscle.
- The spinal accessory nerve is identified at the posterior border of the SCM and skeletonized as it traverses the posterior triangle to its point of entry into the trapezius muscle. CN XI is distinguished from other nerves traveling parallel deep to the anterior border of the trapezius muscle for 1 to 2 cm before inserting into the muscle. CN XI is protected as level V is dissected from the posterior scalene and levator scapulae muscle, leaving fascia on the muscles (Fig. 64.5).

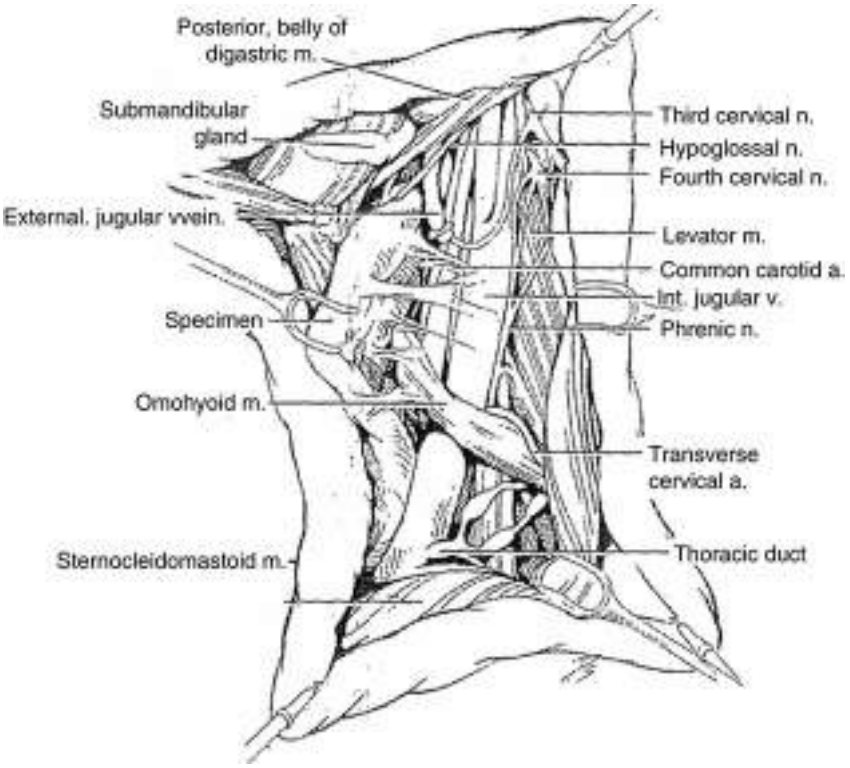

FIG. 64.4 Level IIa, III, and IV dissection. From Cohen JI, Clayman GL: Atlas of Head and Neck Surgery. 2012 [9781416033684, Fig. 20.6A], Elsevier, with permission.

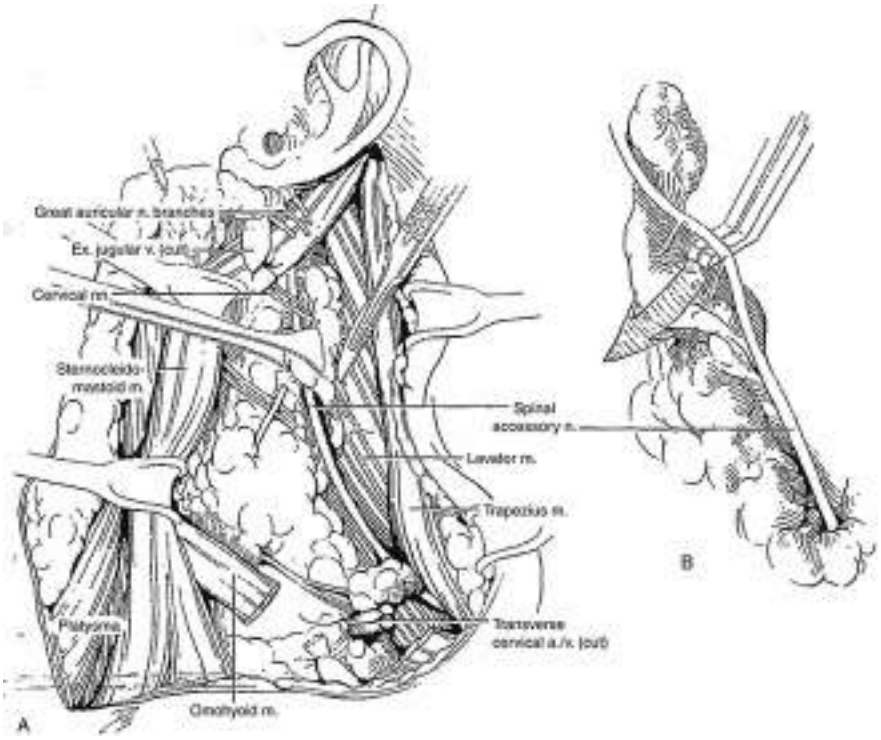

FIG. 64.5 Transposition of spinal accessory nerve. **A,** Spinal accessory nerve is identified. **B,** Spinal accessory nerve is skelatonized and the contents of Level 5 are brought deep to the nerve for further dissection. From Cohen JI, Clayman GL: Atlas of Head and Neck Surgery. 2012 [9781416033684, Fig. 21.5], Elsevier, with permission.

- Contents of level V are dissected off the splenius capitus, levator scapulae, and scalene muscles, leaving a deep layer of the deep cervical fascia intact to protect the brachial plexus.
- If included with level II–IV, the contents of level V are brought deep to the SCM and removed with the jugular chain lymphatics.

Level VI Dissection

- Identify the boundaries of dissection: carotid sheath laterally, cricoid superiorly, trachea medially, innominate artery inferior.

- Identify and preserve the recurrent laryngeal nerves (RLNs) and parathyroid glands. Frozen section analysis and autotransplantation can be used to distinguish the parathyroid glands from the lymph nodes.
- Skeletonize the RLN through the central compartment and remove lymphatic tissue deep to the RLN.

Steps Once Dissection Is Complete

- The specimen is divided into respective levels, labeled accordingly and sent to pathology.
- The surgical bed is inspected for bleeding and leakage of chyle. A Valsalva maneuver performed by the anesthetist assists with identification of both. Identify and ligate lymphatic ducts if there is evidence of a chyle leak. Repeat inspection after ligation to ensure the leak has been repaired.
- Closed suction drains placed carefully to ensure drainage of the most dependent aspect of surgical bed. Drains connected to wall suction during skin closure to prevent blood clotting in the drain tubing and rendering the drain nonfunctional.
- Layered closure starting with the several interrupted dissolvable sutures placed in the platysma. Subcutaneous layer reapproximated with interrupted dissolvable sutures at close interval. Drain tubing changed from wall to bulb suction now ensures closure is airtight prior to skin closure.
- Skin closed with running nylon, Prolene suture, or surgical skin staples

Common Errors in Technique

- Maintain the deep layer of the deep cervical fascia intact on the floor of the neck dissection to protect the brachial plexus and phrenic nerve.

Preservation of the cervical plexus nerves minimizes shoulder dysfunction and numbness of the skin.

- If microvascular reconstruction is planned, preservation of the external

jugular vein and transverse cervical vessels will be available as anastomotic options and, when possible, maintain a generous pedicle when ligating branches of the external carotid artery and internal jugular vein.

- Torsion of the jugular vein during carotid sheath dissection prevents adequate visualization of the vein walls and inadvertent entry. This is prevented by exposing the lateral border of the jugular vein at the superior and inferior extent of the dissection prior to performing carotid sheath dissection.
- CN XI enters the trapezius muscle on its under surface about 1 cm from the free edge, distinguishing it from branches of the cervical plexus traveling through the posterior triangle.
- The thoracic duct and right lymphatic duct are in predictable locations, and when the dissection involves these structures, carefully inspect for chyle leak at the completion of the procedure. This is accomplished by having the anesthetist perform a Valsalva maneuver and/or applying firm, constant pressure to the abdomen while inspecting the area. If chyle is identified, every effort must be made to stop the leak. A variety of techniques can be used, including clips, clamp, suture ligation, and interposition of local muscle flaps or using the Ligasure or Harmonic scalpel to seal the lymphatic vessels to ensure that the leak is completely stopped and then reinforcing the area with fibrin glue.

Postoperative Period

Postoperative Management

- Wound care—antibiotic ointment to incision
- Measure and record drain output.
- Shoulder physical therapy starting POD 1 or 2

Complications

- See operative risks.

Alternative Management Plan

- Radiation or observation for poor surgical candidates

Discussion

Evidence-Based Medicine Question

Is an SND as effective as comprehensive neck dissection for pathologic staging of the clinically negative neck?

Beginning in the middle of the 20th century, surgeons began to modify the classical radical neck dissection when performing elective neck dissection. The evolution toward procedures that remove only lymph node groups that were at risk for occult metastasis based on the location of the primary tumor (e.g., selective procedures) was guided by clinical studies that demonstrated cervical lymph node metastasis occurs in predictable drainage pathways. A key motivation for the development of selective procedures was better functional and cosmetic outcomes relative to comprehensive procedures. Since their initial adoption, multiple studies have shown acceptable regional recurrence rates following selective procedures, as shown in the review of Barzan et al. 2015.

Editorial Comment

Based upon his milestone paper in 1906, Dr. George Crile's name is indelibly linked with the radical neck dissection. The operation, as he described it, called for the removal of both lymphatic and non-lymphatic structures in the neck which contained cancer from various sites in the head and neck metastatic to the cervical lymph nodes. This procedure, despite its negative impact on form and function, remains the "standard of care" for metastatic cancer in the neck. However, if one reads Crile's paper analytically, it appears that less than one half of the more than 100 patients described had undergone a true radical neck dissection so that Dr. Crile was removing metastatic lymph nodes at various levels in the neck while preserving non-lymphatic structures and thereby describing

both the RND and SND in this important paper.

In the 1960's, Professor Gavilan and Suarez described the "functional neck dissection" in which the lymph nodes could be removed while preserving the non-lymphatic structures thereby preserving form and function. Professor Ettore Bocca, in 1991, published his landmark paper describing the results using bilateral SND's in 1000 patients in the management of cancer of the supraglottic larynx which resulted in a decreased rate of recurrence in the neck while preserving cosmesis and function.

Dr. Jatin Shah and colleagues published a paper, in 1991, which was a review of the records of more than 1000 patients who has undergone RND in the Memorial Hospital and correlated the levels in the neck when metastatic lymph nodes were present with the site of the primary cancer. This important work made the selection of the proper type of SND more precise since it demonstrated that cervical lymph node metastasis have predictable drainage pathways.

As part of the movement towards surgical minimalism the SND was embraced because of its preservation of form and function. While obviously these important issues they only matter if the control of cancer in the neck is comparable to the more comprehensive procedure. Publications from our Department, including Dr. Pitman's important work "Effectiveness of Selective Neck Dissection for Management of the Clinically Negative Neck" as well as others cited in the references, including Myers and Gastman and Hosal, Carrau, Johnson et al has demonstrated that the versatile operation results in cancer control rates comparable to the new comprehensive operation and may be employed in the management of the NO or the N+ neck.

Review Questions

1. Indications for selective neck dissection include

   a. T2 N0 oral tongue cancer

   b. T2 N0 tonsil cancer

c. T2 N1 oral tongue cancer

d. **All**

2. Selective neck dissection for cutaneous malignancy of the posterior scalp includes the occipital lymph nodes.

   a. **True**

   b. False

3. Shoulder dysfunction is observed in 15% of individuals following SND II-IV.

   a. **True**

   b. False

Modified Radical Neck Dissection

Steven Parnes, and Anna Butrymowicz

Introduction

In the early 1900s, George Crile recognized that cancer of the head and neck was primarily a locoregional disease and felt that patients could be cured if the cancer was completely excised. The cervical lymph nodes were recognized as the initial area of spread and so the best chance for cure was excision of the primary cancer sites in concert with the ipsilateral cervical soft tissue.[1] He described and popularized radical neck dissections for the treatment of regionally metastatic head and neck cancer. Crile's radical neck dissection remained the standard of care for cervical metastases for almost 70 years.

Modifications of the traditional radical neck dissection came after 1963, when Suarez demonstrated that the nonlymphatic structures (sternocleidomastoid muscle and internal jugular vein) were anatomically separated by fascia from the lymph nodes. Oncologic outcomes were found to be similar to radical neck dissections, and the functional and aesthetic outcomes of patients were clearly superior.[2-4] In addition, particularly with the advent of radiation therapy, preservation of the sternocleidomastoid muscle was found to protect the carotid artery from subsequent damage and potential blowout.[5]

Several classification schemes for a neck dissection were introduced, and in an effort to present a common language the Committee for Head and Neck Surgery and Oncology of the American Academy of Otolaryngology–Head and Neck Surgery introduced the most widely accepted classification system in 1991. A modified radical neck dissection was defined as "the excision of all lymph nodes routinely removed by the radical neck dissection, with preservation of one or more non-lymphatic structures."[6]

Key Operative Learning Points

- Modified radical neck dissection is strictly defined as the removal of lymph nodes from levels 1 to 5 while preserving one or more of the nonlymphatic structures (sternocleidomastoid muscle, spinal accessory nerve, internal jugular vein).
- Decisions to perform a modified radical neck dissection are often made intraoperatively, when those nonlymphatic structures are found to be involved with cancer.
- Preservation of the spinal accessory nerve maintains normal shoulder function.
- Neck dissections can be done safely when the surgeon has thorough knowledge of the anatomy.
- Soft tissue in level 4 should be clamped and ligated to prevent chyle leaks.
- Manipulation of the carotid artery can cause excessive stimulation of the carotid body reflex, resulting in bradycardia and hypotension. This can be resolved with injection of lidocaine directly into the carotid sinus.
- When approaching the carotid sheath, it is important to keep the plane of dissection over the jugular vein to prevent inadvertent damage to the sympathetic trunk, vagus nerve, or carotid artery.

Preoperative Period

History

- History of present illness
  - Presentation at diagnosis
  - Location of the primary cancer: The primary site will dictate which nodal levels are at risk for metastases and therefore will determine the extent of surgery. For example, cancer of the floor of the mouth rarely metastasizes to level V, and so if these nodes are not clinically

or radiographically involved, level V nodes can be preserved, thereby obviating the need for a radical neck dissection.

- Symptoms related to the site of the primary
- Restriction in range of motion of the neck
- Shortness of breath: can be secondary to the primary lesion or medical comorbidities secondary to tobacco use; however, involvement of the phrenic nerve is possible. A chest radiograph will help to determine the integrity of the phrenic nerve.
- Numbness of the anterior tongue
- Dysgeusia
- Dysphagia
- Voice changes
- Weight loss: The patient's nutritional status should be optimized before undergoing any surgical procedure because this will affect his or her wound healing. If a patient has had significant weight loss secondary to dysphagia or odynophagia, it may be beneficial to place a feeding tube and improve the patient's nutritional status before intervention to prevent postoperative complications.
- Any neoadjuvant or definitive treatment

- Past medical/surgical history
  - Medical illness: cardiovascular disease, stroke, carotid insufficiency
  - Neck surgery: carotid endarterectomy, anterior approach to the cervical spine
  - Family history of cancer
  - Medications
    - Antiplatelet drugs
    - Vitamins/herbal products: i.e., vitamin E, Ginkgo biloba
    - Opiates: Postoperative pain control in chronic pain patients is very different from opiate-naive patients. Consultation should be sought in those particularly complex cases (e.g., patients on suboxone or methadone).

- Social history
  - Opiate abuse
  - Drug rehabilitation programs
  - Smoking
  - Occupation
  - Alcohol intake: Extent of alcohol intake is important in anticipating a patient's postoperative needs and the risk for delirium tremens.
- Informed consent

Physical Examination

- Thorough examination of the head and neck with documentation of nodal levels involved as well as relevant surgical findings that may affect surgical decision making such as fixation to overlying structures (e.g., skin) or underlying structures (e.g., deep muscles of the neck)
- Fiberoptic nasopharyngoscopy
- Auscultation of the carotid for bruits
- Neurologic examination
  - Invasion of major nerves
    - Facial nerve: Observe symmetry with facial movement, with focus on the inferior division.
    - Lingual nerve: difficult to examine, nerve injury often elicited through history
    - Vagus nerve: ipsilateral vocal cord paresis and palate asymmetry
    - Hypoglossal nerve: deviation of the tongue toward the injured side
    - Spinal accessory nerve: winged scapula, sternocleidomastoid and atrophy of the trapezius
    - Sympathetic trunk: ipsilateral Horner syndrome
    - Phrenic nerve: History and imaging will help to determine phrenic nerve involvement.

- Brachial plexus: motor-sensory dysfunction in the ipsilateral arm

Imaging

- Chest radiograph
  - Metastases
  - Synchronous primary cancer in the lung
  - Pulmonary and cardiac status
- Computed tomography (CT) (Fig. 65.1)
  - Adequate for radiographic staging when imaging of the chest is added
  - May help to anticipate involvement of nonlymphatic structures
- Positron emission tomography (PET)-CT: In a multicenter prospective trial assessing the CT versus PET/CT for initial staging, PET/CT upstaged and changed management in almost 14% of patients.[7] Studies like this have prompted the National Comprehensive Cancer Network to include recommendations for PET/CT in stage 3 or 4 cancer in the majority of subsites in the head and neck.[8]
  - Assesses local involvement
  - Identifies distant metastases
  - Second primary cancers
- Magnetic resonance imaging (MRI)
  - Not required in many cases
  - Helps to identify the presence of perineural invasion and the extent of the cancer
- Angiography
  - Balloon occlusion testing helps anticipate the risk of stroke in patients with carotid involvement who may require carotid resection.

Indications

Modified radical neck dissection is indicated when the spinal accessory nerve, internal jugular vein, or sternocleidomastoid muscle can be preserved without affecting oncologic outcomes and when a selective neck dissection would not adequately remove the volume of cancer in the neck. The decision to proceed with a modified radical neck dissection is often made intraoperatively, when the sternocleidomastoid muscle, spinal accessory nerve, or internal jugular vein are found to be involved with cancer.

For a neck dissection to be classified as a modified radical neck dissection, all lymph node levels must be dissected. Level 5 nodes are infrequently involved with noncutaneous head and neck squamous cell carcinoma. As demonstrated by Lindberg in 1972 and in many subsequent publications, nasopharyngeal primaries frequently metastasize to level 5 nodes; however, other head and neck sites rarely involve this level.[9,10] Therefore, without palpable or radiographic evidence of metastases to level 5, dissections of level 5 is not indicated, with the exception of nasopharyngeal and some oropharyngeal primaries.

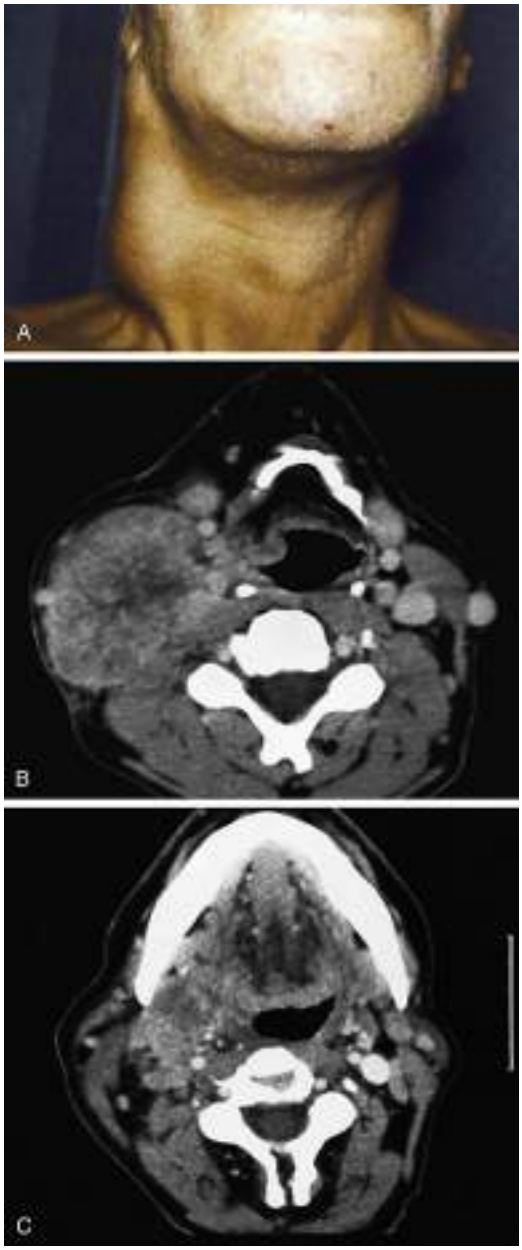

FIG. 65.1 **A,** Photograph and **B** and **C** axial computed tomography (CT) scans of the neck of a patient with massive cervical lymphadenopathy. The CT scans demonstrate encasement of the left carotid artery and suggest tumor invasion of the sternocleidomastoid muscle and the deep cervical muscles.

Contraindications

- N0 neck (see Selective Neck Dissection Chapter)
- Extensive metastasis

    - Encasement of the carotid artery
    - Invasion of the deep muscles of the neck
    - Invasion of the skull base
- Distant metastases
- Comorbidities that prevent safe administration of general anesthesia

Preoperative Preparation

- Chlorhexidine wash: Despite the Centers for Disease Control and Prevention (CDC) recommending chlorhexidine washes preoperatively to decrease the bacterial load on the skin, there has been little to no evidence that it decreases the rate of soft tissue infections in head and neck surgery. For patients with a history of methicillin-resistant *Staphylococcus aureus* infections, a preoperative chlorhexidine wash may be of benefit.

Operative Period

Anesthesia

- General anesthesia
- Avoid paralysis: The anesthesia team should be aware of the need to monitor stimulation of particular muscles during the surgery; therefore paralysis should be avoided.
- Intubation: Technique varies depending on the site of the primary. Regardless, the otolaryngologist should be involved during the intubation to guide the anesthesiologist through the altered anatomy and to provide a surgical airway if necessary.

Positioning

- Supine, head extended with adequate shoulder support and turned to the nonoperative side to provide adequate exposure of the surgical site
- Table turned 90 degrees; 180 degrees if bilateral procedure is planned

- Shoulder roll or inflatable surgical pillow (e.g., surgical thyroid pillow) can be used for shoulder support and to provide neck extension.

Perioperative Antibiotic Prophylaxis

- There is no clear evidence that prophylactic perioperative antibiotics decrease the incidence of surgical site infections in clean neck dissections, although Carrau et al. did show a trend for a higher incidence of infections in untreated patients.

Monitoring

- Facial nerve monitor can be used to help with identification of the marginal mandibular nerve during dissection of level 1.

Instruments and Equipment to Have Available

- Head and neck set
- Bipolar and monopolar cautery
- 2.0 and 3.0 silk reel

Key Anatomic Landmarks

- External landmarks:
  - Angle of the jaw
  - Mastoid tip

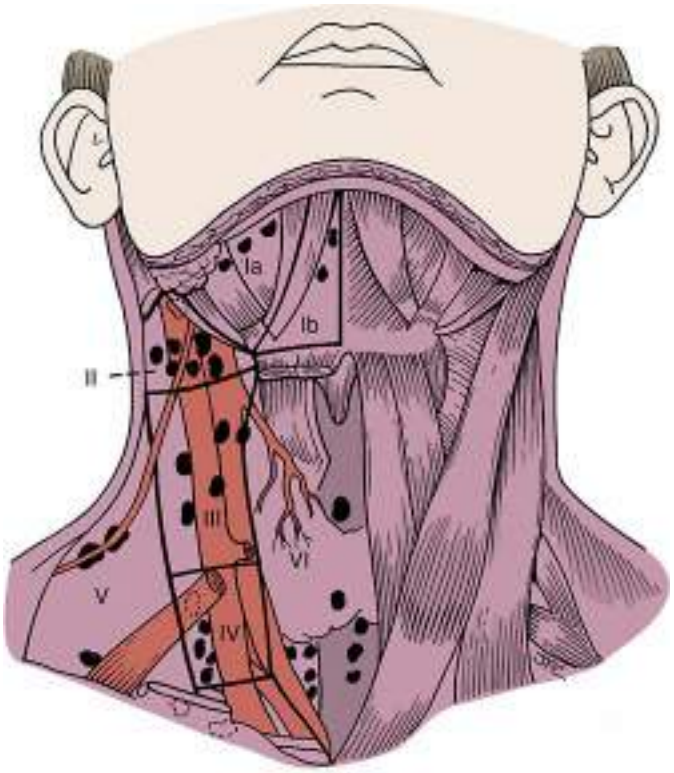

FIG. 65.2 Levels of neck nodes. Selective neck dissections are labeled according to the levels of nodes removed.

  - Midline of the neck
  - Anterior and posterior borders of the sternocleidomastoid muscle
  - Clavicle
- Levels of the neck (Fig. 65.2):
  - Level Ia: submental triangle
    - Boundaries: anterior belly of the digastric muscles and the hyoid bone
  - Level Ib: submandibular triangle
    - Boundaries: body of the mandible and the anterior and posterior belly of the digastric muscle
  - Level II: upper jugular nodes
    - Anterior boundary: border of the stylohyoid muscle
    - Posterior: posterior border of the sternocleidomastoid muscle
    - Superior: skull base

    - Inferior: Level of the hyoid bone
    - Further divided into level IIa and IIb by the spinal accessory nerve
- Level III: middle jugular nodes
    - Anterior boundary: lateral border of the sternohyoid muscle
    - Posterior: posterior border of the sternocleidomastoid muscle
    - Superior: hyoid bone
    - Inferior: omohyoid muscle or cricoid cartilage
- Level IV: lower jugular nodes
    - Anterior boundary: lateral border of the sternohyoid muscle
    - Posterior: posterior border of the sternocleidomastoid muscle
    - Superior: omohyoid/cricoid
    - Inferior: clavicle
- Level V: posterior triangle
    - Anterior boundary: posterior border of the sternocleidomastoid muscle
    - Posterior: anterior border of the trapezius muscle

FIG. 65.3 A patient with paralysis of the right trapezius and a dropped shoulder, resulting from 11th nerve sacrifice.

- Inferior: clavicle
- Further divided into level Va and Vb by a horizontal extension at the level of the cricoid cartilage

Prerequisite Skills

- Soft tissue surgery
- Neurovascular dissection
- Radical neck dissection (see Chapter 66 on Radical Neck Dissection)

Operative Risks

- Stroke and/or death
- Scarring of skin
- Bleeding, infection, edema
- Neck asymmetry (Fig. 65.3)
- Shoulder weakness and pain (Fig. 65.3)
- Tongue weakness with resultant swallowing or articulation difficulties
- Voice and swallowing dysfunction from vagal injuries
- Weakness of lower lip and/or face
- Horner syndrome
- Chyle leak
- Risk of significant facial or cerebral edema, particularly in bilateral internal jugular vein injury/sacrifice
- Necrosis of the skin flap
- Possible need for further intervention
- Salivary fistula: of concern when the neck dissection is combined with

oral or pharyngeal procedures or if a part of the parotid is included in the neck dissection

Surgical Technique

- Prep: 10% povidone iodine; prep should include rectangular area anteriorly just past the midline of neck, posteriorly beyond the posterior border of the sternocleidomastoid muscle, inferiorly below the level of the clavicle, superiorly just above the mandible to include the mastoid tip
- Incision: The Lahey (hockey stick) incision is marked from the mastoid tip down diagonally tracking just posterior to the anterior border of the sternocleidomastoid muscle. At the level of the cricoid or cricothyroid membrane, the incision continues vertically toward the midline. Care is taken to make this incision in a pre-existing neck crease to help to conceal the scar.
- Skin flap elevation: The superior skin flap should be grasped with sharp Senn retractors or Lahey tumor forceps to tent the skin edge up perpendicular to the plane of dissection. With Bovie electrocautery, the skin flap is elevated in a subplatysmal plane leaving the cervical plexus and external jugular vein down. If the mass closely abuts the platysma muscle, a cuff of healthy muscle should be taken with the mass. Involvement of the skin requires removal of the involved segments. As the flap is elevated toward the mandible, it is essential to identify and preserve the marginal mandibular branch of the facial nerve. Although its course is highly variable, a number of landmarks can help to identify the marginal branch during this point in the dissection. Dissection should transition from sharp to dull to allow proper identification. The antegonial notch and the pulse of the facial artery can be palpated along the inferior border of the mandible. Careful dissection in the soft tissue overlying the facial artery and vein will allow safe identification of the marginal mandibular nerve. After being identified, the soft tissue overlying the nerve should be carefully dissected anteriorly and posteriorly. As the facial vein, inferior to the nerve, is ligated, the soft tissue can be deflected superiorly to the skin flap, protecting the marginal nerve from inadvertent injury. The maneuver will also allow for dissection of the perifacial lymph nodes.

The skin flap should then be elevated to the anterior border of the trapezius muscle and inferiorly to the clavicle and sternal notch. The spinal accessory nerve emerges from behind the sternocleidomastoid muscle in a relatively superficial plane, and because the platysma muscle does not continue beyond the sternocleidomastoid muscle, the spinal accessory nerve is vulnerable to injury. The nerve can be identified in relation to Erb's point, which can be identified by following the greater auricular nerve to the posterior border of the sternocleidomastoid muscle. The spinal accessory nerve can be found approximately 1 cm above this point.

- Level 1 dissection: First, identify the contralateral anterior belly of the digastric muscle. Incise the fascia over its medial surface and dissect the submental adipose tissue pad in a lateral direction over the ipsilateral anterior belly of the digastric and the mylohyoid muscle. The mylohyoid muscle is then retracted anteriorly while the submandibular gland is retracted inferiorly. The specimen can be swept inferiorly with a sponge, exposing the lingual nerve and the submandibular ganglion. The attachment of the lingual nerve at the ganglion is then clamped, ligated, and tied. This will in turn expose Wharton's duct, which should also be clamped, ligated, and tied as distally as possible. The facial artery is again ligated at the posterior aspect of the gland, and the dissection continues laterally over the posterior belly of the digastric muscle. The level 1 lymph nodes are now pedicled on the level 2 nodal basin.
- Superior ligation of nonlymphatic structures: Continue dissection along the posterior belly of the digastric muscle until the sternocleidomastoid muscle is identified. The spinal accessory nerve can be identified as it continues deep to the muscle and over the internal jugular vein (Fig. 65.4). The soft tissue overlying the nerve should be bluntly dissected posteriorly, under the sternocleidomastoid to the anterior border of the trapezius muscle. The medial aspect of the sternocleidomastoid muscle should be dissected away from the underlying soft tissue superior to the spinal accessory nerve toward the mastoid tip. If the internal jugular vein is to be included in the specimen, the posterior belly of the digastric muscle is retracted superiorly, and the internal jugular vein is dissected free of the surrounding soft tissue, clamped, ligated twice with a 2.0 silk tie and

then suture ligated. At this point, the spinal accessory nerve can be divided or retracted, depending on the preoperative plan. If the muscle is being excised, it should be dissected off of the mastoid tip and reflected inferiorly.

FIG. 65.4 Cadaveric specimen after right-sided dissection of levels 1 to 4 with preservation of the submandibular gland, jugular vein, and spinal accessory nerve.

- Level 2 and 5 dissection superior to the cranial nerve XI: If the spinal accessory nerve is preserved, it can be carefully retracted inferiorly with a nerve hook. Level 2 nodes can be retracted inferiorly while the Bovie electrocautery aids in deep dissection down to the fascia of the splenius capitus and levator scapulae muscles. The dissection is continued at this depth posteriorly, to the anterior border of the trapezius muscle, slowly retracting the specimen inferiorly. After the plane of dissection has reached the level of the spinal accessory nerve, the specimen can be draped under the nerve. Alternatively, if the spinal accessory nerve is being removed, the nerve can be clamped and ligated at the level of the posterior belly of the digastric muscle.
- Completing lymphadenectomy: The dissection is then carried anteriorly away from the anterior border of the trapezius muscle. The omohyoid muscle should be ligated at the border of the trapezius muscle and should be dissected along with the main specimen. It is

helpful to leave the fascia on the deep muscles to protect the neural supply to the levator scapulae muscle, as well as the roots of cervical plexus. As the dissection is continued medially, beyond the posterior border of the sternocleidomastoid muscle, care must be taken to stay superficial to the level of the cervical rootlets keeping the transverse cervical artery, phrenic nerve, and brachial plexus deep to the plane of dissection (Fig. 65.5). The soft tissue between the level of the omohyoid and clavicle (level 4) should be bluntly dissected, clamped, and ligated to prevent inadvertent damage to the lymphatic vessels, which could lead to a chyle leak. If the surgical plan includes removal of the sternocleidomastoid muscle, it can be transected off the clavicle and the sternal head, one fingerbreadth above the bone. The jugular vein should be identified and protected prior to transection of the muscle. At this point, the anesthesiologist should be asked to provide positive pressure to aid in identification of a chyle leak.

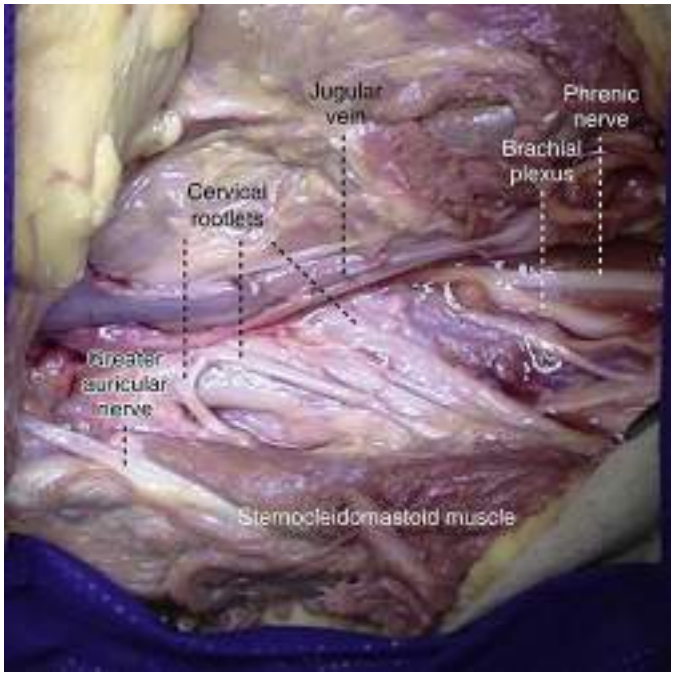

FIG. 65.5 Cadaveric specimen after right-sided dissection of levels 1 to 4 with preservation of the jugular vein with identification of the phrenic nerve and brachial plexus.

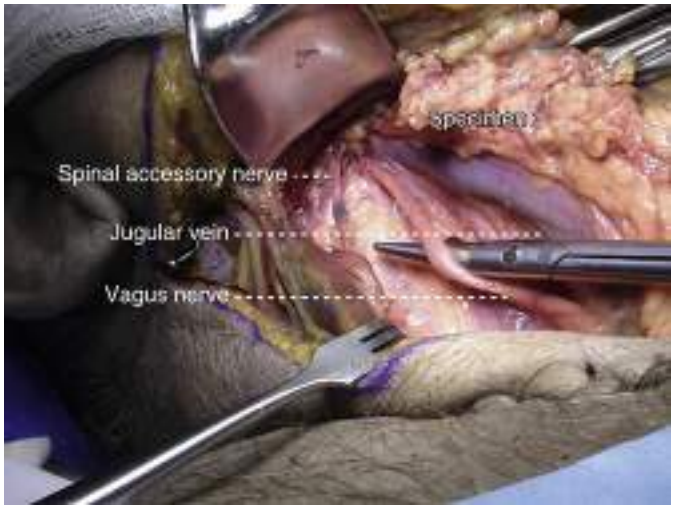

FIG. 65.6 Cadaveric specimen after right-sided dissection of levels 1 to 4 demonstrating the relationship of the jugular vein to the spinal accessory nerve and the vagus nerve.

- With continued dissection, the carotid sheath is approached posteriorly. The jugular vein should be skeletonized, carefully, 2 cm above the clavicle, clamped, and ligated, as described previously (if resection of the vein is planned). Otherwise, the fascia of the carotid sheath should be carefully dissected, anteriorly, over the jugular vein (Fig. 65.6). Small tributaries should be carefully divided with silk ties or bipolar cautery, depending on their size. Dissection continues superiorly as the ansa cervicalis and ansa hypoglossi are elevated away from the sheath and divided.
- If significant and sustained bradycardia or hypotension result during dissection around the carotid artery, it may be necessary to inject the carotid bulb with plain lidocaine. The specimen should now only be attached to the area overlying the hyoid bone, which can be dissected with ease. Once the specimen is removed from the underlying healthy soft tissue, hemostasis should be confirmed. Finally, copious irrigation with warm saline is followed by insertion of #10 Jackson Pratt drains, to drain the surgical defect. The platysma is re-approximated with 4.0 chromic sutures, and the skin is closed with surgical staples.

Common Errors in Technique

- Failure to both tie and suture ligate the internal jugular vein stump may result in slipping of the silk tie off the vascular stump.
- If the marginal mandibular nerve is not identified during the elevation of the skin flap, it can be easily injured during subsequent dissection.

Postoperative Period

Postoperative Management

- Drain management: Drains are maintained on bulb suction, and the output is strictly monitored. After the output had decreased to 20 mL or less in an 8-hour period, the drain is removed. The quality of the drain output is monitored to ensure that there is no chyle-like fluid.
- Monitor for delirium tremens:
  - Onset 48 to 72 hours
  - Leads to increased morbidity and mortality
  - Increases length of hospital stay
- Dressing: After the Jackson Pratt drain is removed, a circumferential pressure dressing is placed and maintained for 24 hours. Circumferential dressings are avoided when a free flap is used to reconstruct the primary resection site to prevent strangulation of the vascular anastomosis.
- Staples are removed 10 to 14 days postoperatively.
- Shoulder rehabilitation is recommended.

Complications

- Chyle fistula
  - Intraoperative diagnosis: Chyle fistulas can result from inadvertent damage to chyle vessels located in the inferior aspect of the neck (level 4). Most of the time, the thoracic duct is present in the left neck but can be found on the right approximately 5% of the time. These fragile lymphatic channels are difficult to visualize and so the soft

tissue dissected in level 4 should be tied to prevent a chyle leaks. If a leak is suspected intraoperatively, increase in intrathoracic pressure by the anesthesiologist can help to identify the location of the stream of clear fluid. If a lymphatic channel is identified, these vessels are so fragile that manipulating the vessel in an attempt to tie it off frequently results in more damage. And so, the soft tissue surrounding the location of the leak should be clamped or plicated and tied with a 3.0 or 4.0 silk tie. If the source is not identified, figure-of-eight sutures can be placed in the general area of the leak with good effect. Fibrin glue and/or muscle flaps have been helpful in obtaining an effective seal in these situations.

- Postoperative diagnosis
  - A collection of milky fluid in the neck drain after the patient is fed
  - Fluid can be sent for identification of chylomicrons if the diagnosis is in question.
  - A patient's fluid and electrolyte balance must be closely monitored and maintained, especially in high volume leaks.
- Conservative management
  - Pressure dressing
  - Medium chain fatty acid diet is frequently effective in resolving low output leaks.
  - Octreotide: a hormone that acts in a number of endocrine and paracrine pathways to reduce chyle production and has been found to be a useful adjunct in the treatment of low output leaks
  - Negative pressure wound management
    - Should be avoided if great vessels are exposed to wound vacuum
  - Total parenteral nutrition: should be considered in leaks that persist beyond 5 days or for leaks >1 L/day
- Surgical management
  - Indications: failure of conservative measures, uncontrolled electrolyte imbalance, persistent high output fistula
  - Lymphatic duct embolization

        - Therapeutic lymphography
        - Thoracic duct ligation
        - Locoregional flaps
        - Microsurgical lymphatic-venous anastomosis
- Hematoma
    - Prevention: thorough hemostasis, blood pressure control
    - Treatment
        - Small, nonexpanding hematomas can be aspirated.
        - Expanding hematomas should be explored emergently.
- Salivary fistula: increased risk if neck dissection is completed in concert with resection of oral or pharyngeal primary
- Stroke
    - Increased risk of perioperative stroke after neck dissection (with preservation of carotid) associated with comorbidities: stroke, diabetes, hypertension
    - Incidence of stroke similar to that after thoracic surgery or colectomy
- Infection
    - Rare in isolated neck dissections
    - Risk increases with opening of the upper aerodigestive tract mucosa
- Deep vein thrombosis (DVT)
    - Cancer patients are twice as likely to develop venous thromboembolus compared with the general postoperative population.
    - Most common cause of death in postoperative period in cancer patients.
    - Prevention with early ambulation, chemoprophylaxis, and compression stockings
    - Anticoagulant prophylaxis decreases the risk of DVT but increases bleeding complications.

Alternative Management Plan

- Selective neck dissection (see Chapter 64)
- Concomitant chemoradiation for select patients
- Palliative treatment

Discussion

Evidence-Based Medicine Question

Does carotid artery encasement preclude patients from undergoing a safe and effective surgical treatment of cervical metastases?

Traditionally, because of the morbidity of carotid resection and poor overall prognosis, patients with carotid artery involvement were not considered surgical candidates. However, with the evolution of vascular reconstruction techniques and preoperative testing to identify those at risk for stroke, carotid artery resection is no longer an uncommon procedure. Kennedy recognized that patients with carotid artery involvement had a dismal prognosis and often died of local disease as opposed to distant metastases. He questioned whether resection of the carotid would result in improved survival. Since then, a number of studies have shown that carotid resection can be completed safely, frequently with saphenous vein or synthetic grafting, and with improved survival compared with untreated patients.

Editorial Comment

Modified radical neck dissection has become an increasingly uncommon operation due to evidence supporting selective and superselective dissection of nodal basins. However, it continues to be an important component of head and neck cancer surgery for indications already discussed in this chapter. Carotid artery sacrifice, although feasible, must be considered after careful consideration of pros and cons with the patient and his or her family due to the likelihood of significant complications associated with carotid artery sacrifice. The case for carotid

artery sacrifice becomes stronger when the carotid artery involvement is the only reason why the patient is otherwise unresectable. If complete resection cannot be obtained, carotid artery sacrifice becomes less justifiable.

Review Questions

1. The borders of a modified radical neck dissection include all, except

   a. Clavicle

   b. Anterior border of the trapezius muscle

   c. Stylohyoid muscle

   d. **Posterior border of the sternocleidomastoid muscle**

   e. Mandible

2. The following situations are contraindications to modified radical neck dissection, except

   a. Carotid artery encasement

   b. Invasion of the deep neck muscles

   c. **Invasion of the spinal accessory nerve**

   d. Skull base involvement

3. A patient presents with miosis, ptosis, and anhydrosis after neck dissection. This presentation is secondary to damage to the

   a. Vagus nerve

   b. **Sympathetic trunk**

   c. Spinal accessory nerve

   d. Ansa cervicalis

   e. Phrenic nerve

Radical Neck Dissection

Stephen Hernandez, Rohan R. Walvekar, and Daniel W. Nuss

Introduction

The cervical lymphatics remain an important area of consideration in the evaluation of advanced cancer of the head and neck. Metastasis to cervical nodes carries negative prognostic implications, and therefore management of the neck is a critical topic of discussion. Although operative management of the neck has become more selective over time,[1] radical neck dissection (RND) still plays an important role in the management of advanced stage neck metastasis.

Key Operative Learning Points

1. RND includes removal of the cervical lymphatics in levels I through V *in addition to* nonlymphatic structures including the sternocleidomastoid muscle (SCM), internal jugular vein (IJV), and spinal accessory nerve (cranial nerve [CN] XI) (Fig. 66.1).

2. The brachial plexus and phrenic nerves are important structures in the floor of the neck to identify and preserve.

3. It is important to clearly identify and delineate the IJV before ligating it to prevent injury to the vagus nerve (CN X) in the carotid sheath.

4. It is important to secure the inferior vascular stump of the IJV with double ligation, one of which must be a suture-ligature to prevent slippage of these surgical ties. This method is also important for ligation of the superior stump of the IJV at the skull base.

5. Identification of lymphatic vessels and control of an intraoperative lymphatic duct injury are important: right lymphatic duct in the right

neck and thoracic duct in the left neck, respectively.

6. Dissection must stay superficial to the deep cervical fascia in order to prevent injury to the phrenic nerve.

Preoperative Period

History

1. History of presenting illness: Patients will often present with a sizable mass in the neck. Important questions include:

   a. *Duration and rate of growth of the mass?* Rapidly growing masses or a sudden increase in the size of the neck mass may indicate an aggressive cancer that requires expedited management.

   b. *Are there any other associated factors?* Patients may also complain of dysphagia, dysphonia, otalgia, epistaxis, hemoptysis, rapid weight loss, or other symptoms that may help in identifying the site of the primary cancer.

2. Past medical history

   a. The medical history should seek to identify significant medical comorbidities that may influence or, in some cases, preclude operative management.

   b. Recognition of comorbid disease helps to identify patients who will require close observation or specialized intervention during the perioperative course. For example, those with history of deep venous thromboembolism or atrial fibrillation will require a coordinated effort to ensure appropriate perioperative management of their coagulation status.

3. Past surgical history

   a. It is important to consider whether there has been any prior operative management including fine-needle aspiration (FNA), open biopsy, or previous neck dissection. Such prior interventions may influence incision planning and the extent of resection.

   b. Any previous operative and/or pathology reports should be reviewed. When possible, discussion with the previous operating

surgeon can be of tremendous value in reoperative situations.

c. Prior history of radiation is important. Surgical incision planning to avoid three-point closures over the carotid system and carotid coverage with vascularized tissue may be considerations in radiated patients due to the high incidence of wound infection and breakdown, increasing the risk of carotid blowout.

4. Social history

a. Alcohol and tobacco are known to be risk factors for cancer of the head and neck; addiction history (including use of illicit drugs) also helps in preparation for postoperative management. For example, chronic alcohol abuse requires very close observation and frequently involves medical management for prevention of delirium tremens and other associated sequelae of alcohol withdrawal syndrome.

Physical Examination

1. A complete examination of the head and neck including the cranial nerves and flexible fiberoptic laryngoscopy is critical in evaluating the primary cancer, residual disease, or recurrence.

2. A general examination of the patient may reveal signs of temporal wasting (indicating malnutrition), previous surgical incisions, or post-radiation skin changes.

3. All patients considered for RND should have clinically apparent lymph node metastasis. There is no indication for RND in the N0 neck. Questions to consider during examination of a neck mass should include:

a. *Is the mass in the neck mobile?* If the mass appears firm, ill-defined, and partially fixed to underlying structures, RND is likely indicated. If the mass is well defined and mobile, the patient may be a candidate for a modified radical neck dissection (MRND) instead.

b. *Where is the mass in the neck located*? Large, fixed, and matted nodes high in level II or low in level V may portend the need for RND, as these tend to be overlapping locations for the critical nonlymphatic structures (SCM, IJV, CN XI).

c. *Is there involvement of the overlying dermis or skin*? If the skin is inseparable from the underlying neck mass, this may be a sign that

an extended neck dissection with resection of the skin is warranted. This is important when considering design of the incision, as the resulting defect will likely require consideration of different reconstructive options.

4. Examination of the cranial nerves: Examination of the cranial nerves, particularly the lower cranial nerves (VII and IX to XII), will give an indication of the extent of the cancer, help to anticipate postoperative morbidity, and allow estimation of prognosis; the latter may impact the treatment plan.

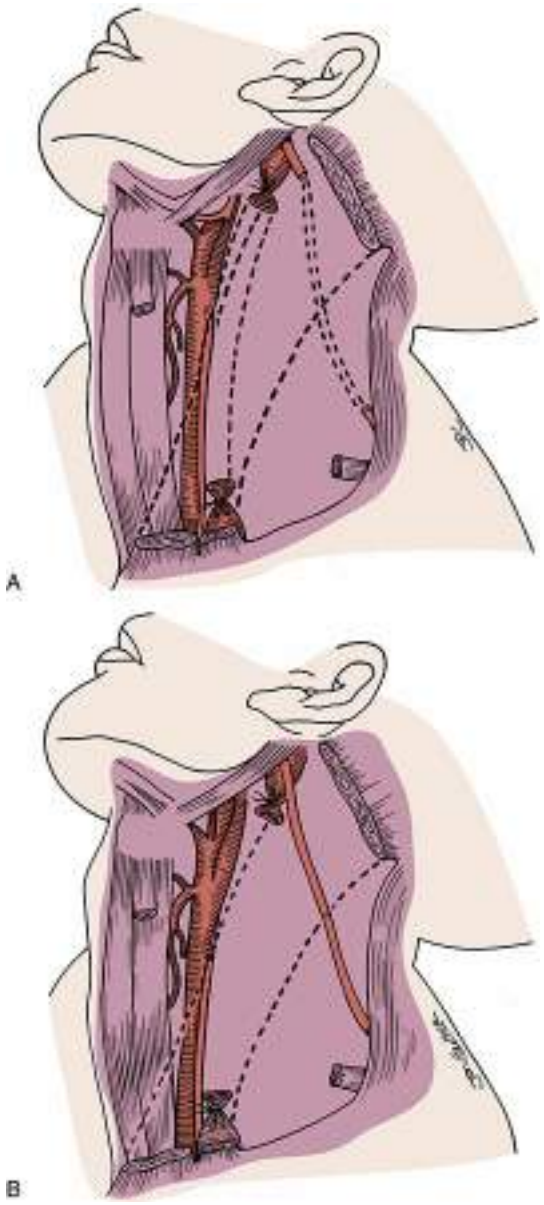

FIG. 66.1 Radical neck dissection—the

sternocleidomastoid muscle, the internal jugular vein, and the 11th nerve have all been resected with the specimen; dotted lines reveal outlines of the resected structures.

Imaging

1. Contrasted computed tomography (CT) scan of the neck with and without contrast (1 mm sections)
    a. A contrasted CT scan is complementary to the physical examination and allows preoperative assessment of lymph node metastasis, levels involved, and critical information regarding proximity/involvement of major vessels, skin, and deep muscles of the neck.
    b. In these situations of advanced cancer of the head and neck, CT imaging may assist in determining the resectability of the cancer. Invasion of the prevertebral/paraspinal musculature or encasement of the carotid artery may guide the surgeon away from operative management.
2. Positron emission tomography (PET)-CT
    a. Those patients being considered for RND have advanced stage cancer. A preoperative PET-CT assists in ruling out distant metastases, as the latter would preclude operative management of the neck, unless planned only for palliation.
3. CT angiography or formal angiography
    a. Some patients who have bulky lymph node metastasis will be found to have involvement of the carotid artery. In select patients, evaluation of the carotid artery with angiography and balloon occlusion testing may assist in the preoperative evaluation if extended RND with carotid resection is being considered (see Discussion).

Indications

1. MRND and selective neck dissections (SNDs) have been validated to

show similar oncologic outcomes to RND but with much less morbidity.[2] As such, the RND is not as frequently performed as it has been in the past.

2. RND is still indicated when there is bulky lymph node metastasis involving the SCM, IJV, and CN XI. These are often found in close proximity high up in level II (Fig. 66.2) or lower in the posterior triangle of the neck.

3. Rather than attempting dissection of these structures away from the cancer, it is more oncologically sound to include these nonlymphatic structures in the specimen, generally speaking.

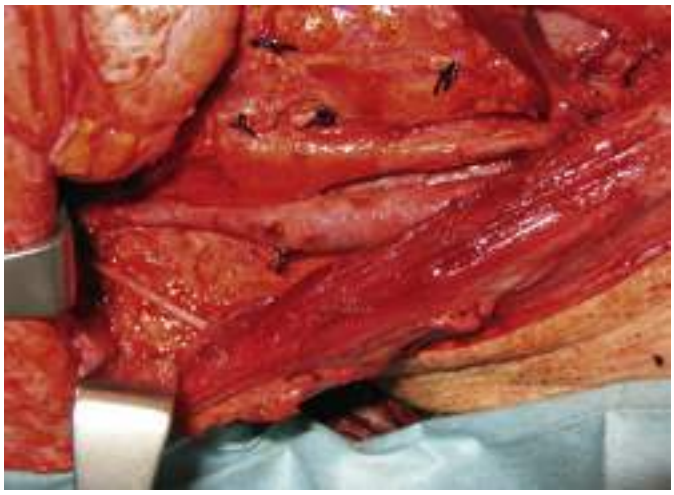

FIG. 66.2 Operative photo of right neck contents, demonstrating close association of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve in level II.

Contraindications

1. Invasion of the prevertebral or paraspinal musculature

2. Involvement of the brachial plexus

3. Complete encasement of the carotid artery is a relative contraindication.

a. Studies have shown that carotid artery resection and grafting are

feasible and can be considered, provided adequate collateral cerebral circulation can be gauged with preoperative balloon occlusion studies.[3]

4. Involvement of the cranial base

5. Inability to completely control the primary cancer

6. Distant metastasis

Preoperative Preparation

1. Medical comorbidities should be appropriately addressed prior to consideration for surgery. Those patients with significant cardiopulmonary issues should be evaluated by the anesthesiologist and undergo a comprehensive medical evaluation for clearance.

2. Patients may also be severely malnourished, and when possible, the nutritional status should be optimized prior to surgery.

3. Informed consent and patient understanding are critical. Specifically, patients should comprehend the morbidity of facial lymphedema as well as shoulder dysfunction and associated pain (Fig. 66.3), which may require intensive postoperative physical therapy.

Operative Period

Anesthesia

1. General anesthesia

2. Paralytic agents are generally avoided so that motor nerves can be stimulated and monitored.

   a. The marginal mandibular nerve should be identified and protected after elevating the subplatysmal skin flaps. Avoiding paralysis can help with identification, allowing use of the handheld nerve stimulator. Identification of CN XI can also be facilitated, especially in the posterior triangle of the neck.

FIG. 66.3 A patient with "shoulder syndrome" resulting from 11th nerve sacrifice.

Positioning

1. The operating table is turned 180 degrees from anesthesia.
   a. This facilitates adequate positioning for retraction by assistants around the head of the table.
   b. This position also moves the anesthesia circuit to the foot-end of the patient, permitting adequate working space for the surgeons around the head and neck region.
2. A shoulder roll is placed to allow for appropriate neck extension.
3. The arms are tucked, and the chest should be included in the prep field in the event that a pectoralis major flap is required.

Perioperative Antibiotic Prophylaxis

1. A first-generation cephalosporin is generally used for RND.
2. If RND is being performed in conjunction with resection of the primary cancer in which mucosal spaces will be exposed, the perioperative

antibiotic regimen may change accordingly.

Monitoring

1. An arterial line is generally placed while positioning the patient. In addition, for prolonged cases, central venous access may be required.

2. Nerve monitoring systems are not routinely used. However, as noted, paralytic agents are avoided and the handheld nerve stimulator can be used if needed.

Instruments and Equipment to Have Available

1. A basic head and neck set

2. Monopolar and bipolar electrocautery

3. Harmonic focus (Ethicon)

4. A handheld nerve stimulator

5. Vessel loops

Key Anatomic Landmarks

1. The marginal mandibular nerve

   a. This should be identified and dissected free to be retracted with the elevated subplatysmal flap along with the posterior facial vein and facial artery, protecting the nerve from injury (Hayes-Martin maneuver) (Fig. 66.4).

2. The posterior belly of the digastric muscle

   a. Many critical structures are deep to the digastric muscle, so it can be an important landmark, especially in a field with distorted anatomy.

   b. Dissection of the posterior belly may sometimes facilitate identification of the hypoglossal nerve.

   c. A safe dissection can be created over the posterior belly of the

digastric ("digastric tunnel"). The only structure to identify and ligate is the retromandibular vein while dissecting over the posterior belly of the digastric muscle.

3. CN XI

   a. Should be identified in "unwrapping" the SCM, although this may be difficult if RND is being done for bulky metastasis high in level II

4. The lateral process of C2

   a. This is a consistent and palpable landmark for identifying the junction of the spinal accessory nerve where it crosses the IJV just below the skull base. The superior end of the IJV lies just anterior to the lateral process of C2.

5. The omohyoid muscle

   a. The contents of the carotid sheath can be found just deep to the omohyoid muscle lower in the neck. (This is similar to the relationship of the digastric muscle to the sheath in the upper neck.)

6. The phrenic nerve

   a. This should always be identified, lying on the superficial aspect of the anterior scalene muscle. It is an important landmark, especially when bringing the specimen anteriorly. Keeping the nerve in view and staying superficial to the deep cervical fascia will prevent injury to the nerve.

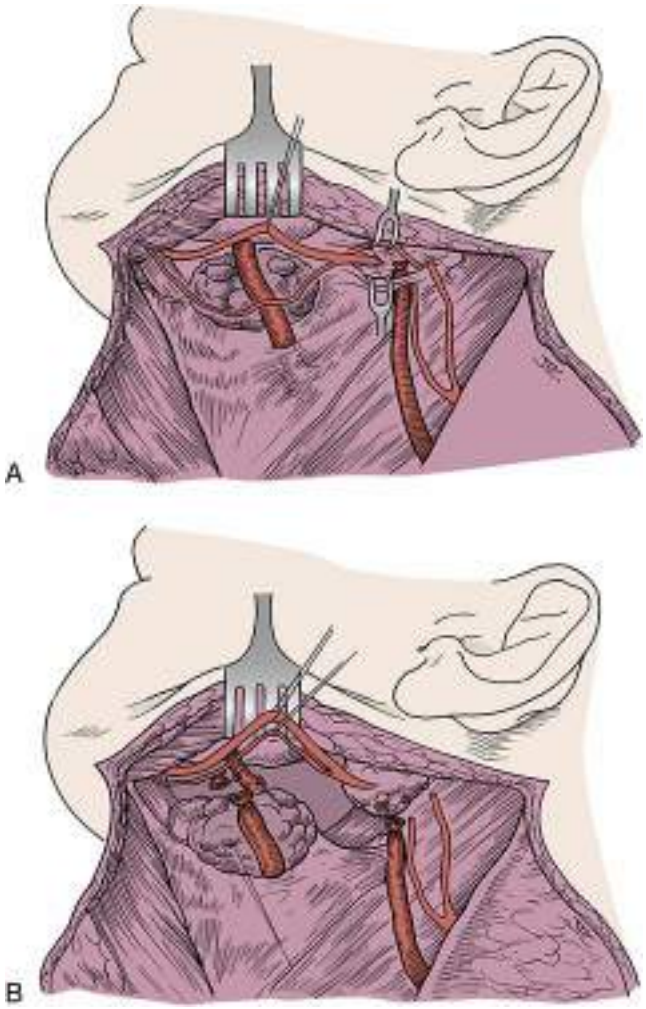

FIG. 66.4 Dissection of the marginal mandibular nerve from the submandibular gland posteriorly in order to preserve the nerve. **A,** Marginal mandibular nerve, emerging from the tail of the parotid gland, passes across the inferior border of the submandibular gland. **B,** Marginal mandibular nerve dissected free of the submandibular gland and elevated along with subplatysmal skin flap. Facial artery and vein have been ligated and divided. Note that all branches of the great auricular nerve have been divided in this illustration. In practice, the posterior branch can usually be preserved.

Prerequisite Skills

1. Techniques from previous chapters discussing selective neck dissection and modified radical neck dissection also apply here.

2. Open head and neck surgery skills

Operative Risks

1. Infection
2. Injury to the marginal mandibular nerve
3. CN XI injury
4. Injury to the phrenic nerve
5. Injury to the brachial plexus
6. Carotid artery rupture
7. Injury to the vagus nerve
8. Chylous fistula
9. Air embolism
10. Hemorrhage

Surgical Technique

1. Surface landmarks should be identified and marked out.
    a. We delineate and mark out the mastoid tip, the angle of the mandible, suprasternal notch, and the cricoid cartilage.

2. Incision is planned. We use an extended "hockey stick" incision or half-apron incision for unilateral neck dissection, designed from the mastoid tip and extending to a skin crease in the lower neck (Fig. 66.5).
    a. If bilateral neck dissections are planned, the incision carries over to the opposite mastoid tip (an "apron" incision).

3. Subplatysmal flaps are elevated to define the boundaries of the neck dissection.
    a. Superior boundary: inferior border of the mandible that extends to a line joining the angle of the mandible to the mastoid tip
    b. Anterior boundary: superior belly of the omohyoid and anterior belly of the digastric muscle

c. Inferior boundary: suprasternal notch and clavicle

d. Posterior boundary: anterior border of the trapezius

1) Initially, the great auricular nerve and external jugular vein are identified and protected unless involved by cancer, in which case they may be sacrificed.

4. The marginal mandibular nerve should then be identified (Fig. 66.4).

FIG. 66.5 Operative photo of "hockey stick" incision used for unilateral radical or elective neck dissection.

a. Its course can be quite variable, but generally blunt dissection starts about 1 cm below the antegonial notch near the point where it exits the parotid gland. Identification can be assisted with the use of magnifying loupes and the handheld nerve stimulator.

b. Once located, it should be dissected anteriorly and posteriorly, freeing it from the submandibular fascia to allow for retraction with the superior subplatysmal flap that was elevated.

c. Multiple branches may be identified, and they should all be preserved if possible.

d. The Hayes-Martin maneuver involves identifying the facial artery and vein below the course of the marginal mandibular nerve, ligating these vessels and reflecting them superiorly with the subplatysmal flaps, in effect, preserving the marginal mandibular nerve.

5. Level 1 neck dissection

a. With the marginal mandibular nerve safely elevated, the fascia deep to it is incised and the anterior belly of the digastric muscle is identified. The submental adipose tissue and nodes are grasped and dissection is carried inferiorly along the anterior belly of the digastric muscle.

b. As the dissection continues, the mylohyoid muscle will come into view. The mylohyoid muscle is dissected and the free edge exposed posteriorly, then retracted with an Army-Navy retractor. Care must be taken to identify and cauterize the submental branches of the facial vessels. The edge of the mylohyoid muscle is delineated in its entirety and then retracted anteriorly. The submandibular gland is retracted posteriorly and inferiorly. This maneuver helps to identify the lingual nerve, the submandibular ganglion, and the submandibular duct (Fig. 66.6).

c. The submandibular duct and submandibular ganglion are then clamped and ligated, bringing the contents of submandibular triangle (level Ib) along with the specimen.

d. The facial artery and vein are ligated at the level of the posterior belly of the digastric and the submandibular gland with level 1b contents delivered.

6. Dissection is then continued over the digastric tunnel. The retromandibular vein is ligated, and this dissection often involves resecting the lower-most portion of the tail of the parotid gland. In this maneuver, the marginal branch of CN VII is again protected. The gland is suture ligated with a silk tie to promote fibrosis and prevent salivary leak and sialocele formation.

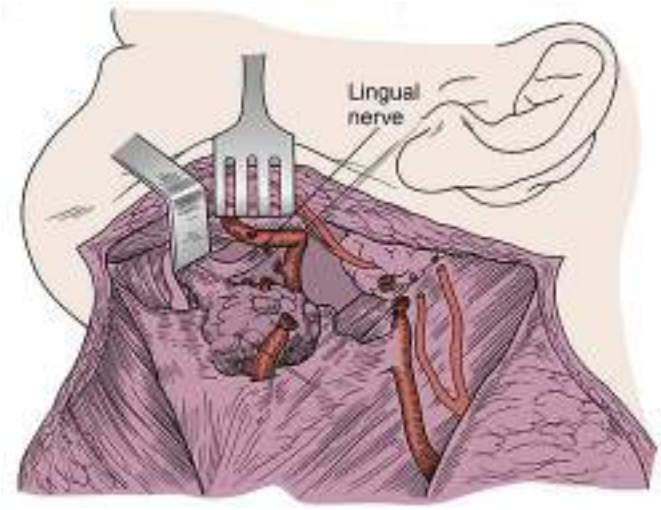

FIG. 66.6 Retraction of the mylohyoid muscle to expose the lingual nerve, submandibular ganglion, and Wharton's duct.

7. Level II dissection
   a. The digastric muscle is retracted superiorly and CN XI is identified and traced to its point of entry into the SCM (assuming it is not encased in tumor at this level).
   b. The superior aspect of the IJV is isolated.
   c. The hypoglossal nerve is identified and preserved. Attention is then directed to the inferior border of the neck dissection.
8. Dividing the inferior attachments of the SCM (Fig. 66.7)
   a. The sternal and clavicular heads of the SCM are divided approximately 1 cm above the clavicle.
   b. The proximal end of the muscle is then retracted superiorly, and the omohyoid muscle can be seen. This is an important landmark, as it is just anterior to the contents of the carotid sheath.
   c. The omohyoid is divided and traced toward the midline, marking the anterior limit of the neck dissection.
9. Level IV dissection
   a. Blunt dissection in level IV should be performed until the phrenic nerve and brachial plexus are identified. The phrenic nerve is located on the anterior surface of the anterior scalene muscle. The

brachial plexus is located between the anterior and middle scalene muscles.

b. With the phrenic nerve in view, the surgeon can then clamp and ligate the contents of the supraclavicular adipose tissue pad, retracting it superiorly as part of the specimen.

c. Care must be taken to clamp and ligate the contents of level IV to avoid damage to the thoracic duct on the left and right lymphatic duct on the right side of the neck.

d. The lower end of the IJV is identified and secured. It is dissected free from the common carotid artery and clearly defined from the vagus nerve.

10. Level V exposure

a. The dissection is continued posterior-lateral to the SCM, releasing the contents of the supraclavicular fossa, defining the transverse cervical vessels and brachial plexus. Working from the critical structures identified in level IV, the dissection is carried posteriorly until the anterior border of the trapezius muscle is identified.

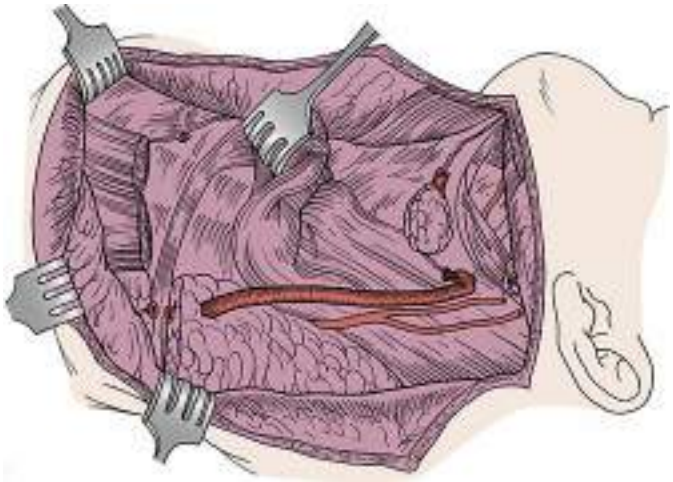

FIG. 66.7 Dividing the clavicular head of the sternocleidomastoid muscle and supraclavicular tissue lateral to the omohyoid muscle. The brachial plexus, carotid sheath, and phrenic nerve are protected by their deep position to this muscle.

b. The anterior border is dissected superiorly toward the skull base.

c. The spinal accessory nerve is usually encountered in level V. It is sacrificed here and brought anteriorly with the specimen.

11. Dividing the superior attachments of the SCM

a. The SCM is then divided just inferior to the mastoid tip, and the dissection carries down to the fascia overlying the deep musculature of the neck.

b. The SCM is now free both superiorly and inferiorly. With the anterior border of the trapezius delineated, the dissection (of fibroadipose and lymph-node bearing soft tissues) now carries anteriorly, taking care to leave some fascia on the deep neck musculature, thus sparing as much as possible of the cervical plexus.

c. The dissection continues, and the nerves of the cervical plexus are divided from the specimen high in the neck. The phrenic nerve should always be kept in view during this stage to avoid inadvertent injury (Fig. 66.8).

12. Dividing the IJV

a. As the specimen is reflected anteriorly, the carotid sheath will be encountered.

b. The isolated IJV is now ligated and included within the specimen. This is first done inferiorly in level IV. The IJV should be clearly delineated, and the vagus nerve should also be identified to avoid iatrogenic injury.

c. The IJV is then doubly clamped and suture ligated. With the critical anatomic structures under direct visualization, the lymphatic pedicle can now be clamped and ligated, freeing the inferior portion of the specimen.

d. Dissection is now brought superiorly along the carotid sheath. The posterior belly of the digastric muscle is retracted superiorly and the IJV isolated in level II. The spinal accessory nerve is sacrificed here, and the IJV is then again doubly clamped and suture ligated. Branches of the IJV including the common facial, lingual, and superior thyroid, which are variable in size and location, must also be ligated at this step.

1) In difficult cases with large cancers, the lateral process of C2 is a

consistent palpable landmark for identification of the IJV and the accessory nerve at its junction with the IJV.

13. Bringing the specimen anteriorly to the midline

a. Now free superiorly and inferiorly, the specimen is connected to the previous level I dissection and brought to the midline with the lateral border of the strap muscles being the anterior limit. The specimen is removed.

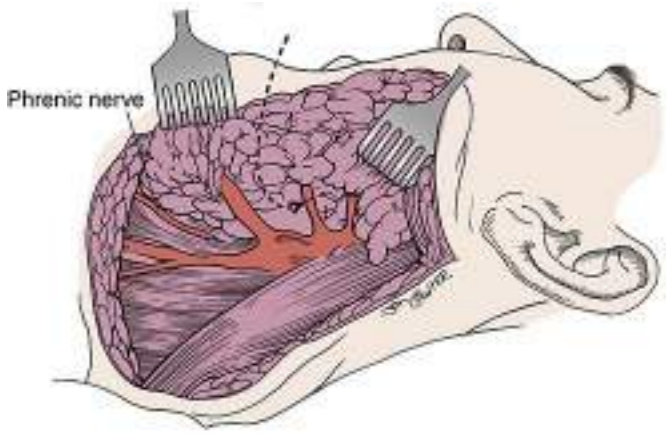

FIG. 66.8 Exposure of the cervical nerves (shown here in red) as they leave the cervical plexus. Care must be taken to avoid stripping the cervical plexus off the deep muscles.

14. The neck is then copiously irrigated and the Valsalva maneuver is performed to check for hemostasis and/or any evidence of chyle leak.

15. After hemostasis is achieved, suction drains are placed in the wound. The platysma is re-approximated, and the skin incision is closed with staples.

Common Errors in Technique

1. Inadequate identification of the marginal mandibular nerve

2. Failure to isolate and control the IJV or its branches

3. Failure to adequately ligate the lymphatic pedicle

4. Failure to identify the phrenic nerve and brachial plexus

Postoperative Period

Postoperative Management

1. Patients should be admitted to a monitored unit following RND.

2. Perioperative antibiotics should continue for 24 to 48 hours.

3. Drains are maintained on suction with accurate recordings.

4. Physical therapy should be initiated early in the postoperative period to address shoulder dysfunction and minimize pain.

Complications

1. Infection

   a. Perioperative antibiotics reduce the risk of infection and should be continued for 24 to 48 hours postoperatively. There is a greater risk of infection when the upper aerodigestive tract is involved in the surgical field.

   b. Postoperative wound infections may manifest as erythema, edema, or purulent drainage from the suction drains.

   c. Broad-spectrum antibiotics should be initiated and cultures sent. Antibiotics can be narrowed down following isolation and appropriate sensitivities.

   d. If there is no improvement with medical management, the neck may require exploration and drainage of an abscess in the operating room.

2. Hematoma

   a. Most commonly occurs due to inadequate hemostasis intraoperatively

   b. Hematomas should be managed in the operating room with re-exploration, irrigation, and identification of the underlying bleeding vessel. Often, no definite vessel is found, but it is still important to

evacuate an expanding hematoma and replace the drains, as they may now be clotted off and are no longer useful.

3. Marginal mandibular nerve injury

   a. An injury to the marginal branch may not be noticed until the postoperative period. Some of the asymmetry may be related to a neuropraxic injury from retraction or even weakness from the plastysmal contribution to the lower lip.

   b. Most patients have no issues with oral competency, and it can be managed expectantly in the immediate postoperative period.

4. Phrenic nerve injury

   a. It is important to always keep the phrenic nerve in view during the dissection.

   b. Unilateral phrenic nerve injury is tolerated by most patients, but for some patients with underlying pulmonary disease it can be problematic.

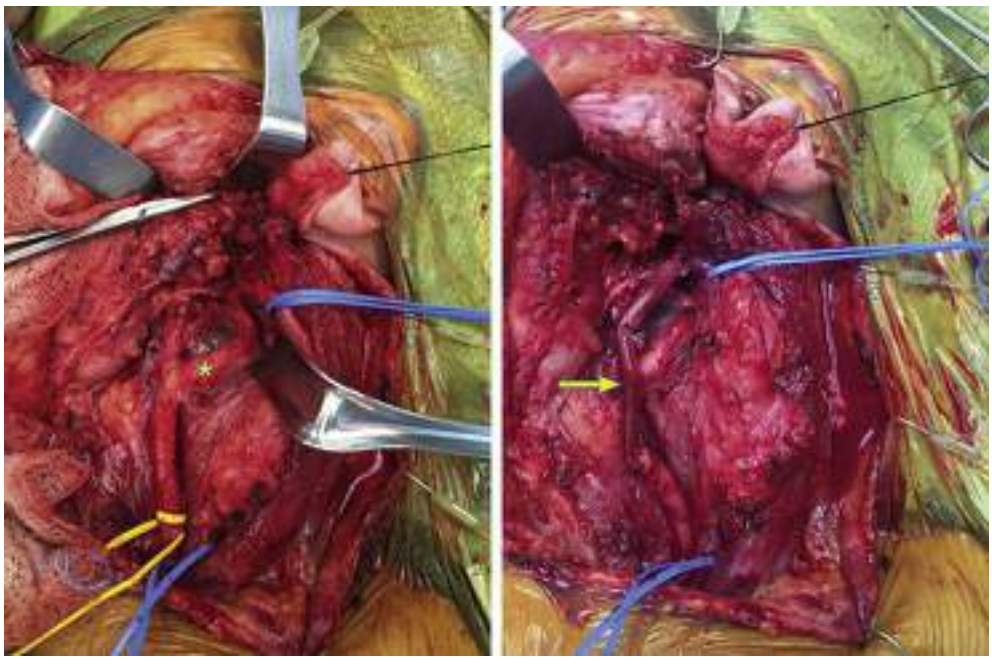

FIG. 66.9 Extended neck dissection with sacrifice of the common and internal carotid artery with saphenous vein interposition grafting. *Left:* Star shows the internal carotid artery involved with cancer just distal to the bifurcation.

Right: Arrow demonstrates the saphenous vein interposition graft from the common to the internal carotid artery.

5. Brachial plexus injury
   a. Injury to the brachial plexus can be avoided by careful dissection and identification in level IV.
   b. The physical therapy team should be involved early if there are findings of brachial plexopathy.
6. Chylous fistula
   a. The lymphatic pedicle is clamped and ligated during the RND. Most chyle leaks are recognized intraoperatively; however, there can still be problems that manifest during the postoperative course.
   b. Low output fistulas can be managed conservatively with a medium chain triglyceride diet, pressure dressing, and medical management.
   c. For higher output fistulas or those that are not responding to conservative management, surgical re-exploration may be required.

Alternative Management Plan

1. MRND
   a. There may be some instances where RND is anticipated, but operative findings may determine that RND is not required.
   b. During the initial portions of the procedure, there should be an attempt to determine the status of the SCM and spinal accessory nerve.
   c. Occasionally, one or more of the nonlymphatic structures can be preserved, significantly reducing morbidity without necessarily compromising outcome (Fig. 66.8).
2. Extended neck dissection
   a. With these advanced cancers of the head and neck, there may be an occasion where other structures should be included in the specimen for oncologic reasons.

b. This may include other nodal groups (e.g., paratracheal, suboccipital, or mediastinal nodes) or other nonlymphatic structures such as overlying skin, muscle (digastric muscle, levator scapulae muscle), or cranial nerves (hypoglossal nerve, vagus nerve). This is classified as an extended neck dissection.

3. Nonoperative management

a. A clinical and radiographic preoperative evaluation should be completed to determine resectability of the primary cancer and regional lymph node metastasis. With rare exceptions, RND should not be performed in those instances where there is involvement of the cranial base, the deep neck musculature/prevertebral fascia, encasement of the carotid artery, or evidence of distant metastasis.

b. Additionally, there may be some patients who cannot tolerate the surgery or perhaps do not want to proceed with surgery. It is important to provide specific and detailed informed consent while respecting the patient's wishes.

Discussion

Evidence-Based Medicine Question

Is there a role for surgical management of the neck with advanced stage cancer when there is radiographic evidence of carotid artery involvement?

Historically, involvement of the carotid artery has been a contraindication to surgical management of cervical lymph node metastasis. With initial complications and stroke rates greater than 50%, the morbidity and mortality of such intervention did not outweigh any potential benefits. With the advent of advanced imaging and new testing, there have been recent attempts to identify those patients who may tolerate carotid resection or ligation.[4] Angiography and temporary balloon-occlusion testing have now become standard in the evaluation of those patients who are being considered for extended RND with resection and reconstruction of the common or internal carotid artery. Freeman et al. reviewed a series of 58 patients who underwent either ligation or carotid resection with saphenous vein interposition grafting

(Fig. 66.9).[5] Cerebrovascular accident (CVA) was found to occur in 20% of patients; however, disease-specific and disease-free median survival were found to be only 12 months. Furthermore, 24% of patients were found to ultimately have distant metastases. There are other retrospective studies to suggest an impact on survival in those patients with involvement of the carotid artery.[6] However, the data remain limited with regard to this topic, and it is still a difficult avenue of discussion with patients and their caregivers. The current standard is to perform preoperative balloon-occlusion testing to assess for patient tolerance and acceptable collateral cerebral perfusion. For those patients with reasonable collateral flow, surgery may be offered with the patient having reasonable expectations and understanding the risk of CVA and potential mortality even in the presence of a normal balloon occlusion test.

Editorial Comment

Metastasis to the cervical lymph nodes is a documented indicator of poor prognosis for patients with head and neck cancer. The appropriate management of the neck is vital to outcomes, quality of life, and palliation. Although RND has lost favor in the recent years due to increasing evidence of oncologic safety and viability of more functional forms of neck dissection, it still has an important place in the management of advanced neck disease and surgical palliation. The changing paradigm from primarily surgical management of head and neck cancer to nonsurgical approaches has brought on its own set of challenges, that is, operating in radiated fields with a high incidence of complications and equally important wound breakdown and infection that may lead to life-threatening complications such as carotid artery rupture. Head and neck surgeons have to be cognizant of these challenges and be prepared to reconstruct the neck when indicated. A thorough knowledge of rotational flaps such as the pectoralis major myocutaneous flap or levator flaps can be instrumental in providing robust and efficient options for carotid artery cover. RND is the foundation of all forms of neck dissection; every practicing head and neck surgeon must be competent in performing this procedure.

Review Questions

1. A radical neck dissection (RND) involves removal of the sternocleidomastoid muscle (SCM), internal jugular vein (IJV), and cranial nerve (CN) XI along with which nodal levels?

   a. Levels II to IV

   b. Levels II to V

   c. **Levels I to V**

   d. Levels I to IV

2. Which of the following is not a contraindication to RND?

   a. Skull base involvement

   b. **Skin involvement**

   c. Distant metastasis

   d. Brachial plexus involvement

3. Which structure is at risk if not appropriately identified before ligating the lymphatic pedicle?

   a. **The phrenic nerve**

   b. The cervical plexus

   c. The internal carotid artery

   d. The vagus nerve

Central Compartment Neck Dissection

Cherine H. Kim, and Alfred Simental Jr.

Introduction

The central compartment contains the first nodal basin for cancer originating in the thyroid and parathyroid and can be involved in cancers of the laryngotracheal complex. This space encompasses the prelaryngeal, pretracheal, and paratracheal lymph nodes, also known as the level VI lymph nodes, although superior mediastinal nodes and retro-esophageal nodes are often included and represent level VII. In cases of squamous cell cancer involving the central compartment viscera or parathyroid carcinoma, comprehensive central compartment lymph node dissection is routinely employed, often in combination with ipsilateral thyroidectomy. However, the central compartment lymph nodes are most commonly affected by the regional spread of thyroid cancers. Well-differentiated thyroid cancer (WDTC) will prove to have metastases in the central compartment in 20% to 50% of cases.[1] In these cases, central compartment neck dissection is unquestionably indicated, given the strong relationship between loco-regional control and treatment of clinically positive central compartment disease. Subclinical micrometastases have been shown to be present in up to 90% of cases of thyroid cancer,[1] presumably with less defined clinical significance when compared with macrometastases. There has been no survival benefit associated with prophylactic treatment of the central neck, with equivocal data on local control.[2] Patients with known metastasis in the central compartment are more likely to experience recurrence than their counterparts. Prophylactic central compartment dissection with total thyroidectomy has shown increased rates of postoperative hypocalcemia when compared with total thyroidectomy alone. However, the use of prophylactic central compartment neck dissection results in improved local control and decreases the potential risk of morbidity of reoperative

surgery. Additionally, the pathologic assessment of the central compartment lymph nodes may help in risk stratification for additional adjuvant treatment such as radioactive iodine (RAI).

The literature fails to offer definitive evidence advocating prophylactic treatment of the central compartment in the management of well-differentiated thyroid cancer (WDTC). The role of prophylactic central compartment neck dissection remains controversial, largely due to the lack of a large randomized prospective trial—the feasibility of which is questionable given the prohibitively large sample size it would require.[3] Ultimately, comprehensive preoperative evaluation and appropriate risk assessment and anatomic knowledge are imperative for successful surgical treatment of the central neck. The presence of medullary thyroid carcinoma, with or without evidence of nodal involvement, is an indication for dissection of the lymph nodes in the central compartment.[4]

Key Operative Learning Points

1. Central compartment dissection is often a reoperative surgery and may require a different surgical strategy (lateral to medial).

2. Identification and continued observation of the recurrent laryngeal nerve (RLN) is the best way to avoid injury to the nerve.

3. Identify and lateralize the superior parathyroid glands with their blood supply.

4. A low threshold for auto-transplantation of inferior parathyroid glands after pathologic verification

5. Complications are more common with paratracheal dissection, especially hypocalcemia, vocal fold paralysis, and injury to the esophagus.

Preoperative Period

History

1. History of present illness

a. Determine if this is primary or secondary disease. Central compartment dissection is often employed in the case of a loco-regional recurrence of thyroid cancer.

1) Obtain operative and pathology reports from previous surgeries.

b. Evaluate for pre-existing morbidity.

1) chronic obstructive pulmonary disease (COPD) or cardiovascular disease

2) History of gastric bypass or gastrointestinal absorption abnormality

a) May require calcium challenge if parathyroid hormone (PTH) is elevated to ensure gastric absorption

c. Invasive symptoms: hemoptysis, skin fixation, or voice changes from vocal cord paralysis

1) Fiberoptic laryngoscopy

2) Advanced imaging

2. Risk factors for severe morbidity

a. Pre-existing vocal fold paralysis

1) Contralateral deficit may result in tracheostomy

b. History of previous neck surgery or radiation

c. Hemoptysis or cough

1) May signify invasive component

2) Require cross-sectional imaging

3. Past medical history

a. Well-differentiated thyroid cancer (WDTC)

b. Medullary thyroid carcinoma, multiple endocrine neoplasia (MEN)

Physical Examination

1. Complete examination of the head and neck

a. Palpate thyroid bed and paratracheal regions.

1) Note location of masses with, relation to swallowing, fixation to skin, or underlying structures.

b. Palpate lateral neck for lymphadenopathy.

c. Listen for hoarseness, stridor.

d. Determine location of native anatomy.

1) Low-lying larynx/cricoid

2. Direct or indirect laryngoscopy

a. Essential in detecting vocal cord paralysis

b. The voice may be normal despite a paralyzed vocal cord.

Diagnostic Studies

Laboratory Studies

1. Thyroid stimulating hormone (TSH)

a. Verify that the patient is euthyroid.

2. Thyroglobulin (Tg)/thyroglobulin antibody (Tg Ab)

a. Determine relative burden of disease, especially in reoperative cases.

3. Calcitonin

a. Patient with a family history of medullary thyroid carcinoma or MEN-2, or biopsy shows medullary thyroid carcinoma

4. Parathyroid hormone

Imaging

1. High-resolution ultrasound (US)

a. Microcalcifications are associated with markedly increased risk of malignancy, while cystic and spongiform appearance may be associated with benign lesions.

b. Low-cost, no radiation, and reliable when performed by experienced

clinicians

c. Low sensitivity of detecting lymphadenopathy in the central neck due to shadowing effect of the thyroid gland

2. Computed tomography (CT) and magnetic resonance imaging (MRI)

a. Helpful for:

1) Substernal extension

2) Cervical and mediastinal lymphadenopathy

3) Invasion of surrounding structures such as trachea and esophagus

4) Metastasis to distant sites

b. High sensitivity and specificity in detecting cervical lymphadenopathy, and less operator dependence, offers visualization of adjacent structures

c. Expensive, radiation exposure, and use of iodinated contrast may preclude the use of RAI for 1 to 3 months

3. Radionuclide scanning

a. Useful for rising Tg with negative imaging

4. positron emission topography (PET) imaging

a. Useful for RAI negative, Tg positive patients

Fine-Needle Aspiration

1. Essential for reoperative surgery

a. Minimally invasive, safe, and cost-effective

b. Sensitivity 65% to 98%, specificity 72% to 100%

c. US guidance increases accuracy and success of fine needle aspiration (FNA).

2. Suspicious cervical lymph nodes or masses should undergo FNA.

3. When multiple nodules are present, the largest and/or most sonographically suspicious should be biopsied preferentially.

a. Multiple nodules may need to be biopsied to increase diagnostic yield.

b. Biopsies should direct surgical planning.

Molecular Biomarkers

1. Newer studies introduced to increase accuracy of FNA and better characterize the risk of malignancy, especially in indeterminate cytology, Atypia of Undetermined Significance (AUS), and Follicular Lesion of Undetermined Significance (FLUS). These markers may:

a. Reduce unnecessary surgery for benign lesions

b. Reduce completion thyroidectomy by guiding initial use of total thyroidectomy

c. Provide prognostic information such as:

2. BRAF, RAS, TIMP1, RET/PTC, Pax8-PPARγ, galectin-3, cytokeratin, microRNA, gene sequencing

3. Uncertain evidence regarding efficacy and utility

Indications

1. Differentiated thyroid cancer

a. Initial surgery

1) BRAF positive disease

2) Gross extrathyroidal extension

3) Presence of suspicious paratracheal lymph node (LN)

a) Microcalcifications

4) Initial presentation of well-differentiated thyroid carcinoma (WDTC) with lateral neck metastasis

b. Contralateral thyroid nodule or distant metastasis

c. Multinodular goiter with radiation exposure to the head and neck

d. First-degree family members with thyroid cancer

2. Medullary thyroid carcinoma

   a. May require concomitant lateral neck dissection

3. Parathyroid cancer

   a. Ipsilateral thyroid lobectomy

Contraindications

Relative Contraindication

1. Uncontrolled medical disease

2. Pregnancy

   a. May elect to postpone until postpartum

   b. If substantial growth, surgery may be performed in second trimester to reduce risk of miscarriage.

3. Significant distant metastasis unresponsive to suppression

4. Contralateral vocal fold paralysis

Absolute Contraindications

1. Unresectable mediastinal disease

2. Intracranial metastasis

Preoperative Preparation

1. Screen for comorbidities.

2. Document vocal cord movement with indirect laryngoscopy prior to surgery.

3. Ensure euthyroid state.

4. Accurately map disease and surgical plan.

Operative Period

Anesthesia

1. General anesthesia with endotracheal intubation

Positioning

1. Supine
    a. Shoulder roll to extend neck slightly and elevate laryngeal framework
    b. Head placed in a donut to prevent rotation
2. The bed can be shifted away or rotated 180 degrees from anesthesia to provide more surgical space.
3. The back and head may be elevated 10 to 30 degrees to reduce venous congestion.
4. Prepare neck and upper chest with povidone-iodine or chlorhexidine (entire chest if sternotomy anticipated).
5. Arms tucked at the side with padding of elbows and heels
6. Protect face and eyes.

Perioperative Antibiotic Prophylaxis

1. Perioperative antibiotics are not necessary in clean thyroid surgery.
    a. A single preincision intravenous dosing of antibiotic is administered.
        1) Cefazolin or clindamycin

Monitoring

1. Intraoperative laryngeal nerve monitoring (IONM) may be used.
    a. Endotracheal tube with surface electrodes placed at the level of the vocal cords
    b. Likely greater utility in reoperative setting than primary setting
    c. Increased cost and setup time

d. Useful adjunct for identification of recurrent nerve, which may result in decreased operative time and surgeon comfort

Instruments and Equipment to Have Available

1. Basic head and neck set

2. Monopolar and bipolar cautery

   a. Consider advanced energy such as ultrasonic technology if a thyroidectomy is planned.

   b. Surgical clips should be available in room (unopened).

3. Mahorner, Lone Star, or Weitlander self-retaining retractors may be helpful if an assistant is not available.

4. Kittner/peanut sponges are helpful for blunt dissection, retracting, and protecting nerves or parathyroid tissue from the heat of electrocautery or ultrasonic technology.

5. Babcock forceps are helpful in grasping and retracting thyroid tissue.

6. McCabe dissector

   a. Has curved, precise, nonlocking tips

   b. Excellent for identifying and dissecting out the nerves

Key Anatomic Landmarks

1. Trachea/cervical spine

2. Vasculature[5]

   a. Arterial

      1) Superior thyroid artery: first branch of the external carotid artery (branch of the common carotid in 16%)

      2) Inferior thyroid artery: branch of the thyro-cervical trunk

      3) Thyroidea ima artery (in thyrothymic adipose tissue)

         a) Branch of the innominate, subclavian, or right common

carotid, internal thoracic arteries, or aortic arch

b) Supplies thyroid isthmus inferiorly

c) Present in 2% to 12% of cases

4) Carotid artery system

a) Lateral border of central compartment

5) Innominate artery

a) Inferior extent of dissection

b) Right common carotid artery may branch early

b. Venous

1) Innominate vein inferiorly

2) Internal jugular system

a) Lateral border

c. Lymphatics: prelaryngeal, pretracheal, paratracheal, parapharyngeal, deep cervical, and supraclavicular nodes

3. RLN[5]

a. Descends within the vagus nerve

1) Left: wraps around the aortic arch below the ligamentum arteriosum and returns to the neck in the trachea-esophageal groove

2) Right: branches from the vagus higher than the left and wraps around the subclavian artery before ascending along the tracheoesophageal groove more laterally than the left

3) Courses beneath the inferior pharyngeal constrictor muscle and passes posterior to the cricothyroid joint

4) Enters the larynx above the first tracheal ring, below the cricoid cartilage

b. Landmarks

1) Simon's triangle: bound by common carotid artery laterally, esophagus medially, and inferior thyroid artery superiorly

2) Variably associated with the inferior thyroid artery

a) Found behind or between branches of the artery in 80%

b) The relationship between the RLN and the inferior thyroid artery is different on the left and right in about 50% of cases.

3) Usually in the vicinity of the inferior parathyroid gland

4) Majority found within 3 mm of Berry's ligament, often laterally, and sometimes passing through the ligament

5) May pass through the capsule of the thyroid gland

6) Deep to the tubercle of Zuckerkandl in 98% of patients

7) Non-RLNs can be found in up to 0.7% of patients.

a) Primarily on the right (associated with aberrant subclavian artery), except in cases of situs inversus (dextrocardia)

b) May arise at the level of the thyroid cartilage or superior pole of thyroid and course directly into the larynx

8) May divide at various levels, and 40% to 65% bifurcate or trifurcate—more than 5 mm below the cricoid cartilage

4. Superior laryngeal nerve (SLN)

a. Arises from the nodose (inferior) ganglion of the vagus nerve about 4 cm above the carotid bifurcation, near the jugular foramen

1) Descends lateral to the pharynx and posteromedial to the carotid sheath

2) Splits into internal and external branches about 2 cm above the superior pole of the thyroid, with the former penetrating through the postero-inferior thyrohyoid membrane

b. Function

1) Internal branch: sensation and secretomotor function to the supraglottis, epiglottis, base of the tongue, piriform sinus, and upper esophageal sphincter

2) External branch: cricothyroid and inferior constrictor muscles

c. SLN external branch landmarks

1) Sternothyrolaryngeal triangle (Joll's triangle): bound by the

midline medially, superior thyroid pole laterally, and attachments of the strap muscles superiorly

2) Deep to the superior thyroid artery 82% to 86% of the time and penetrates the inferior constrictor muscle at variable levels

3) Can be found below, and up to 1 cm above, the level of the upper pole of the thyroid in 37% of patients

5. Parathyroid glands

a. Superior parathyroids

1) Fourth branchial arch structure

2) Superior or inferior thyroid vessels

3) Frequently above cricoid cartilage

b. Inferior parathyroids

1) Third branchial arch structure

2) Variable location

a) Frequently below cricoid cartilage

Prerequisite Skills

1. Intimate knowledge of the use of surgical instruments and meticulous soft tissue/neural dissection

Operative Risks

1. RLN injury

a. Preferential visual identification of the RLN before the thyroid or lymph nodes are dissected off the trachea and esophagus

2. SLN injury

a. Carefully dissect out the superior pole to ensure the SLN is not coursing within the vascular pedicle before ligation.

b. Avoid thermal injury or excessive dissection of cricothyroid and constrictor muscles.

3. Parathyroid injury or devascularization
    a. Lateralize parathyroids with their blood supply when medializing the thyroid gland.
    b. Reimplant normal, frozen biopsy confirmed parathyroids.
4. Intraoperative hemorrhage
    a. Anterior jugular veins: Carefully undermine subplatysmal skin flaps and ligate large vessels.
    b. Carotid artery: Use a blunt instrument when dissecting in this region, especially the superior pole, and be aware of depth of dissection at all times.
    c. Thyroid gland and surface vessels: Use blunt dissection close to the thyroid capsule and meticulously seal or ligate the vasculature.
5. Tracheoesophageal injury
    a. Most commonly occurs at Berry's ligament or subcricoid trachea
    b. Primary repair is usually satisfactory.

Surgical Technique

1. Marking
    a. Mark a 5-to 6-cm horizontal incision line between the cricoid cartilage and suprasternal notch.
        1) Usually 2 to 3 cm above the sternal notch
    b. Use an existing neck crease or line of relaxed skin tension that could be lengthened if lateral neck dissection is ever needed.
    c. Mark the incision higher in younger patients because the scar will migrate lower over time and a scar below the clavicle is unsightly.
    d. If sternotomy is possible, the incision should be at the clavicles or lower.
2. Local anesthesia
    a. Inject 0.25% bupivicaine with 1:200,000 epinephrine 1 to 2 cm above and below the incision line to reduce distortion and maximize hemostasis in the incision.

3. Incision

   a. Use a #15 blade to incise the dermis to the platysma.

   b. Incise through the platysma to the subcutaneous tissue with electrocautery to the investing fascia.

   c. Avoid injuring the communicating anterior jugular veins.

4. Elevate skin flaps

   a. Using skin rakes for tension, subplatysmal flaps are elevated with blunt dissection and electrocautery in the plane just above the investing fascia and anterior jugular veins up to the thyroid notch and down to the sternal notch.

   b. Ligate large vessels with 2-0 silk ties.

   c. Protect the skin with occlusive material such as Steri-Strips (preferred by the senior author; Fig. 67.1).

      1) Suture in place with locking 2-0 silk running sutures.

      2) Protects the skin from heat or instrument injury

   d. Place a self-retaining retractor in the wound if an assistant is not available.

FIG. 67.1 Occlusive skin dressing for protection. Steri-Strips with 2-0 silk.

5. Split and elevate the strap muscles.
   a. Identify the median raphe of the strap muscles.
   b. Divide the straps in the midline up to the thyroid notch and down to the sternal notch with electrocautery.
   c. Elevate the strap muscles off of the thyroid (if present) and trachea.
      1) Elevate bluntly with a Freer elevator, peanut sponge, or with electrocautery.
      2) The strap muscles should be sacrificed with a healthy margin if there is any infiltration of the muscles by the tumor.
      3) Electrocautery, surgical clips, or ties may also be used to augment ligation of the superior pedicle.
6. Mobilize the thyroid/trachea medially.
7. Identify and skeletonize the carotid artery.
   a. In reoperative surgery, this may be done before dissection of the

trachea.

b. If the strap muscles are adherent to the thyroid or trachea

1) Identify the carotid artery by dissecting lateral to the strap muscles.

2) The strap muscles can be horizontally transected to gain access to the paratracheal compartment and facilitate dissection.

8. Identify the recurrent laryngeal nerve.

a. Rotate the thyroid gland and trachea medially.

b. Using the McCabe dissector, dissect near the cricothyroid joint and the tracheoesophageal groove to identify the RLN.

1) Do not close the clamp when the tips are buried in tissue.

2) Once the RLN is identified, dissecting parallel and directly on the nerve sheath prevents damaging the nerve and its branches.

FIG. 67.2 Paratracheal packet being retracted medially away from recurrent nerve. *RLN,* Recurrent laryngeal nerve, *IJV,* internal jugular vein.

3) Trace the RLN from the paratracheal region up to the

cricothyroid muscle, being careful not to damage either the anterior or posterior branch.

a) In reoperative surgery, starting lateral near the carotid will facilitate a safe and focused dissection.

4) Grasp the paratracheal tissue with a Babcock clamp (Fig. 67.2).

a) Pull the packet superior and medial away from the nerve.

b) All fibroadipose tissue and lymph nodes overlying the trachea and medial to the carotid artery should be removed.

c. Carefully dissect and lateralize the parathyroid glands with their blood supply (Fig. 67.3).

1) The parathyroid glands usually receive their blood supply from the inferior thyroid arteries, but the superior parathyroids may derive their arterial supply from the superior thyroid artery.

2) Inferior glands may need to be autotransplanted after frozen section verification.

3) Glands superior to the cricoid cartilage can often be preserved.

9. Achieve hemostasis (Fig. 67.4).

a. Irrigate the wound thoroughly; evaluate bleeding during Valsalva by anesthesia. Bipolar cautery used for hemostasis.

b. Hemostatic agents such as Surgicel may contribute.

c. A drain may be used at the surgeon's discretion.

10. Wound closure

a. The strap muscles are approximated with absorbable sutures (3-0 Vicryl).

1) Leave a space inferiorly to allow drainage of potential hematomas.

b. Approximate the platysma layer carefully.

c. Close the skin with absorbable subcuticular sutures (4-0 Monocryl).

d. Dress the skin with an adhesive such as Mastisol and apply Steri-Strips.

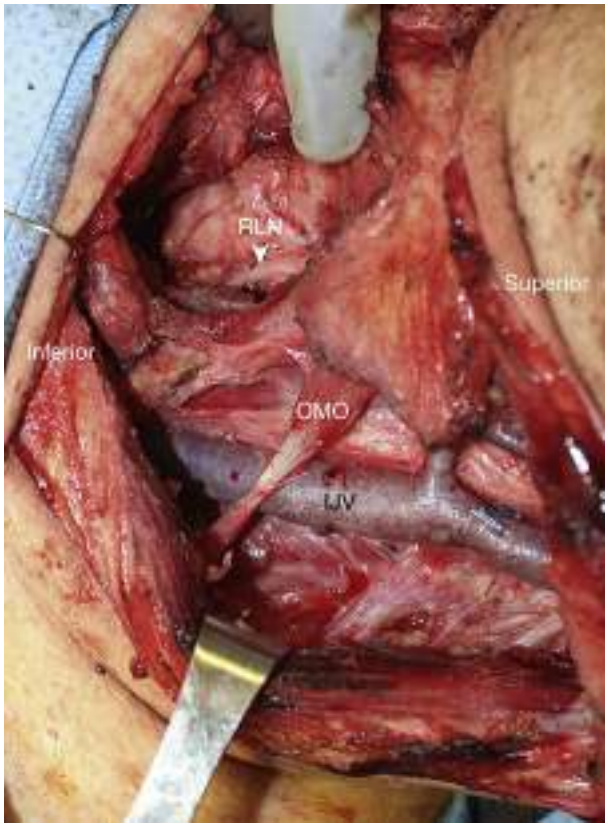

FIG. 67.3 Paratracheal dissection in combination with lateral neck dissection with preserved parathyroid gland medial to the recurrent nerve. *RLN,* Recurrent laryngeal nerve, *IJV,* internal jugular vein, *OMO,* omohyoid.

FIG. 67.4 Bilateral paratracheal dissection with carotid to carotid exposure and preservation of superior parathyroid tissue.

Common Errors in Technique

1. Failure to preserve or recognize devascularized parathyroid glands

2. Failure to identify the RLN, and preserve both branches

3. Leaving tissue in the superior mediastinum overlying the trachea

4. Inadequate hemostasis throughout surgery puts nerves and parathyroids at risk.

5. Overstretching and burning the skin edges with hot instruments

Postoperative Period

Postoperative Management

1. Check serum PTH after 1 hour in the recovery unit for total or completion thyroidectomy.

   a. Overnight observation if PTH is less than 15 pg/mL

   b. Serum calcium may take more than 12 hours to stabilize with a change in PTH.

2. Pain medications: ibuprofen or acetaminophen with narcotics for breakthrough

3. Wound care

   a. Neck incision to be kept dry for 48 hours, after which it may be wet

   b. Examine patient in 1 week and replace Steri-Strips to prevent scar formation.

   c. Surgical drains

4. Thyroid replacement medication is needed if total thyroidectomy is performed.

   a. Thyroid hormone withdrawal for RAI treatment

   b. May start liothyronine and stop 2 weeks prior to RAI

5. RAI therapy will depend upon the pathology of the tumor and

presence of metastasis.

Complications

1. Hematoma
    a. Usually detected within 2 hours of surgery
        1) Dyspnea
        2) Dysphagia
        3) Expanding mass in the neck
    b. Assure patency of drains.
    c. Immediately open incision and evacuate blood clots to prevent airway compromise.
    d. Take the patient back to the operating room to explore the wound and achieve hemostasis.
2. RLN injury
    a. Hoarseness and a weak voice with vocal cord in the paramedian position
    b. May have aspiration
    c. Intraoperative transection may require immediate reanastomosis, which may provide tone and decrease vocal cord atrophy.
    d. Consider early vocal cord medialization for known transection.
    e. Bilateral RLN injury will result in airway distress and stridor after extubation and may necessitate reintubation and tracheostomy.
3. SLN injury
    a. Results in difficulty projecting voice or poor pitch control in high frequencies
    b. Voice therapy may be helpful.
4. Hypoparathyroidism
    a. Risk with total or completion thyroidectomy or patients previously operated for hyperparathyroidism

b. Treat severe symptoms with intravenous (IV) calcium gluconate.

c. Cardiac monitoring if severe hypocalcemia

d. May need oral calcium carbonate and vitamin D supplementation temporarily or for life

5. Tracheoesophageal injury

a. Subcutaneous air or increased drainage

b. Usually heralded by wound infection

c. Often self-limited

d. Surgical exploration for persistent or massive output

Alternative Management Plan

1. Radioiodine therapy

2. External beam radiation

3. Chemotherapy (tyrosine kinase inhibitors)

Discussion

Evidence-Based Medicine Question

In what setting may prophylactic central compartment neck dissection warrant a stronger consideration?

A meta-analysis carried out in 2013 of 11 studies capturing 2318 patients with papillary thyroid carcinoma demonstrated recurrence rates of 7.9% in those who received total thyroidectomy alone, versus 4.7% in those who underwent total thyroidectomy with prophylactic central compartment neck dissection; however, this result did not reach statistical significance. However, the study points out the recurrence rate of 3.8% in five single cohort studies performed by high-volume thyroid cancer surgeons. On the basis of calculated risk reduction, the number of patients needed to treat to achieve a lower recurrence rate is 31. In addition, the relationship of surgeon volume and patient outcomes has been examined over the years, with studies demonstrating that high-

volume surgeons have the lowest complication rates. A stronger consideration may be given to prophylactic central compartment neck dissections, particularly when performed by high-volume thyroid surgeons.

Editorial Comment

Central compartment dissection is an operation that requires skill and patience. A meticulous central compartment dissection is not only important for disease control and oncologic completeness but also permits maximum preservation of RLN and parathyroid gland function. The dissection must be an anatomic one, with limits of the dissection defined by the anatomic landmarks earlier described in the chapter. Due to the complex anatomy, critical structures, and impact of surgical expertise and experience on complications and surgical outcomes, central compartment dissection should be performed by high volume endocrine and head neck surgeons, rather than the occasional thyroid surgeon.

Review Questions

1. Each of the following is a strategy to avoid complications in central compartment neck dissection, except:

   a. Skeletonize the superior pole of the thyroid prior to ligation

   b. Trace the RLN from the paratracheal region up to the cricothyroid muscle

   c. Immediately autotransplant devascularized parathyroid glands

   d. **Medialize the parathyroid glands with their blood supply**

2. According to the American Thyroid Association guidelines, which of the following is not an indication for a central compartment neck dissection?

   a. A 1-cm follicular thyroid carcinoma with clinically involved central nodes

b. A 5-mm medullary thyroid carcinoma with clinically negative nodes

c. **A 2-cm papillary thyroid carcinoma with clinically negative nodes**

d. A 1-cm follicular thyroid carcinoma extending beyond the thyroid capsule with clinically negative nodes

3. Which of the following is not a benefit of a prophylactic central compartment neck dissection?

a. **Improvement of long-term survival in WDTCs**

b. Obtaining accurate pathologic staging to direct postoperative RAI therapy

c. Reducing recurrence in high-risk primary tumors

d. Avoiding morbidity of reoperation in the central compartment

Retropharyngeal Neck Dissection

Vikas Mehta

Introduction

The retropharyngeal lymph nodes (RPLNs) are a small chain of lymph nodes located in the retropharyngeal space (RP) where they are divided into the medial and lateral groups. The boundaries of the RP are the carotid sheath laterally, skull base superiorly, prevertebral fascia posteriorly, and the pharynx anteriorly, and inferiorly, the RP is in continuity with the posterior mediastinum. The medial group of nodes are usually ill-defined and often absent in adults, thus not having a significant role in RPLN metastases. The lateral RPLN, which lies superior to the sympathetic ganglion at the level of C1, can harbor metastases from a variety of cancers; oropharyngeal cancer being the most common. There may be one to three nodes that are often difficult to identify in the absence of metastatic involvement. Typically, the lateral RPLNs are usually smaller than 4 to 4.5 mm in the greatest diameter of their shortest axis, where 6 to 10 mm has been described as the pathologic threshold for RPLNs.

Rouviere, in 1938, first mapped lymphatic drainage of the oropharynx and characterized the spread of oropharyngeal carcinomas to the RP.[1] RPLN positivity in all oropharyngeal squamous cell carcinomas (OPSCC) has been found to be 10% to 27%, using a variety of imaging modalities.[2–5] Additionally, RPLN involvement in OPSCC is an important prognostic factor and has been shown that there is an increased risk for regional recurrence (45% vs. 10%) and reduced rates of disease-specific survival (38% vs. 58%).[6] RPLN metastases are more common from the soft palate and posterior pharynx, but they can occur from any subsite within the oropharynx. Due to the incidence of metastases, the RPLNs are routinely targeted during radiation therapy for OPSCC. Currently, when the lateral lymphatics of the neck are

dissected in a conventional selective neck dissection, the RPLNs are not routinely dissected. With increasing use of transoral surgery (TOS) as a primary treatment modality for OPSCC, dissection of the RPLN during cervical lymphadenectomy becomes more important, especially in cases where no adjuvant treatment is recommended.

Key Operative Learning Points

- Approach can be transcervical or transoral
  - Transcervical approach preferred if a concurrent neck dissection is being performed
- Avoid injury to the sympathetic chain that is located lateral to the RPLN and can often be mistaken for lymphadenopathy
- A positive positron emission tomography (PET)/computed tomography (CT) of the RPLN has an excellent PPV and suggests that the RPLN needs to be addressed when primary or recurrent squamous cell carcinomas (SCC) are present.

Preoperative Period

The keys to deciding when to perform the surgery in the primary setting are: (1) to ascertain the risk of RPLN metastases based on the oropharyngeal cancer subsite and nodal cancer burden and (2) decide whether primary surgical treatment will be employed. If preoperative imaging suggests metastasis in the RPLN and a neck dissection is being performed, the RPLN can be safely dissected in this situation. If the RPLN is negative on PET/CT and another imaging modality (CT or magnetic resonance imaging [MRI]), then the RPLN can either be ignored or treated electively with radiation therapy, depending on the TNM staging and subsite (Fig. 68.1).[7] In the setting of lymph node metastasis persistence or recurrence after chemoradiation, PET/CT has demonstrated adequate accuracy at predicting RPLN disease and can be used to guide whether the RPLNs need to be addressed during a salvage-neck dissection. As with all head and neck cancers, I advocate for presenting the patient to a multidisciplinary tumor board and considering various factors, for example, the patient's comorbidities,

preferences, and social situation prior to proceeding with primary treatment.

The RPLN can be approached by using either a transcervical or transoral technique. I suggest a transcervical approach in the primary setting when performed in conjunction with an elective neck dissection. The technique for the transcervical approach, as outlined below, has been demonstrated to be a safe and reliable method of RPLN sampling during primary surgical management. For therapeutic removal of a metastatic RPLN, both the transcervical and transoral techniques can be used. If a concurrent neck dissection is being performed, I prefer using the transcervical approach to avoid violating the pharynx and creating a potential salivary fistula. If, however, the RPLN is the only node being removed (i.e., in the case of a previously dissected neck with only a RPLN positive node or a solitary papillary thyroid cancer metastasis), then a transoral approach can be considered to avoid an external incision based on the familiarity of the surgeon with the anatomy and techniques.

If primary surgical therapy is being considered for the oropharyngeal cancer, informed consent must include the usual potential morbidity associated with the primary resection of the cancer and the selective neck dissection. In addition to these risks, the RPLN dissection through a transcervical approach increases the risk of a salivary fistula due to the close proximity to the pharynx. Also, the dissection of the RPLN can include potential damage to cranial nerve (CN) IX and the sympathetic chain, which can increase the risk of aspiration and result in Horner's syndrome, respectively. If the transoral approach is performed in isolation, there is minimal risk of a salivary fistula but the incidences of postoperative aspiration, Horner's syndrome, and damage to major vessels are likely increased due to the limited exposure and technical difficulties associated with this approach.[8]

History

1. History of present illness
    a. Risk factors: smoking, alcohol, Human papillomavirus (HPV) infection
    b. Weight loss, nutritional status

c. New onset of pain in the pharynx or otalgia

d. Dysphagia/odynophagia

e. Neurologic deficits

f. Voice changes

g. Presence of masses or lesions in the throat or neck

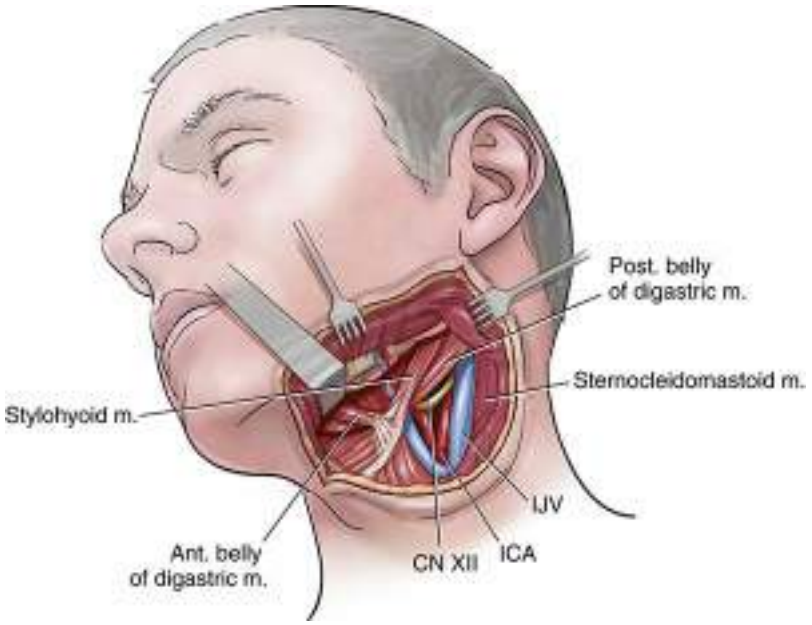

FIG. 68.1 Depiction of the transcervical approach to the retropharyngeal lymph nodes following a selective neck dissection. *ICA,* Internal carotid artery. *IJV,* Internal Jugular Vein.

2. Past medical history

   a. Previous squamous cell carcinomas or thyroid cancer

   b. Previous radiation to the head and neck

   c. Previous surgery or trauma to the neck or pharynx

3. Prior treatment of oropharynx or neck

   a. Previous (chemo)radiation for oral/oropharyngeal cancer

   b. Prior surgery for metastatic thyroid cancer

4. Medical illness

a. Cardiopulmonary disease

b. Alcoholism, risk of perioperative alcohol withdrawal syndrome and substance abuse

c. Sexual history for risk of HPV exposure

5. Medications

a. Anticoagulants

b. Allergies to antibiotics

6. Mental and social status

a. Ability to give informed consent

Physical Examination

1. Oropharyngeal cancer

a. Determine primary site and tumor extent (if present)

1) Tonsil

a) Extension to soft palate, base of tongue (BOT), and posterior oropharynx

b) Invasion of the mandible

2) Palate

a) Extension into the mucosa on the nasal side

b) Involvement of the hard palate or other oropharyngeal structures

3) Posterior oropharynx

a) Extension into nasopharynx

b) Direct extension to the RPLN space

4) BOT

a) Extension to contralateral BOT

b) Involvement of other oropharyngeal structures or mandible

5) Invasion of major nerves

a) Lingual nerve (loss of sensation of anterior tongue and floor of mouth)

b) Inferior alveolar nerve (loss of sensory function of mental nerve)

c) Hypoglossal nerve (deviation of tongue)

d) Glossopharyngeal nerve (lack of palate sensation, may be difficult to assess)

2. Assessment of nodal extension

   a. Oropharyngeal examination and palpation (if tolerated)

3. Cervical lymph node metastasis

   a. Palpate the neck for the presence of cervical metastases.

   b. Examine the neck for previous surgery and scars that may affect surgical planning.

4. Examine the oral cavity, pharynx, and larynx for synchronous primaries.

5. Thyroid

   a. If there is a history of thyroid cancer and the RPLN appears to be a thyroid metastasis

6. Fiberoptic laryngoscopy

   a. Particular attention to superior and inferior extent of primary cancer and RPLN

7. General health

   a. Nutrition

   b. Cardiovascular

   c. Respiratory

   d. Mental

Imaging

1. Chest radiograph

a. Metastases

b. Synchronous lung cancer

c. Pulmonary and cardiac status

2. CT scan of the neck with contrast

a. Important to assess the relationship of the node(s) with the prevertebral fascia and carotid artery

b. Assess the extent of the primary cancer.

3. PET/CT

a. Data suggest it is an extremely sensitive modality to assessing for recurrent disease and RPLN metastasis.

b. Provides information regarding distant metastasis

4. Thyroid scan

a. Required only if thyroid metastasis suspected

b. Can provide information regarding adjuvant treatment with I131, in addition to information on other metastatic sites

Indications

- Salvage following previous (chemo)radiation with PET/CT demonstrating persistent cancer
- Presence of a metastatic node from a primary cancer in the thyroid
- Primary surgical treatment of an oropharyngeal cancer with advanced lymph node metastasis (N2b or higher)

Contraindications

1. Patient factors

a. Medically unfit

b. Poor nutritional status

c. Inability to give informed consent

d. Severe trismus

2. Tumor factors
   a. Early stage oropharyngeal SCC in the primary surgical setting
   b. Distant metastases
   c. Negative PET/CT scan for RPLN disease
   d. Unresectable cancer with gross fixation to the prevertebral musculature
3. Surgical factors
   a. Inadequate expertise with resection via a transcervical approach

Preoperative Preparation

1. Evaluations by
   a. Oncologic Surgeon
   b. Radiation and Medical Oncologist
   c. Speech and swallowing therapist
   d. Anesthesiology
   e. Tumor board presentation
2. Postoperative care planning
3. Discontinue antiplatelet drugs if possible.

Operative Period

Anesthesia

- Ask the anesthetist to insert an oral endotracheal tube.
- The anesthetic machine is positioned at 90 degrees from the patient's head if performing a transcervical approach and at 180 degrees if a transoral approach is to be attempted.
- One dose of steroids should be given intravenously. I prefer to use Decadron 8 to 12 mg depending on the patient's size/weight.

Positioning

- The surgery is performed with the patient in a supine position with the neck extended.
- The lower face and neck are prepared and appropriately draped if performing a transcervical approach.

Perioperative Antibiotic Prophylaxis

- Clean-contaminated surgery
- Antibiotics are administered during induction of anesthesia and continued for 24 hours if a transoral approach will be used. No antibiotics are needed for a transcervical approach unless there is a violation of the pharynx during neck surgery.
- Choices
  - Clindamycin
  - Amoxicillin-clavulanate
  - Cephalosporin and metronidazole

Monitoring

- Routine anesthesia monitoring
- Patient should not be paralyzed to facilitate preserving the spinal accessory and marginal mandibular nerves.

Instruments and Equipment to Have Available

- Monopolar and bipolar electrocautery
- Resection and neck dissection sets
  - Standard instruments used for head and neck cancer surgery
- Transoral robotic approach

- Mouth-retractor (FK, Crow-Davis, or Dingman)
- The 5-mm Monopolar spatula electrocautery and 5-mm Maryland dissector
- Thirty- and 0-degree endoscopes available
- Robotic surgery platform (daVinci system, Intuitive Surgical; Flex robotic system, Medrobotics)

Key Anatomic Landmarks

- Neck dissection: See neck dissection.
- Retropharyngeal node dissection
  - Transcervical
    - Posterior belly of the digastric Chapters 64 and 65
    - Stylohyoid muscle
    - Hypoglossal nerve
    - Common carotid and the internal and external carotid arteries (Fig. 68.2)
    - Pharynx
    - Glossopharyngeal nerve
    - Sympathetic trunk
  - Transoral
    - Tonsil anterior and lateral to the incision
    - Sympathetic trunk may overlie or be lateral and can resemble lymphadenopathy
    - Internal carotid artery (ICA) lateral to the RPLN space
    - Prevertebral fascia (posterior limit of dissection)
    - Level of hyoid (not seen but identifies inferior limit of dissection)

Prerequisite Skills

- Neck dissection: selective levels 1 to 5; modified; and radical

- Radical tonsillectomy
- Resection of the base of the tongue
- Transoral robotic surgery

Surgical Technique

- Intraoperative evaluation after the patient has been intubated
  - Panendoscopy to exclude synchronous cancers in upper aerodigestive tract
  - Reassess extent of primary cancer, especially posterior and lateral extents.
  - Re-evaluate the neck for cervical lymph nose metastases.
- Surgical approach (transcervical)
  - Perform after the standard neck dissection is completed
  - Identify and retract superiorly the posterior belly of the digastric muscle, the stylohyoid muscle, and the hypoglossal nerve (see Fig. 68.2). The muscles can be divided to provide additional exposure if necessary.
  - Dissect within the carotid sheath between the ICA and the pharynx, which are retracted laterally and medially, respectively.

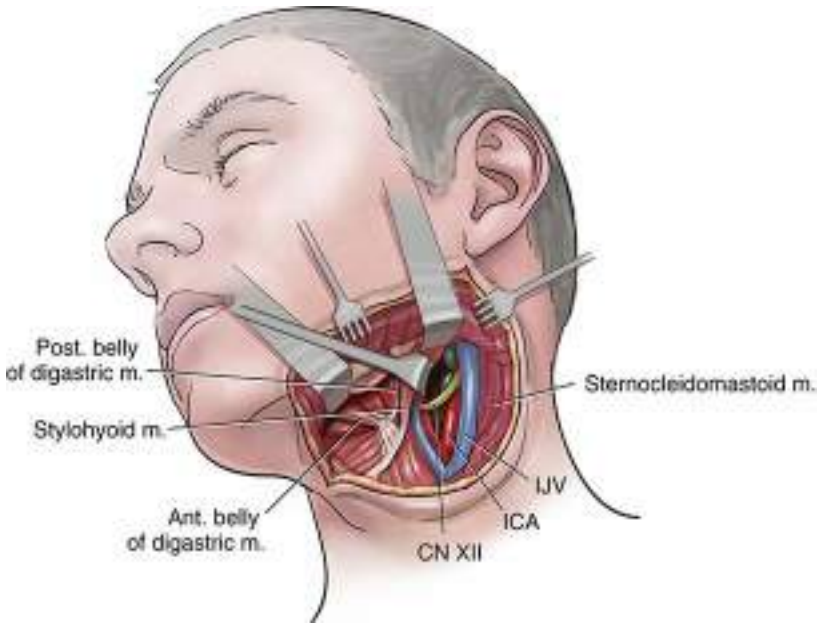

FIG. 68.2 After retraction of the hypoglossal nerve and posterior belly of the digastric, blunt and sharp dissection medial to the internal carotid artery will identify the retropharyngeal lymph node. *ICA,* Internal carotid artery. *IJV,* Internal Jugular Vein.

- Incise the alar fascia medial the ICA, and dissect the node with scissors and bipolar cautery.
- The sympathetic trunk can be identified lateral to the RPLN and should be preserved. Monopolar cautery should be avoided in this area to prevent injury to this structure.
- Visualize and palpate for residual lymph nodes. Send the packet of lymph nodes for frozen section to be certain that at least one RPLN has been obtained.

- Surgical approach (transoral)
  - In OPSCC cases, the RP can be entered directly through the primary site defect.
  - Identify the ICA and dissect medial to it using blunt dissection.
  - The superior and inferior mucosa can be retracted to get around the entire node.
  - Blunt dissection should be used as much as possible to avoid injury to the sympathetic chain, which lies in close proximity and can resemble the RPLN.

- The prevertebral fascia serves as the posterior limit of dissection.
- In cases of metastatic modes with no primary site, the assistant at the head retracts the tonsillar fossa laterally exposing the posterior pharyngeal wall.
- A vertical mucosal incision is made just medial to the posterior tonsillar pillar directly overlying the RPLN.
- Dissection is performed using the same technique as described above.

- Closure
  - The neck is irrigated and then closed over suction drains.
  - The oropharyngeal wound is left to heal by secondary intention or can be approximated by interrupted sutures if easily accessible and can be closed without excess tension.

Common Errors in Technique

- Creating an inadvertent pharyngotomy during the transcervical technique by not properly identifying the pharynx
- Failing to identify the sympathetic trunk and causing injury

Postoperative Period

- Antibiotics: when drain is in place or if pharyngeal/cervical communication encountered
- Remove suction drains when less than 50 mL drainage/24 hours
- Feeding
  - Oral feeding with liquids that can be advanced to soft diet (if transoral approach used)
  - Speech and swallowing therapist assists the patient with swallowing if needed
- Postoperative (chemo)radiation generally commenced within 6 weeks of surgery if indicated

Complications

- Hematoma
  - A hematoma in the neck usually occurs within the first 24 hours after an operation. If the hematoma is rapidly expanding, the incision may need to be opened at the bedside to avoid airway compromise.
  - The patient should be returned to the operating room as soon as possible to avoid airway-related complications.
  - Since the dissection is intimately involved with the carotid arteries, injury to these structures should be ruled out first given the potential serious complications of damage to the internal carotid.
- Oral hemorrhage
  - A small amount of blood in the sputum is common after a transoral approach.
  - The patient may present with oral hemorrhage up to 2 weeks postoperatively or longer.
  - The first priority in severe hemorrhage is to secure the airway.
  - After securing the airway, the pharynx can be packed with gauze to tamponade the bleeding.
  - If an injury to the carotid arterial system is suspected, interventional radiology should be consulted for an emergent angiogram with intervention.
  - If the external carotid system is the source of bleeding, ligation through a surgical transcervical approach should only be taken as a last resort, since it has the potential to create a salivary fistula and/or create a situation in which collateral flow contributes to further bleeding and there is difficulty accessing the area via angiography due to the ligated vessel.
- Alcohol withdrawal syndrome
  - Onset on day 2 to 3
  - Additional morbidity and mortality and prolongs hospitalization
  - May require deep sedation and ventilation

- Involve internist or intensivist in care

- Dysphagia and aspiration
  - Uncommon after an isolated injury to CN IX
  - Assess with a modified barium swallow and/or functional endoscopic evaluation swallow (FEES).
- Horner's syndrome
  - This can result from inadvertent injury to the sympathetic chain, which can be mistaken for a lymph node.
  - The patient presents with the triad of miosis, ptosis, and anhidrosis.
- Salivary leak
  - A salivary leak may occur in both the transcervical and transoral approaches.
  - Transcervical—inadvertent injury to the pharynx during dissection. Sutures should be placed to attempt a primary repair. In an irradiated patient, Use a local muscle flap (i.e., the digastric muscle) to further bolster the repair.
  - Transoral—Since the neck is not usually compromised in these cases, a leak is rarely encountered and may be more common in radiated patients due to the delayed secondary healing.

Alternative Management Plan

In the primary setting, patients can be managed with nonsurgical therapy alone. In the recurrent setting, surgical resection remains the only option for cure. The patient can be offered re-irradiation (if already performed) and/or chemotherapy as palliative measures.

Discussion

Evidence-Based Medicine Question

What are the common risk factors for RPLN metastasis in patients with OPSCC?

The overall rate of RPLN positivity in oropharyngeal cancer has been reported as ranging from 14.5% to 36%.[5,7,8,9,10] Advanced cancers of the soft palate and posterior pharyngeal wall have a higher incidence of RPLN metastasis than the BOT and tonsil subsites. With the increasing incidence of HPV positive oropharyngeal cancer, the latter two subsites (tonsil and BOT) become increasingly more common. In a study by Moore et al.,[7] the authors performed elective RPLN dissection in 72 OPSCC patients undergoing primary surgical management with Transoral Robotic Surgery (TORS) and selective neck dissection. They found the RPLN to be positive in 14.5% of the patients with all the positive nodes in patients with tonsil cancer only and either cT3/4, cN2b/N2c/N3, or with positive imaging preoperatively. There were no positive RPLNs in patients with BOT primary SCCA. Therefore, the authors advocate addressing the RPLN electively, with surgery or radiation, in patients with either positive imaging (CT or PET/CT) or those with more advanced cancer of the tonsil, soft palate, and posterior pharynx. Additionally, the authors found that while the negative predictive value of PET/CT and CT was quite good (92.6% and 91.7%, respectively), imaging failed to detect micrometastases in 37.5% of patients, thus suggesting that a negative scan in advanced disease patients should be interpreted with caution.

Editorial Comment

Cancers of the oropharynx are managed with nonsurgical approaches in most institutions. HPV status has introduced the possibility of de-intensified therapy and consideration of surgery as a primary modality for management of cancers of the oropharynx. Additionally, TORS has created the opportunity to manage primary cancers of the oropharynx and retropharyngeal nodes with surgery. As RPLN surgery becomes more commonplace consideration must be given because both transoral and transcervical dissection of the RPLN can lead to significant dysphagia due to disruption of the pharyngeal plexus. Surgical or nonsurgical management of the RPLNs must be carefully considered with emphasis on obtaining the best functional and oncologic outcomes while staying within the parameters of evidence-based protocols.

Review Questions

1. Which of the following structures is NOT in close proximity to the retropharyngeal lymph node (RPLN)?

   a. Sympathetic chain

   b. Internal carotid artery

   c. Glossopharyngeal nerve

   d. **Accessory nerve**

2. Which cancer is most at risk for having a RPLN metastasis?

   a. T1N1 base of tongue (BOT) squamous cell carcinoma (SCC)

   b. **T3N2b tonsil SCC**

   c. T1N1 tonsil SCC

   d. T3N2a BOT SCC

3. Which of the following structures is commonly encountered and can be sacrificed when approaching the RPLN transcervically?

   a. Hypoglossal nerve

   b. Mandible

   c. Sympathetic chain

   d. **Stylohyoid muscle**

Management of Tumors in the Prestyloid Parapharyngeal Space

Jessica H. Maxwell, and Jonas T. Johnson

Introduction

The management of a patient with a tumor of the parapharyngeal space (PPS) is a challenging task. The complex nature of the anatomy of the PPS and the diversity of its contents gives rise to a wide variety of tumors. This presents an opportunity for technically challenging surgery. Current imaging modalities, including computed tomography (CT) and magnetic resonance imaging (MRI), have characterized the intricate anatomy of the PPS.[1] Once these imaging techniques became readily available, surgical techniques were subsequently devised to remove the tumors identified within the PPS.

The PPS has historically been subdivided into the prestyloid and poststyloid compartments (Figs. 69.1 and 69.2).[1] The two compartments are divided by the fascia of the tensor veli palatini as it extends from the styloid process to its insertion on the lateral pterygoid plate. The prestyloid compartment lies deep to the masticator space, with the deep lobe of the parotid extending into its lateral aspect. The prestyloid PPS contains the deep lobe of the parotid gland, adipose tissue, small blood vessels, lymphatics, and minor nerves. The poststyloid compartment, also termed the carotid space, encompasses the carotid sheath and is traversed by cranial nerves IX, X, and XII. The cervical sympathetic chain lies posterior to the carotid artery.[1] This information is invaluable in developing a differential diagnosis and plan of management for these tumors. The remainder of this chapter focuses on the management of tumors found within the prestyloid PPS.

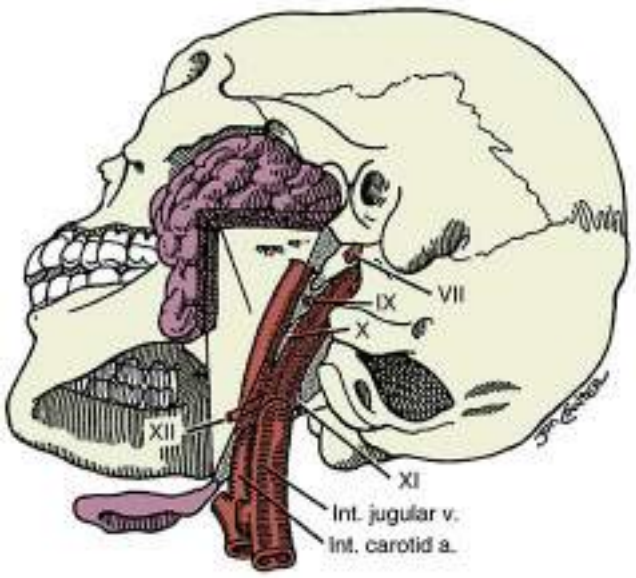

FIG. 69.1 Diagram of parapharyngeal space. Reprinted with permission from Carrau RL, Myers EN, Johnson JT: Management of tumors arising in the parapharyngeal space. Laryngoscope 100:583-589, 1990.

Key Operative Learning Points

1. The PPS is described as being an inverted triangle extending from the skull base to its apex at the hyoid bone (see Fig. 69.1).

2. The vast majority of tumors within the prestyloid PPS are of salivary gland origin, most commonly pleomorphic adenomas.[2-4]

3. The prestyloid PPS is ideally approached using the transcervical submandibular operative technique.

Preoperative Period

History

1. History of present illness: The signs and symptoms associated with tumors that arise in the PPS are numerous and depend on both the location within the PPS as well as the histologic type.

a. Location

1) The most common presentation is an asymptomatic mass in the lateral wall of the oropharynx with or without a mass in the

parotid or neck (Figs. 69.3 and 69.4).[2,3]

2) Large tumors in the prestyloid PPS may present with otalgia, aural fullness, or temporomandibular joint tenderness likely related to the mass effect of the tumor on surrounding structures.[2]

3) Tumor expansion may interfere with swallowing, breathing, or the proper fit of dentures.

b. Histology

1) Benign tumors often present as a submucosal asymptomatic mass in the oropharynx.

2) Malignant tumors are more often associated with the presence of pain or neuropathy or, less frequently, facial nerve weakness.

2. Past medical and surgical history

a. A prior history of parotid tumors or cancer should be elicited from the patient.

b. Has the patient had parotid surgery in the past or a history of radiation?

c. Is there a history of autoimmune disease, skin cancer, or lymphoma?

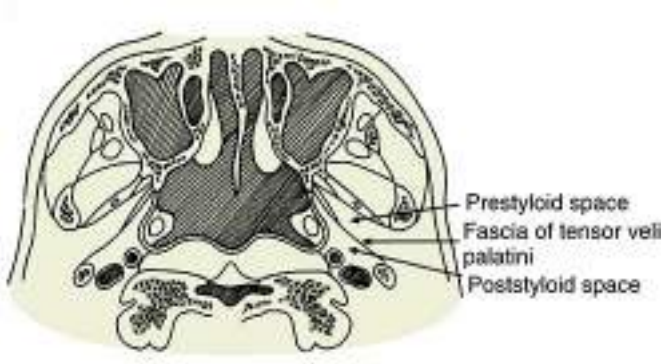

FIG. 69.2 The fascia of the tensor veli palatini muscle divides the parapharyngeal space into a prestyloid and a poststyloid compartment.

3. Family history

a. In patients suspected of having paragangliomas within the

poststyloid compartment, a family history of paragangliomas should be sought.

4. Medications

   a. Antiplatelet and anticoagulation medications, including herbal products, should be elicited prior to surgery.

FIG. 69.3 Typical appearance of a tumor of the parapharyngeal space displacing tonsil and uvula medially *(arrow).*

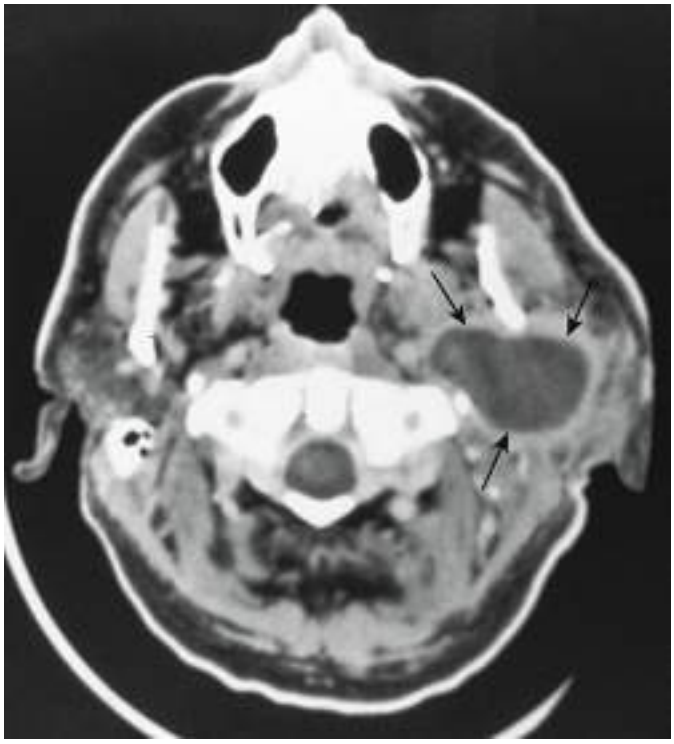

FIG. 69.4 Axial computed tomography scan of a pleomorphic adenoma originating in the deep lobe of the parotid gland with extension through the stylomandibular tunnel into the prestyloid parapharyngeal space *(arrows)*.

5. Social history

   a. A tobacco and alcohol history should be obtained.

Physical Examination

1. Oral cavity/oropharynx

   a. The PPS is bounded laterally by the mandible, superiorly by the skull base, and medially by the buccopharyngeal fascia and the constrictor muscles of the pharynx. Because two sides of the PPS are bone, tumors arising in the PPS expand along the path of least resistance toward the soft tissue of the pharyngeal wall, displacing the wall and the tonsil to present as a submucosal and often asymptomatic mass in the pharynx.

   b. Direct palpation of the tumor both intraorally and extraorally is essential.

c. Deviation of the uvula away from the affected side is occasionally seen with large tumors.

2. Cranial nerve examination

   a. Cranial nerve VII neuropathy may indicate facial nerve involvement of a tumor arising from the deep lobe of the parotid gland.

   b. Other cranial nerve neuropathies suggest poststyloid involvement of a PPS lesion.

3. Neck

   a. Large prestyloid PPS tumors may present with fullness in the neck and/or parotid region.

   b. Palpable cervical lymphadenopathy may represent metastatic disease.

4. Flexible fiberoptic laryngoscopy

   a. This is a critical aspect of the head and neck examination in a new patient with a lesion of the PPS. Often a submucosal lateral pharyngeal mass is visualized on flexible laryngoscopy. Vocal cord movement should also be evaluated for cranial nerve X involvement of a poststyloid PPS lesion.

Imaging

All patients suspected of having a tumor in the PPS should undergo imaging studies. Both contrast-enhanced CT and gadolinium-enhanced MRI provide excellent detail for evaluating lesions of the PPS.[1,5] The distinction between tumors of the prestyloid and poststyloid space is determined radiographically based on a clear understanding of the anatomy in this region.

CT scan with contrast is often used due to its excellent anatomic detail, ease of use, and accessibility and can be done in patients with contraindications to MRI (Table 69.1). However, when possible, many radiologists advocate the use of gadolinium-enhanced MRI with T1- and T2-weighted images for optimal characterization of tumors in the PPS.[1,5] Furthermore, MRI is the optimal technique when there is suspicion of intracranial extension or nerve involvement.

Prior to evaluating imaging characteristics of a lesion, it is critical to identify that the lesion originates in the PPS and is not an extension of a lesion from an adjacent space.[1] Visualizing a margin of adipose tissue separating the lesion from the bordering space is paramount to not only confirming that a lesion originated in the PPS but also formulating the differential diagnosis. Tumors that arise de novo in the PPS independent of the parotid gland have an adipose tissue plane separating it from the deep lobe of the parotid gland (Fig. 69.5). Conversely a deep lobe parotid mass located within the prestyloid PPS will show obliteration of the adipose tissue plane at the posterolateral margin of the PPS.[1,5] This is a very important point in the differential diagnosis, because tumors that are independent of the parotid gland may be removed through a cervical approach, whereas tumors arising in the deep lobe of the parotid gland with extension into the PPS must be approached through a parotid-submandibular approach in order to avoid injury to the facial nerve.

TABLE 69.1

Correlation of Imaging Studies and Operative Findings in Tumors of the Parapharyngeal Space

Computed Tomography Scan

- Accurately defined position of the tumor relative to the styloid in 96% (43/45) of the cases
- Correct identification of the origin of salivary gland tumors (parotid vs. nonparotid) in 88% (14/16) of the cases
- Assessment of the tumor vascularity correlated with the angiographic findings (28/28) as well as with the surgical findings (45/45)

From the Department of Otolaryngology, University of Pittsburgh.

Indications

Patients with prestyloid PPS tumors should be offered surgical treatment if they are healthy enough to undergo a general anesthesia. Even patients

with pleomorphic adenomas of the prestyloid PPS benefit from surgery, given the risk of malignant transformation if these tumors are merely observed.

Relative Contraindications

1. Medical comorbidities with increased risk for general anesthesia

2. Significant cervical stenosis or fusion preventing neck rotation and extension

3. Vascular tumors with variable vascular supply

   a. These are more likely to present in the poststyloid PPS.

Preoperative Preparation

1. Review imaging studies to confirm tumor location in the prestyloid PPS.

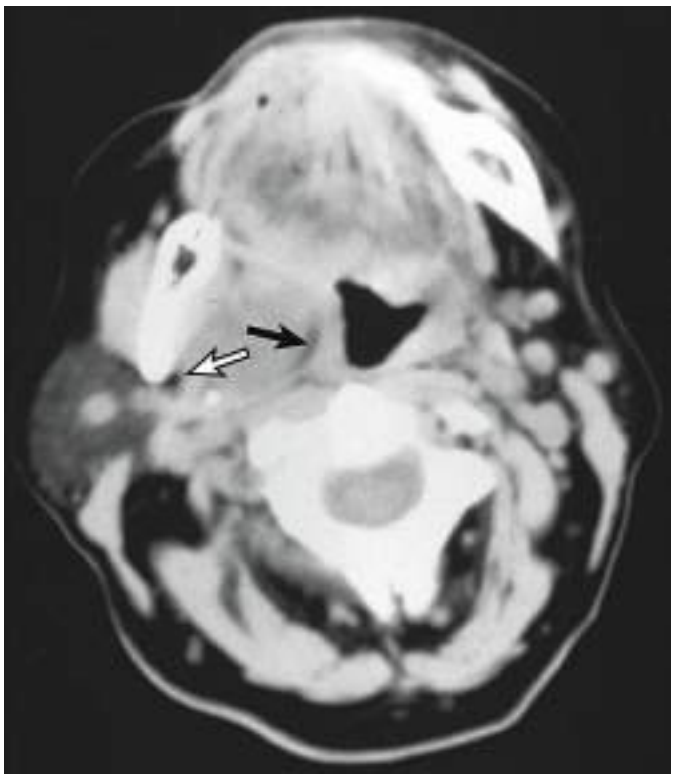

FIG. 69.5 Computed tomography scan demonstrating a

pleomorphic adenoma arising de novo in the prestyloid parapharyngeal space. The tumor displaces adipose tissue medially *(closed arrow).* An adipose tissue plane separates the tumor from the parotid gland *(open arrow).*

2. Consider fine-needle aspiration (FNA) to obtain preoperative diagnosis.

   a. The role of FNA in the evaluation of patients presenting with a PPS mass is controversial.[6,7] Some clinicians advocate its use for unusual cases, given that non-neoplastic processes, such as branchial cleft cysts and inflammatory masses, may occasionally present in the PPS.[7] Given the difficult location of the PPS, CT-guided FNA is typically employed via a transfacial approach.[7]

3. Discontinue antiplatelet medications, if possible, and optimize the patient's medical status prior to surgery.

Operative Period

Anesthesia

General anesthesia: Given the deep location of the prestyloid PPS and the amount of dissection necessary to expose this area, general anesthesia with oral intubation is recommended.

Positioning

The patient is placed in the supine position with the neck extended and rotated away from the surgeon. A shoulder roll is helpful to achieve maximum extension.

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin
- Second-generation cephalosporin
- Clindamycin, if the patient is allergic to penicillin

Monitoring

Facial nerve monitoring may be used depending on surgeon preference. If the PPS tumor originates from the deep lobe of the parotid gland, the trunk of the facial nerve may be in close proximity to the tumor. In these instances, facial nerve monitoring is often employed. A handheld nerve stimulator may also be used. The surgical team must communicate to the anesthesia team at the start of the case that muscle relaxants should be avoided.

Instruments and Equipment to Have Available

1. A standard head and neck set

2. Depending on surgeon preference, 0- and 30-degree endoscopes may be useful for visualizing the deepest (superior) extent of the tumor.

3. Large hemoclips and vascular instruments should be available in the event that large vessel injury occurs during the dissection.

Key Anatomic Landmarks

1. Stylomandibular ligament: Transecting this ligament improves exposure provided by the transcervical approach.[8] The styloid musculature and posterior belly of the digastric may also be removed if necessary to further enhance exposure.

2. Main trunk of the facial nerve: For prestyloid PPS tumors originating in the deep lobe of the parotid, identification and careful preservation of the facial nerve are paramount.

Prerequisite Skills

1. Parotidectomy

2. Neck dissection

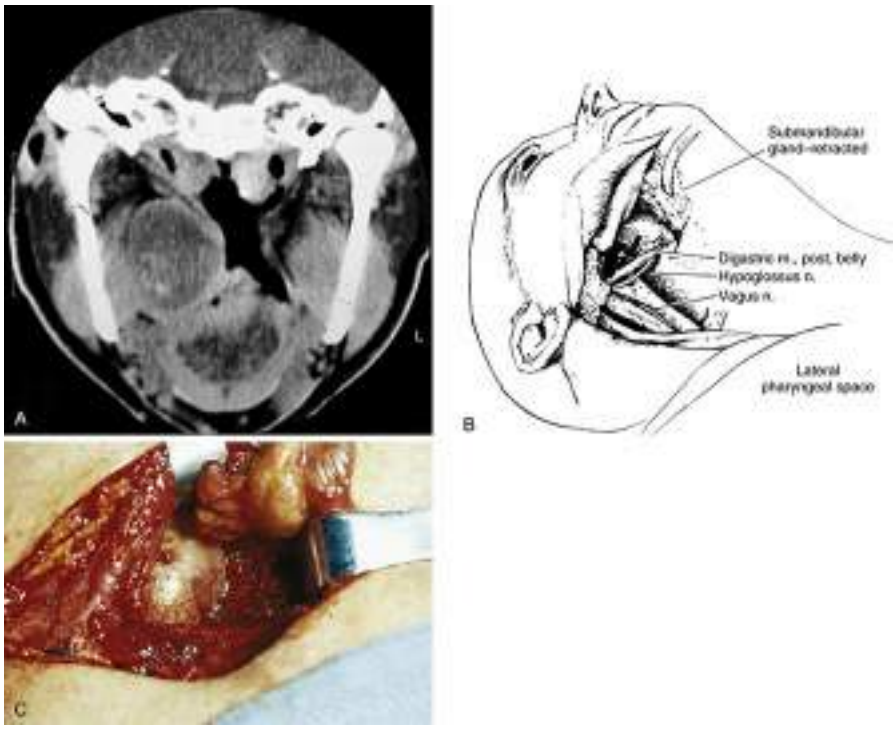

FIG. 69.6 **A,** Computed tomography scan demonstrating tumor of parapharyngeal space. **B,** Diagram of transcervical approach to prestyloid parapharyngeal space. Submandibular gland retracted anteriorly. **C,** Tumor seen in prestyloid parapharyngeal space. **B,** Reprinted with permission from Rabuzzi DD, Johnson JT: Diagnosis and Management of Deep Neck Infections. Washington, American Academy of Otolaryngology–Head and Neck Surgery Foundation, 1976.

Operative Risks

1. Facial nerve injury
   a. If transection occurs inadvertently, the two transected ends should be identified and reapproximated if there is minimal loss of nerve tissue. If there is a segment of nerve missing or nonviable, then a nerve graft can be used, often from the greater auricular nerve.
   b. With thermal injury, the extent of nerve damage is often difficult to determine, and clinical outcomes may vary. Typically, the operation should be completed and the patient should be placed on peri- and postoperative IV steroids with supportive postoperative care as needed.

2. Injury to cranial nerves or cervical sympathetic chain

   a. Although uncommon, these injuries tend to occur with large tumors or malignancies. During the transcervical approach, careful dissection along the great vessels and a thorough knowledge of anatomic landmarks are critical to avoiding nerve injury.

Surgical Technique

1. Transcervical submandibular approach (Fig. 69.6)

   a. The skin incision is made in the major transverse skin crease in the neck and carried down through subcutaneous tissue and platysma muscle.

   b. The marginal mandibular branch of the facial nerve must be identified and preserved.

   c. Identification of the anterior border of the sternocleidomastoid muscle facilitates identification of the posterior belly of the digastric muscle.

   d. The submandibular gland is then dissected free of the surrounding tissues and retracted anteriorly.

   e. The facial artery is clamped, transected, and doubly ligated with silk suture.

   f. Improve exposure if necessary.

      1) Transection of the posterior belly of the digastric

      2) Consider dividing the stylomandibular ligament.

      3) Anterior dislocation of the mandible may be necessary for large tumors of the PPS.

   g. Using sharp and blunt dissection, the tumor is dissected free from the surrounding tissues, taking care to preserve the main trunk of the facial nerve.

   h. To prevent recurrence, every effort should be made not to disrupt the capsule of the tumor.

   i. Hemostasis is obtained, and the wound irrigated.

   j. A suction drain is placed to collapse the dead space, and the wound

is closed in a layered fashion.

2. Other surgical approaches

   a. Parotid-submandibular approach (Fig. 69.7)

      1) Ideal for patients with deep lobe parotid tumors

      2) Modified-Blair incision with transcervical extension

      3) Identify the main trunk of the facial nerve via a standard superficial parotidectomy approach; then proceed as described previously via the transcervical approach.

   b. Transoral

      1) Historic approach

      2) No longer recommended as a stand-alone approach due to inadequate exposure and risk of tumor seeding into the pharynx. See Chapter 33 on the transoral robotic approach to tumors to understand selection criteria and indications for a transoral approach.

   c. Transmandibular

   d. Transparotid

   e. Infratemporal fossa

Common Errors in Technique

1. Poor exposure

2. Violation of the tumor capsule

3. Inadequate identification of the facial nerve

Postoperative Period

Postoperative Management

1. Monitor drain output.

   a. Remove drain when output is less than 20 cc per shift.

2. Pain management

3. Swallowing evaluation as needed

4. Resumption of anticoagulants/antiplatelet medications

Complications

1. Facial nerve injury

   a. If the PPS tumor originates from the deep lobe of the parotid gland, then it is possible to injure the facial nerve, either from inaccurate dissection or traction on the nerve. Patients who have weakness or paresis from traction on the facial nerve in whom the nerve is anatomically intact should expect a return of function within 3 months.[9]

   b. Proper eye care is essential for patients with facial nerve injury. In the immediate postoperative period, a moisture chamber is used. Patients who are expected to have a prolonged recovery phase benefit from insertion of a gold weight into the upper eyelid.

2. First bite syndrome

   a. This is characterized by a cramping pain in the parotid region after the first bite of each meal. The pain lasts a few seconds, improves with each bite, and is extinguished over the next several bites. Symptoms are at their worst with the first bite of food in the meal.[10]

   b. Treatment options are limited with no well-documented medical treatment available. Some clinicians advocate the use of Botox injections into the affected parotid gland to reduce the severity of symptoms. Surgical treatment requires transmeatal excision of Jacobson's plexus on the promontory of the middle ear.

3. Sialocele

   a. Exposure of raw parotid tissue or transection of the parotid duct can lead to the accumulation of saliva in the wound. Treatment often begins conservatively with a pressure dressing. If the sialocele grows or fails to resolve, needle aspiration is indicated. Botox injections are useful in reducing the production of saliva into the wound bed. Finally, surgical exploration in the operating room should be

considered in refractory cases.

4. Hemorrhage

   a. Avoidance of anticoagulants preoperatively and careful dissection help prevent this potentially life-threatening complication.

Alternative Management Plan

1. Radiation therapy

   a. Reserved for unresectable disease and/or patients who are medically inoperable

   b. Often delivered as intensity modulated radiation therapy (IMRT) to target tumor cells while sparing adjacent critical tissues and structures

2. Chemotherapy

   a. Platinum-based agents are occasionally used in conjunction with radiation therapy in patients with good performance status and unresectable disease.

Discussion

Evidence-Based Medicine Question

What are the indications for adjuvant radiotherapy in patients with prestyloid PPS tumors?

Although surgery is the mainstay in treatment of prestyloid PPS tumors, adjuvant radiotherapy is recommended at times to improve outcomes. Patients with malignant major salivary gland tumors with high-risk features benefit from adjuvant radiotherapy. High-risk features include advanced stage, high-grade tumor, positive surgical margins, and recurrent tumors. Data from the Surveillance, Epidemiology, and End Results (SEER) database have demonstrated improved locoregional recurrence rates and improved overall survival in such patients who were treated with adjuvant radiotherapy as opposed to surgery alone.

Editorial Comment

PPS tumor surgery is challenging due to the proximity of critical structures and limited access. The success is not gauged only by complete tumor removal but also by avoidance of tumor spillage, which can have significant repercussions. Multifocal recurrence in the PPS of commonly occurring pathology such as pleomorphic adenomas can be devastating for the patient and difficult to treat. Similarly, cranial neuropathy can also cause significant morbidity to the patient affecting speech, swallowing, and facial nerve function. PPS tumor surgery should be systematic and meticulous. Critical cranial nerves pathways (VII, IX, X, XI, and XII) must be identified to allow preservation and maximum mobilization for tumor delivery. Similarly, efforts must be taken to provide wide access by taking steps such as dividing the stylomandibular ligament, facilitating adequate distraction of the mandible. In rare instances, a mandibulotomy may also be necessary to provide wide exposure to avoid tumor spillage. Critical vasculature (carotid and jugular systems) must be identified and proximal control obtained before tumor dissection can begin. With the advent of newer technology, transoral surgery with or without endoscopic or robotic guidance has become a possibility; these sophisticated approaches must be performed by highly experienced surgeons using careful case selection.

Transoral Approach to the Parapharyngeal Space

Christopher H. Rassekh, and Kyle Hatten

Introduction

The management of patients with tumors of the parapharyngeal space (PPS) is a challenge for head and neck surgeons. The diverse anatomic structures in the PPS give rise to many different tumors, and the relationship of such lesions to critical neurovascular contents provides a technical challenge during surgery. Various operative techniques have been described to safely approach this deep neck space. However, while considering that 80% of PPS tumors are benign,[1] the correct approach to minimize surgical morbidity while successfully treating the patient should be chosen. Of the many approaches to the PPS, the transoral approach has been an ideal technique for carefully selected tumors and minimizes complications experienced with other surgical alternatives.

Key Operative Learning Points

- The transoral approach to the PPS should be reserved for benign prestyloid tumors.
- Fine-needle aspiration should be performed preoperatively to rule out malignancy.
- Cross-sectional imaging should identify that the carotid artery is displaced posterolaterally.
- The transoral robotic approach can provide improvement in optics of the surgical procedure and allow for a surgical assistant at the bedside to facilitate dissection.

- Blunt dissection, meticulous hemostasis, and careful attention to closure of the pharyngeal incision are critical in avoiding complications.

Preoperative Period

History

- Most patients are asymptomatic, with tumors incidentally found during unrelated imaging.
- When symptomatic, patients commonly present with awareness of an intraoral mass or a mass in the neck.
- Facial pain or cranial neuropathies are usually associated with malignant lesions, which are not amenable to transoral removal.

Physical Examination

- Oral cavity/oropharyngeal exam ination: The most common finding is a mass displacing the tonsil/soft palate or both, medially. In addition, the mouth opening should be adequate for transoral surgical exposure.
- Examination of the neck may demonstrate a palpable mass. However, only 28% of patients present with both an intraoral and external neck mass.[2]
- Additional findings may include paralysis of the vocal cord and/or palate, middle ear fluid on the side of the lesion, Horner's syndrome, and pulsations over the mass in the neck.

Imaging

- Cross-sectional imaging with contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) is used to determine the relationship of neoplasms to vasculature structures. In addition, imaging provides information on the location of the tumor in the prestyloid versus poststyloid space.

- Imaging can provide information on the vascularity of the mass.
- Transoral fine-needle aspiration (FNA) of palpable and visible lesions is usually well tolerated by patients in the office setting. However, inadequate stabilization of PPS masses as well as limits of intraoral angles may require a CT-guided FNA through the skin, rather than making a "blind" pass toward a mass with large caliber vasculature structures adjacent to the lesion.

Indications

- Benign cysts/neoplasms isolated to the prestyloid PPS
  - Salivary gland neoplasms; most commonly pleomorphic adenomas
  - Trigeminal nerve branch schwannomas
  - Lipomas

Contraindications

- Malignant tumors
- Poststyloid PPS masses
- Patients with significant trismus
- Vascular tumors such as paragangliomas due to proximity to the carotid artery
- Tumors involving the skull base
- Tumors with significant extension to the deep lobe of the parotid or the stylomandibular tunnel

Operative Period

Anesthesia

General endotracheal intubation with the tube in the side of the nose opposite the mass

Positioning

- Supine
- Robotic-assisted cases should have the bed positioned flat and with the operating table as low as possible to maximize the access of mechanical arms in the operative field. A constant communication is important with the anesthesia team to ensure that the bed position is not moved during surgery without adjusting the position of the robotic arms, since the robot with its arms docked in the oral cavity is fixed in position relative to the bed and the patient.

Perioperative Antibiotic Prophylaxis

Preoperative antibiotics may be given within 60 minutes of the mucosal incision to provide coverage for oral flora.

Monitoring

Monitoring by the Anesthesia Team

The patient should be paralyzed to improve mouth opening.

Instrument and Equipment to Have Available

- Modified (for transoral robotic surgery [TORS]) Crowe-Davis mouth gag (Fig. 70.1)
- A da Vinci surgical system robot is not required but improves surgical optics and allows for "4 handed" surgery, rather than a single bedside surgeon.
- 0-degree endoscope placed at center robotic arm. Thirty-degree endoscope is useful in select cases to visualize the superior aspect of the PPS.
- Monopolar cautery with spatula tip placed in robotic arm ipsilateral to PPS lesion

- 5-mm endowrist Maryland dissector can be used in a contralateral robotic arm
- Two Yankauer suctions are used bedside by the assistant to provide retraction and evacuate blood and smoke.
- Bipolar cautery should be available for precise cautery while dissecting in close proximity to neurovascular structures.

Key Anatomic Landmarks

- Surgical view should have exposure of anterior tonsillar pillar and have oral tongue displaced to the contralateral side of the lesion.
- Pterygomandibular raphe should be identified and be the lateral border of surgical dissection.

Prerequisite Skills

- Prior extensive experience with da Vinci surgical system
- Comprehension of anatomic boundaries and contents of PPS
- Experience with open, transcervical approaches to the PPS

Operative Risks

- Injury to lip, gums/teeth during placement of the mouth gag
- Injury to the lingual nerve
- Major hemorrhage
- Dehiscence of mucosal incision
- Infection of surgical site

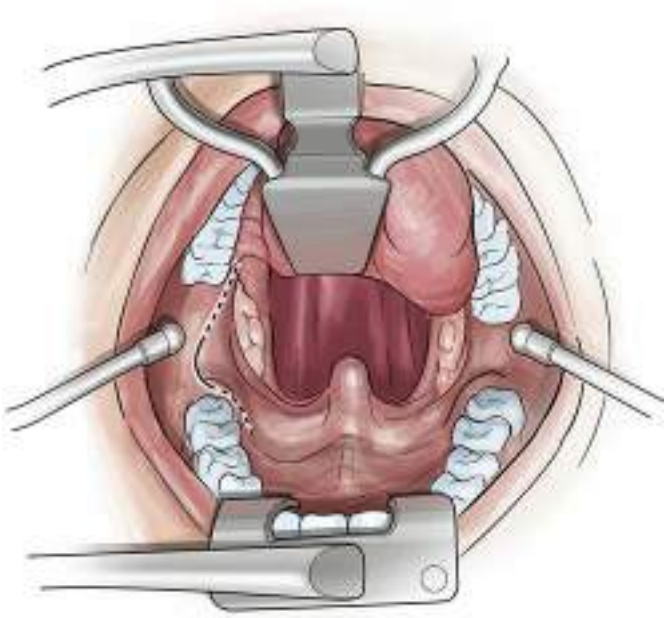

FIG. 70.1 Crowe-Davis mouth gag provides exposure of the surgical field. The tongue is lateralized to improve surgical access.

Surgical Technique

- Approach
  - Exposure of the surgical field is attained with a Crowe-Davis mouth gag, with attention to displacing the oral tongue away from side of the planned surgical incision.
  - The mucosal incision is made in a curvilinear fashion over the soft palate, making sure to stay superficial and not violate the tumor capsule. Care is taken to avoid injury to the lingual nerve and to preserve adequate mucosa for closure.
  - Blunt dissection to approach the pterygomandibular raphe and lateralizing the fascia while maintaining the pharyngeal constrictor musculature medially
  - The exposure of the tumor is aimed toward allowing circumferential access to the border of the lesion. Superior medial pterygoid muscule fibers are dissected and transected as needed to gain exposure superiorly and laterally (Fig. 70.2).
  - The stylohyoid musculature *does not* need to be divided, as the lesion

lies in the prestyloid PPS.

- Tumor dissection
  - The spatula tip cautery can then be used as a blunt dissector to sweep away the soft tissue from the tumor. Meanwhile, the bedside assistant can retract with suctions to provide exposure.

FIG. 70.2 Medial pterygoid musculature is isolated and released to gain access to the parapharyngeal space.

  - It is helpful to have the assistant use one suction for retraction and the other to evacuate fluid and smoke.
  - The Crowe-Davis mouth gag can be removed to allow for finger dissection at the bedside by the surgeon to feel for fascial attachments. In addition, palpation allows for assessment of the

internal carotid artery pulsations to identify the anatomic relationship to the artery (Fig. 70.3).

- If the tumor's superior attachment is not visualized, a 30-degree scope can be used to facilitate exposure and further dissection.
- A hybrid approach is occasionally required when blunt dissection is performed by both the surgeon at the console and the bedside surgeon. The robotic arms can be used for retraction to expose the surgical field, while the bedside assistant performs blunt dissection. Very limited sharp dissection may be cautiously performed and only under direct visualization.

- Closure
  - Following delivery of the tumor, careful inspection of the tumor capsule should be performed to ensure it has not been ruptured.

FIG. 70.3 Finger dissection performed by the bedside surgeon helps facilitate delivery of the mass. Digital palpation also allows for localization of the internal carotid artery in the parapharyngeal space.

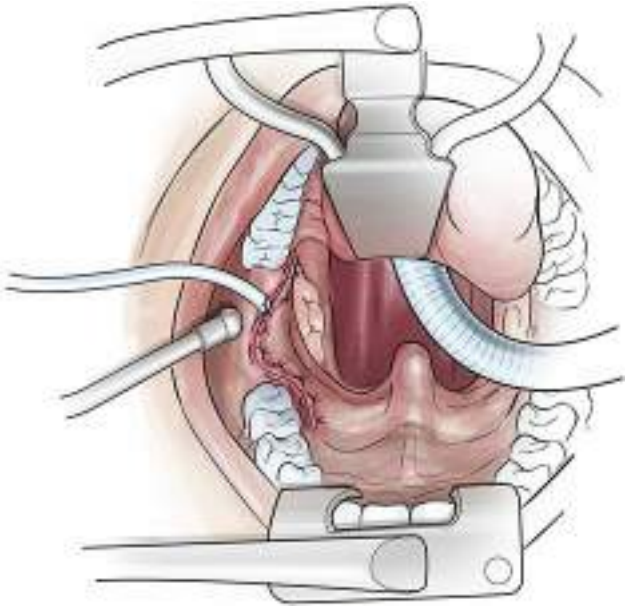

FIG. 70.4 Soft palate mucosa is closed with horizontal mattress suture. Penrose drain is placed within the suture line.

- Irrigation is performed with water followed by normal saline.
- Horizontal mattress 3-0 Vicryl sutures are placed through mucosa and musculature to complete a muscle flap/pharyngoplasty closure. A single ¼″ Penrose drain is placed in the midportion of the incision to allow for drainage of any fluid that may accumulate (Fig. 70.4).
- The drain can be secured with tape on the external skin and removed the following day.
- Jaw Bra may be used to apply pressure to the PPS.
- Extubation is performed at the completion of the procedure.

Common Errors in Technique

- Failure to release the medial pterygoid musculature limits the ability to deliver the tumor from PPS.
- Traumatic blunt dissection resulting in rupture of the tumor capsule
- Inadequate closure around the Penrose drain, resulting in wound dehiscence
- Insufficient hemostasis

Postoperative Period

Postoperative Management

- The drain is removed on the first postoperative day.
- Diet should be limited to liquids until the mucosa is healed. A soft diet should be maintained for approximately 2 weeks.

Complications

- Immediate
  - Edema of the tongue or hematoma requiring delayed extubation
  - Lingual nerve injury while extending the mucosal incision along the floor of the mouth
  - Major nerve or vascular injury, which has not occurred in our series
- Delayed
  - Dehiscence of pharyngoplasty closure may occur and is commonly seen when drain placement leaves a large pharyngeal defect. Management of such a complication with limited oral intake allows for healing by secondary intention. This complication has been largely avoided by using horizontal mattress sutures with careful attention to detail and the dietary regimen noted previously.
  - First bite syndrome that was experienced in a patient who had a resection of a Schwannoma

Alternative Management Plan

- Transcervical, transparotid, or transmandibular or combination approach to PPS. These alternative surgical techniques should be discussed with all patients.
  - In addition, patients should be consented preoperatively for possible transcervical approach, if the surgeon identifies that the patient has inadequate transoral exposure or he/she is concerned with rupture

of tumor capsule.

- Observation of benign prestyloid PPS tumors

Discussion

Evidence-Based Medicine Question

Is there evidence to suggest that the robotic approach has advantages over the open technique?

PPS tumors: TORS versus open approaches

The transoral approach to PPS tumors was described in 1920 as an effective technique for surgical removal; however, piecemeal removal was often required due to anatomic constraints of surgical dissection.[3] Open approaches increased in popularity with the improvement of safety measures during surgery. The transcervical approach became the most widely accepted and described technique. This surgical dissection requires a cervical lymphadenectomy of level II and frequently requires removal of the styloid process and its associated musculature. The access provided by the transcervical approach allows excellent exposure to the neurovascular structures located in the poststyloid PPS, "carotid space," including the internal carotid artery, internal jugular vein, lower cranial nerves, and the sympathetic chain.

In recent years, advances in surgical techniques of the transoral approach were introduced with the da Vinci Surgery System. O'Malley et al. described the first series of patients with benign prestyloid PPS tumors removed using TORS and demonstrated high local control and low complication rates.[4] TORS provided improved visual optics and the ability to use a surgical bedside assistant to enhance exposure and surgical feasibility. The surgical technique was reserved for select patients, including those with benign tumors confirmed on needle aspiration and lesions confined to the prestyloid PPS. TORS approach to the PPS did not result in any of the most commonly described complications reported with open approaches, including first bite syndrome (12%) and facial nerve weakness (4%).[5] In addition, transoral approaches avoid the need for a skin incision and consequently a visible scar.

Critics of the transoral approach express reservations about the risk of tumor rupture that may lead to recurrence. However, reserving this surgical technique for tumors in the prestyloid PPS obviates the risk of traumatic rupture by the styloid process, as this anatomic structure is posterior to the surgical dissection. In addition, we believe the robot offers improvement with visualization and tremor stabilization that enhances the safety profile of the transoral approach. Also, the primary surgeon is removed from the surgical field during TORS to allow an assistant to actively participate in the dissection at the bedside.

The TORS approach to the PPS has most frequently been performed for resection of pleomorphic adenomas arising in minor salivary glands, which are separate from the deep lobe of the parotid gland. Regardless of the surgical technique chosen by the surgeon, transcervical or transoral, the dissection will require blunt dissection. The major advantage in the transoral approach is the avoidance of an external scar, decreased risk of facial nerve injury, and lower incidence of first bite syndrome. However, the transoral approach requires careful surgical technique to avoid injury to the lingual nerve and pharyngeal wound dehiscence. Also, the transoral approach requires long-term follow-up to ensure the tumor rupture and recurrence are not more common.

Transoral approach chosen in appropriately selected patients in very experienced hands offers an approach that minimizes specific aspects of surgical morbidity while still providing excellent tumor removal.

Editorial Comment

The important aspect of TORS or other transoral approaches to PPS tumors is case selection, ensuring that the oral cavity permits adequate surgical exposure and access. One of the key components of PPS tumor surgery is digital palpation and blunt dissection (often blunt finger dissection). While the robot provides excellent visualization, dexterity, and access and permits assistant participation, it does not currently have true haptic feedback. Consequently, hybrid techniques that involve maximizing the benefits of the robotic technology coupled with open surgery concepts (i.e., blunt dissection and finger palpation of the tumor at the bedside) are critical to safe outcomes in these cases. In agreement with the author, transoral approaches (robotic or nonrobotic) must be

considered only by expert surgeons with an extensive experience with open techniques and knowledge of transoral and PPS anatomy.

Review Questions

1. Transoral approach to the parapharyngeal space (PPS) requires release of which muscle to gain better exposure?

   a. Superior pharyngeal constrictor muscles

   b. Styloglossus

   c. **Medial pterygoid**

   d. Stylohyoid

2. What is a contraindication to the transoral approach to PPS?

   a. Displacement of internal carotid artery posteriorly

   b. Trigeminal nerve schwannoma

   c. Elongated styloid process

   d. **Vascular tumors**

3. What is the most common complication of the transoral approach to PPS?

   a. First bite syndrome

   b. Marginal mandibular nerve weakness

   c. **Dehiscence of pharyngeal mucosa closure**

   d. Stroke

Posterolateral Neck Dissection

Natalie L. Silver, and Jeffrey N. Myers

Introduction

The posterolateral neck dissection is an operation that is typically used in the management of cutaneous cancers of the posterior scalp, auricle, or upper neck. It is done either electively, to stage the clinically node-negative neck, or therapeutically, to treat the node-positive neck. In contemporary practice, this operation is most often used to treat a clinically node-negative neck that has been found to have microscopically positive nodal disease in one or more of the regional nodal basins. The posterolateral neck dissection is an extended neck dissection that is often combined with a comprehensive or selective neck dissection. A description of this operation was first published in 1962. More recently, however, in 1980, Drs. Goepfert, Jesse, and Ballantyne of the M.D. Anderson Cancer Center wrote a definitive description of this procedure and their results with it.[1,2] Typically this operation involves the removal of the lymph nodes in the postauricular, suboccipital, spinal accessory, and jugular lymph node basins (Fig. 71.1). In experienced hands, this operation provides excellent oncologic, functional, and cosmetic results.

Key Operative Learning Points

1. The spinal accessory nerve must be identified on the anterior and posterior border of the sternocleidomastoid muscle (SCM) and traced in its entirety to prevent inadvertent injury to this structure.

2. During the procedure, fibroadipose node-bearing tissue is removed from the inferolateral portion of the neck where the trapezius and clavicle meet. Extreme caution must be exercised in this region to avoid

injury to inferolateral branches of the brachial plexus and the terminal aspect of the spinal accessory nerve.

Preoperative Period

History

1. Personal history of skin cancer: The majority of patients undergoing posterolateral neck dissection have skin cancer as the primary indication for the procedure (Fig.71.2); therefore, a history of prior skin cancers is useful in treatment planning. This includes histologic type, location, and previous treatment (history of surgery or radiation treatment for skin cancer).

2. History of sun exposure

3. Family history of skin cancer

4. Occupational history: This operation, when performed without complication, can lead to decreased shoulder function for up to 18 months following surgery. Typically this is manifested by a decreased range of motion and strength on shoulder abduction, which, with intervention by a trained physical therapist, can be improved greatly with anticipated return to baseline.

Physical Examination

1. Skin

   a. Visual evaluation and palpation of the extent of the primary tumor

      1) Include examination of the skin of the head and neck, especially the scalp, and auricle.

2. Neck

   a. Inspect and palpate the postauricular, suboccipital, spinal accessory, and jugular nodal basins.

      1) Note the number and size of each involved node and use as part of the clinical staging.

2) Assess the extent of nodal burden and involvement of regional structures.

3. Nerve function: Evaluate and document preoperative function of the spinal accessory nerve and brachial plexus, because these nerves will be at risk for injury during the dissection.

Imaging

1. Axial computed tomography (CT) scan with contrast

a. Define the location and extent of the primary cancer.

b. Assess regional lymph node metastases.

2. Magnetic resonance imaging (MRI) or positron emission tomography (PET)/CT

a. Systemic imaging may be indicated based on the histology and clinical stage of the disease.

1) For patients with melanoma or Merkel cell carcinoma with thick primary tumors or extensive lymph node metastasis, a PET/CT and brain MRI or brain MRI with CT scan of the head and neck, chest, and abdomen should be ordered for a complete metastatic evaluation.

Fine-Needle Aspiration Biopsy

1. Fine-needle aspiration (FNA) is indicated for patients found to have palpable lymph node metastasis if the results will change the management of the patient's problem.

a. If the presence of histologically confirmed lymph node metastasis is part of the inclusion criteria for a protocol of neoadjuvant systemic therapy, and FNA should be obtained

2. Use to confirm or rule out the presence of regional lymph node metastasis to facilitate treatment planning in cases where the finding of lymph node metastasis is indeterminate by cross-sectional imaging criteria.

Indications

1. The treatment of occult and clinically node-positive metastasis to the neck from a cutaneous malignancy involving the skin of the posterior scalp, auricle, and upper neck

2. The treatment of microscopically positive disease in the lymphatic basin after sentinel lymph node biopsy for cutaneous malignancy

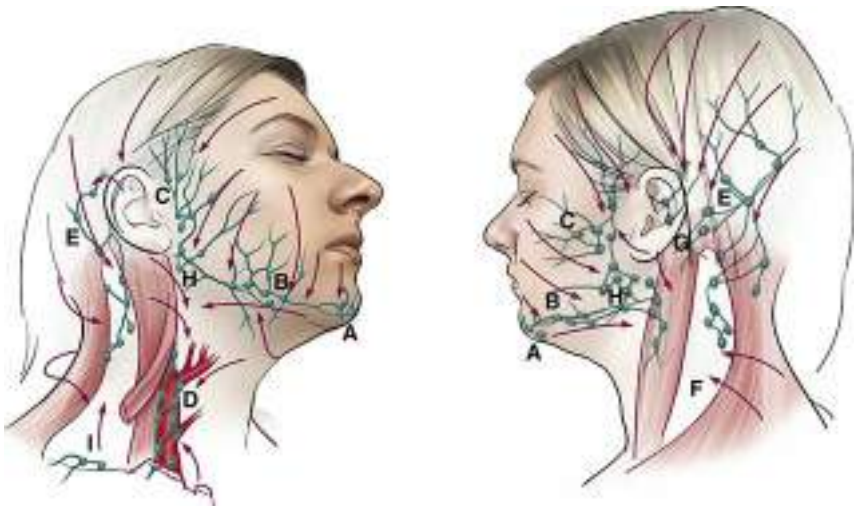

FIG. 71.1 Nodal drainage patterns of the head and neck. *A,* submental. *B,* submandibular. *C,* pre-auricular. *D,* deep cervical/jugular chain. *E,* occipital. *F,* posterior cervical chain. *G,* posterior auricular. *H,* parotid. *I,* supraclavicular.

FIG. 71.2 Given the location, this scalp melanoma may require posterolateral neck dissection for gross disease or positive sentinel lymph node biopsy.

Contraindications

1. Disseminated metastases: This operation is contraindicated in patients for whom the procedure would provide neither prolonged survival nor significant palliation.

2. Patients with extensive lymph node metastasis: Those with involvement of the deep muscles of the neck, vertebrae, or carotid artery are advised to consider systemic therapy options that could help to decrease the risk of distant metastatic cancer and potentially make the locoregional disease burden more manageable by resection.

3. Medical comorbidities with increased risk for general anesthesia: Patients deemed to be medically at high risk for general anesthesia who have microscopic lymph node metastasis can be often be managed successfully with radiation therapy alone.

Operative Period

Anesthesia

General

- Place the endotracheal tube and secure it at the oral commissure contralateral to the side of the neck that is being dissected.
- Use a paralytic agent throughout the procedure. This prevents excess stimulation of motor nerves by electrical dissection. Even in the presence of paralyzing agents, these motor nerves are readily identified by reliable anatomic landmarks and the stimulation provided by electrical dissection.

Positioning

Supine

- Place the patient in the supine position with the ipsilateral upper extremity tucked at the patient's side and the operating table turned at a 90-degree angle such that the side of the dissection is facing out.
- Place a roll under the patient's shoulders to extend the neck and turn the head toward the anesthesiologist.
- When bilateral posterolateral neck dissection is performed, consider placing the patient in the prone position. This occurred in only 3 of 55 patients reported in a large series, making this a rare position for this operation.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Major head and neck soft tissue set
2. Bipolar electrocautery
3. Two half-inch Penrose drains to be used for retraction

Key Anatomic Landmarks

1. Erb's point (punctum nervosum): Located on the posterior border of the SCM midway between its attachments to the mastoid process, sternum, and clavicle. Cutaneous branches of the cervical plexus (C5 and C6 roots) emerge at Erb's point from behind the posterior border of the SCM. The four cutaneous nerves of the cervical plexus are the lesser

occipital nerve, great auricular nerve, transverse cervical nerve, and supraclavicular nerve. The spinal accessory nerve exits the SCM muscle approximately 1 cm superior to Erb's point.

2. The spinal accessory nerve: After exiting the skull base, it most often passes anteriorly to the jugular vein and enters, and innervates, the SCM and exits the SCM at the posterior margin of the muscle. It then courses inferolaterally through the posterior triangle and passes under the trapezius muscle that it innervates.

3. Trapezius muscle: The upper fibers of the trapezius originate from the spinous processes of C1 to C7, the external occipital protuberance, the medial third of the superior nuchal line of the occipital bone, and the ligamentum nuchae. Inferiorly the fibers travel downward and laterally and insert into the posterior border of the lateral third of the clavicle.

Prerequisite Skills

- Neck dissection levels 1 through 5
- Selective neck dissection
- Radical neck dissection
- Posterolateral neck anatomy

Operative Risks

1. Nerve injury: Significant risk to the accessory nerve. Other nerves are at risk, including the brachial plexus and phrenic nerve.

2. Possible disinsertion of the SCM muscle from the mastoid during dissection

3. Chylous fistula

4. Superficial loss of the most distal (superior) aspects of the skin flap

Surgical Technique

- Draping:

- Neck, shoulder, and upper chest are sterilely prepped.
- Using towels, square off the operative field, including exposure of the posterior neck to the nuchal line, the clavicle, the anterior neck to the midline, and the superior aspect of the auricle.
- The ear or scalp should be included in the operative field based on the location of the primary.

- Incision
  - The incision is designed to provide optimal visual access to facilitate the removal of all the nodal groups to be dissected while preserving vital structures and cosmesis.
  - The location of the primary tumor and incisions used for prior procedures such as a lymph node biopsy may dictate the design of the incision.
  - I prefer an S-shaped incision in which a horizontal limb is oriented along the occiput from the midline to the postauricular region, where it then descends vertically just anterior to the anterior border of the trapezius to a lower cervical skin crease, which the incision should follow horizontally anterior to the anterior border of the SCM (Fig.71.3).
- Elevation of the flap
  - Make the incision with a scalpel or cautery.
  - The superior flap is elevated to the pinna anteriorly, the superior aspect of the auricle superiorly, and the midline medially.
  - The posteroinferior flap is elevated to the midline in the superior half of the neck and the anterior border of the trapezius muscle in the inferior half of the neck all the way to the clavicle.
  - The anterior flap is elevated to the anterior border of the omohyoid muscle.

FIG. 71.3 "S" type incision used for posterolateral neck dissection.

- Care should be taken to elevate a very thin flap in a subcutaneous plane, leaving the majority of the subcutaneous adipose tissue on the specimen, since the lymph nodes can be found within the subcutaneous adipose tissue in this portion of the neck.
- Secure flaps with skin hooks.

- Identification of the spinal accessory nerve
  - Incise the superficial layer of the deep cervical fascia from the mastoid tip to the clavicle along the anterior aspect of the SCM.
  - Elevate the fascia on both the medial and lateral aspects of the muscle. This fascia and the external jugular lymph nodes should be entirely removed, as they are important components of the specimen in cutaneous malignancies of the scalp, ear, and/or face.
  - Identify the spinal accessory nerve while dissecting along the anterior aspect of the SCM.
  - Skeletonize the accessory nerve throughout its entire course, from deep to the posterior belly of digastric muscle to its entry into the SCM. Dissection on the lateral aspect of the muscle from anterior to posterior will bring one to the underdeep surface of the SCM, where the spinal accessory nerve can be seen exiting the muscle (Figs.71.4 and 71.5).
  - Follow the nerve to the trapezius muscle and skeletonize the nerve throughout its course in the operative field to ensure its preservation.

- Nodal dissection
  - Dissect the fibroadipose lymph node bearing tissue of the postauricular and suboccipital regions off the underlying bone and muscle in a posteroinferior direction. Prior delineation of the SCM helps to prevent detachment of the SCM insertion from the mastoid/occipital skull during the dissection of these posterosuperior nodes.
  - The suboccipital lymph nodes lie along the course of the occipital artery; divide branches of this artery in order to remove this group of lymph nodes.
  - Wrap two half-inch Penrose drains around the superior and inferior aspects of the SCM, exert traction anteriorly, and secure to the drapes to provide exposure of the posterior aspect of the neck.
  - Identify the internal jugular vein (IJV) just above the clavicle and delineate the posterior aspect of the vein.
  - Divide the fibroadipose tissue overlying the deep layer of deep cervical fascia from the IJV to the trapezius just above the clavicle.
  - Gently spread with gauze sponges and elevate the tissue off the deep layer of deep cervical fascia to expose the phrenic nerve and brachial plexus. Take care to avoid injury to these nerves and prevent avulsion of the transverse cervical vessels or thoracic duct.

FIG. 71.4 The anatomy of a completed posterolateral neck dissection is illustrated. Levels II through V have been removed.

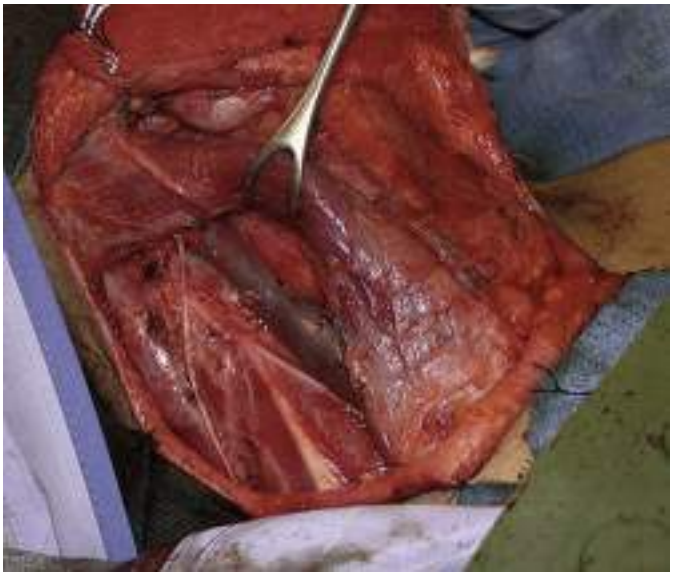

FIG. 71.5 Here the accessory nerve is seen exiting the sternocleidomastoid muscle.

- Remove fibroadipose from the inferolateral portion of the neck where the trapezius and clavicle meet. Use extreme caution in this region to avoid injury to inferolateral branches of the brachial plexus

and the terminal aspect of the spinal accessory nerve. Clamp and oversew this tissue with 2-0 silk sutures.

- Extend the dissection from lateral to medial, elevating the nodal tissue off the trapezius to the midline in the upper half of the neck and the anterior border of the trapezius in the lower neck.
  - Some authors advocate resection of the superior aspect of the trapezius from C1 to C4 in order to remove nodes deep to this muscle.[3]
- Divide the sensory rootlets of the cervical plexus as the dissection transitions anterior to the trapezius and the rootlets and the node-bearing specimen are elevated off of the levator scapulae and splenius capitis muscles.
- Advance the specimen superomedially, and divide the sensory rootlets of the cervical plexus distally in order to preserve their contributions to the phrenic nerve.
- Exert traction on the Penrose drains posteriorly and secure them to provide optimal exposure of the carotid sheath structures and anterior aspect of the neck.
- Dissect the neck specimen onto and off the carotid sheath contents.
- Identify and preserve the hypoglossal nerve throughout its course.
- Dissect the specimen up to the lateral aspect of the omohyoid muscle and release the Penrose drains.
- Provide hemostasis to the wound with bipolar cautery.
- Irrigate the wound with sterile saline solution and inspect it again for signs of bleeding.

- Wound closure and drain placement
  - Place two 7-mm Blake (Ethicon) flat suction drains in the depth of the wound through a separate stab incision and secure them with a suture of 2-0 nylon or 2-0 silk.
  - Avoid placing the drain in the lower neck posterior to the jugular vein, as this can contribute to development of a chylous fistula.
  - Close the wound in layers with 3-0 Vicryl suture for the subcutaneous and platysmal layers and skin staples or 5-0 nylon

suture to approximate the skin edges.[4]

- Specimens
  - Divide the neck dissection specimen into levels 2, 3, 4, and 5 and the postauricular and suboccipital regions and send for permanent section analysis.

Common Errors in Technique

1. Elevating thick superior and posterior skin flaps: The flaps should be elevated in the subcutaneous plane. This is important because the occipital and preauricular lymph nodes can be located within the subcutaneous adipose tissue in this portion of the neck.

2. Failure to gain adequate exposure of both the anterior and posterior neck during the dissection

3. Incompletely visualizing and dissecting the neural structures at risk, such as the spinal accessory nerve and brachial plexus: It is necessary to identify and preserve the spinal accessory nerve in the posterior triangle of the neck.

Postoperative Management

1. Overnight admission for observation: Monitor for hematoma. Inspect drain output for chylous fluid.

2. Consult with physical therapists for shoulder rehabilitation.

Complications

1. Chyle leak, bleeding, neural injury: Complications of the posterolateral neck dissection include all of the complications associated with the more standard selective/comprehensive neck dissection.

2. Injury to the spinal accessory nerve: Owing to the extensive inferoposterior and inferior dissections, the risk of injury to the spinal accessory nerve and/or brachial plexus is greater than in more standard neck dissections. Surgical misadventures involving these neural structures can best be avoided by careful dissection of these nerves under

direct visualization.

Alternative Management Plan

Indications for posterolateral neck dissection include management of lymph node metastasis from primary cancers that are traditionally not radiosensitive. Radiation therapy and chemotherapy may be considered as a palliative approach.

Discussion

Evidence-Based Medicine Question

How effective is posterolateral neck dissection in achieving local control for patients with skin cancer? How effective is postoperative adjuvant radiation?

A case series review of 55 patients treated over a 10-year period from 1982 through 1991 with a minimum of 3 years of follow-up at M.D. Anderson Cancer Center included 35 patients with melanoma, 10 with squamous cell carcinoma, and 10 with other histologic types. In this series, disease was controlled at the site of the primary tumor in 89% of patients (94% of patients with melanoma) and regional disease was controlled in 93% of patients (89% of patients with melanoma).[5]

Additional studies of regional metastatic melanoma of the head and neck region treated at M.D. Anderson Cancer Center show that the addition of postoperative adjuvant radiation therapy can enhance locoregional control. Ballo and et al. reported their experience in administering five 6-Gy fractions of external beam radiation twice weekly in the postoperative setting to 160 patients with melanoma of the head and neck region, 148 (93%) of whom had node-positive disease. Patients in this group had undergone simple lymph node excision (35), selective neck dissection (90), or a radical or modified radical neck dissection (35). The actuarial local, regional, and locoregional control rates in this population at 10 years were 94%, 94%, and 91%, respectively.[6]

Editorial Comment

Posterolateral neck dissection is indicated for skin cancers of the upper neck, posterior scalp, and auricle. Primary resection of these cancers can be quite complex, involving resection of the temporal bone, lateral skull base, temporomandibular joint, and/or mandible. The need for facial nerve sacrifice adds further complexity, consequently posing unique reconstructive challenges. Planning of the surgery and incision for posterolateral neck dissection should take into account the extent of the primary resection, type of reconstruction planned (e.g., cervicofacial rotation flap), and adequate surgical access to lymph node metastasis.

Excision of Neural Tumors of the Parapharyngeal Space

Johan Fagan

Introduction

To safely resect neural tumors of the parapharyngeal space (PPS) and to counsel patients about potential consequences and complications of surgery requires that the surgeon has a detailed knowledge of the surgical anatomy of the PPS, requests appropriate radiological studies from which the likely pathology can be predicted (80% benign), and understands the possibilities and limitations of the various surgical approaches.

Neural tumors in the PPS include solitary schwannomas, neurofibromas, and malignant nerve sheath tumors. There are at least three major types of neurofibromas: neurofibromatosis-1 (NF1), neurofibromatosis-2 (NF2), and schwannomatosis. They all represent genetic abnormalities. With schwannomas, the nerve fibers of the parent nerve may be draped over the tumor, making it possible to preserve the nerve, although transient postoperative paresis is common. However, in most cases the schwannoma is inseparable from the nerve and the nerve must be sacrificed. Neurofibromas are not encapsulated, and because the nerve fibers are part of the tumor, the nerve cannot be preserved. Malignancy occurs in about 10% of patients with NF1 and may be signified by invasion of adjacent tissue, or metastases.

The PPS has prestyloid and poststyloid compartments. It is important to distinguish preoperatively between a prestyloid and a poststyloid mass, as this affects the differential diagnosis and may determine the surgical approach. Poststyloid neural tumors arise from cranial nerves IX–XII or from the sympathetic nerves. Prestyloid tumors are likely to originate from branches of the mandibular division of cranial nerve V.

However, the nerve of origin may not be apparent even at surgery if a tumor has originated from minor, unnamed nerves. Vagal and carotid paragangliomas also arise in the poststyloid PPS and may be difficult to differentiate from a schwannoma on computed tomography (CT) and magnetic resonance imaging (MRI), as flow voids that are typical of a paraganglioma may not be apparent in a small paraganglioma, and schwannomas may also appear vascular. Carotid angiography may be helpful in such situations to draw a distinction. Salivary gland tumors and metastases (e.g., from papillary thyroid carcinoma) should also to be considered in the differential diagnosis.

The PPS extends as an inverted pyramid from the skull base superiorly, to the hyoid bone inferiorly. Fig. 72.1 presents an axial view of the prestyloid (yellow) and poststyloid (pink) components of the PPS separated by the styloid process, *tensor veli palatini* muscle, and its fascia (brown). The poststyloid space contains the internal carotid artery and the internal jugular vein, as well as the lower cranial nerves IX–XII, and the sympathetic trunk. It is confined medially by the pharyngobasilar fascia and the superior constrictor muscle of the pharynx.[1]

Prestyloid tumors may present with bulging of the lateral wall of the oropharynx, which displaces the tonsil medially (Fig. 72.2). The prestyloid PPS is bordered anterolaterally by the medial pterygoid muscle, and posterolaterally by the deep lobe of the parotid gland (see Fig. 72.1). It contains mainly adipose tissue. Radiologically, prestyloid tumors typically displace the adipose tissue of the PPS anteromedially (Fig. 72.3).

Poststyloid masses typically present as a mass extending into the superior lateral neck or the oro- or nasopharynx, dysfunction of cranial nerves IX–XII, or Horner's syndrome. The poststyloid PPS is limited medially by the pharyngobasilar fascia and the superior pharyngeal constrictor. It contains the internal carotid artery and the internal jugular vein, as well as the lower cranial nerves IX–XII, and the sympathetic trunk (see Fig. 72.1). Radiologically, poststyloid tumors typically displace the adipose tissue of the PPS anterolaterally (see Fig. 72.3, Fig. 72.4).

Key Operative Learning Points

Selecting the appropriate surgical approach is very important in

achieving adequate access and in minimizing morbidity. In order to plan the correct surgical approach and before embarking on surgery, the surgeon needs the following information:

- *Is the mass pre- or poststyloid?* This is determined clinically and radiologically with CT/MRI. This information permits the surgeon to narrow down the differential diagnosis, to plan the best approach, and to counsel patients preoperatively about possible sequelae.
- *Is the mass benign or malignant?* This may influence the surgical approach, and even affect the decision whether or not to do surgery. It is generally determined by Fine needle aspiration cytology (FNAC) done transcervically or transorally. The surgeon should not be concerned about puncturing the internal carotid artery with a small-caliber needle, as bleeding can be controlled with digital pressure.
- *Is the mass a paraganglioma?* This is important, as paragangliomas may rarely be hormonally active and may require preoperative embolization. When it is difficult to distinguish a paraganglioma from a schwannoma on CT or MRI, proceed to a diagnostic angiogram.
- *What are the anatomical relations of the internal and external carotid arteries to the mass?* Particularly with a poststyloid mass, knowledge of the position of the arteries in relation to the mass is important in planning and doing the surgery (see Fig. 72.4).
- *What is the cerebral cross-over blood flow like should the internal carotid artery have to be sacrificed?* Should this be a concern, it can be determined by angiography ± balloon occlusion testing.

Preoperative Period

- *What neurological deficits may be caused by surgical excision?* Causing permanent cranial nerve deficits, a cerebrovascular accident, or first bite syndrome can be devastating for the surgeon and patient alike, and may significantly impact on a patient's quality of life.
- *Does the patient have NF1, NF2 or schwannomatosis?*
- *Does the patient require surgery, radiation, or watchful waiting?* Not all benign neural tumors require surgical excision, as they are often slow growing, and growth may be arrested by radiation. Therefore careful

consideration should be given to nonsurgical treatment options, especially in older patients.

History

1. History of present illness
   a. Growth rate
   b. Pain (suggests malignancy or schwannoma)
   c. Neurological deficits of V, IX, X, XI, XII, sympathetic

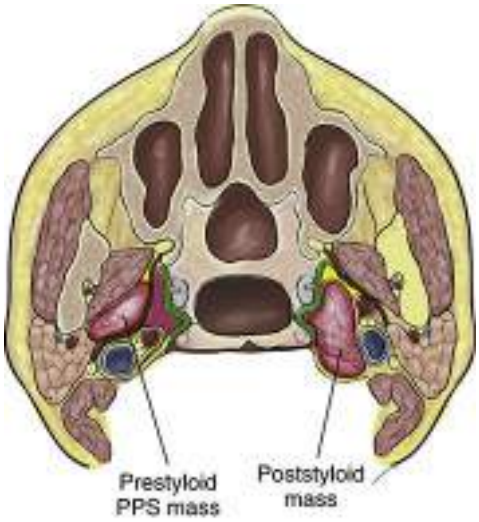

FIG. 72.3 Directions of displacement of adipose tissue as seen on computed tomography or magnetic resonance imaging with prestyloid parapharyngeal space mass (R) and poststyloid mass (L).

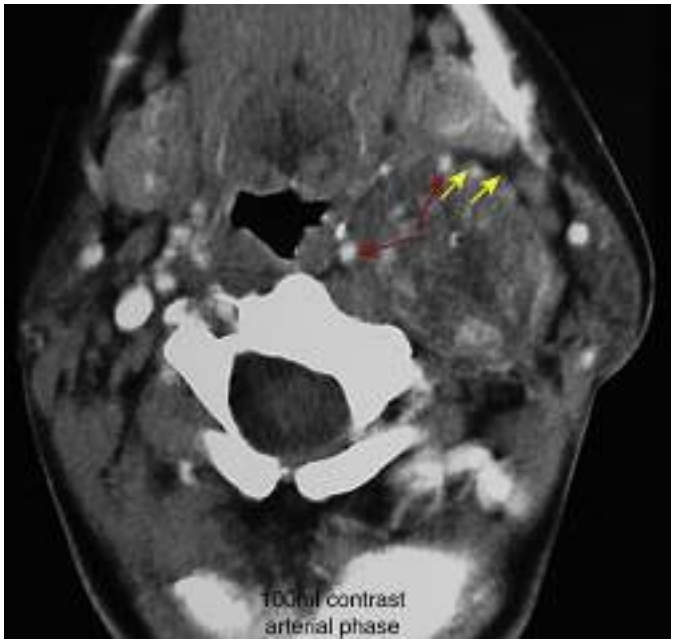

FIG. 72.4 Computed tomography scan of poststyloid vagal schwannoma, demonstrating direction of displacement of adipose tissue *(yellow arrows)* and medial displacement of the carotid vessels *(red arrows).*

d. Pointers to paraganglioma (hypertension, headaches, palpitations, tachycardia, and anxiety)

e. Pointers to NF, as discussed under physical examination

2. Past medical history
   a. Previous malignancy (metastasis)
   b. Cerebrovascular accidents or ischemia (risk of cerebro vascular accident (CVA) at surgery)
   c. NF
3. Family history
   a. NF
   b. Paragangliomas
4. Medical illness
   a. Fitness to deal with aspiration and dysphagia if neurological complications occur
   b. Fitness for surgery
5. Medications
   a. Anticoagulants
6. Mental and social status
   a. Ability to overcome challenges related to speech and swallowing
   b. Ability to give informed consent
   c. Social support
   d. Employment and hobbies may be affected by speech or swallowing impairment.

Physical Examination

1. Primary PPS mass
   a. Confined to the neck? May be resectable by simple transcervical approach
   b. Extends above angle of mandible? May need to include transparotid approach
   c. Does the tumor distort the oropharynx?

2. Neurofibromatoses?

   a. NF1: Café-au-lait spots, axillary and inguinal freckling, subcutaneous or cutaneous neurofibromas, plexiform neurofibroma, Lisch nodules, benign and malignant nervous system neurofibromas, sphenoid dysplasia, long bone abnormalities, scoliosis, pseudoarthroses

   b. NF2: Vestibular schwannomas, meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities

   c. Schwannomatosis: Multiple schwannomas

3. Neurological deficits?

   a. Cranial nerves V3, IX, X, XI, XII

   b. Horner's syndrome

4. Neck

   a. Palpate the neck for cervical metastases.

   b. Examine the neck for the presence of a mass or signs of previous surgery and scars that may affect surgical planning.

5. General health

   a. Nutrition

   b. Cardiovascular

   c. Respiratory

   d. Mental

Laboratory Testing

1. Twenty-four-hour urine and serum metanephrines if a paraganglioma is part of the differential diagnosis to rule out the presence of a secreting paraganglioma or pheochromocytoma

Imaging

1. Chest radiograph

   a. Metastases

b. Pulmonary and cardiac status

2. Swallowing evaluation by a speech language pathologist, if the patient is aspirating

3. CT scan of head and neck (with contrast)

a. All cases

b. Size of tumor

c. Superior extent of tumor

d. Relationship to internal and external carotid arteries

e. Multiple tumors

4. MRI

a. To compliment CT scan findings

b. Multiple tumors

5. Carotid angiogram

a. To exclude a paraganglioma

b. To determine course of carotid vessels if uncertain on CT or MRI

c. To check cross-flow if concern about risk to carotid artery during surgery

Indications

- Not all patients require surgery
- Diagnostic if concerned about malignancy
- Mass effect or potential for future mass effect

Contraindications

1. Patient factors

a. Medically unfit

b. Inability to give informed consent

c. Inability to overcome challenges related to deficits in speech and

swallowing

d. Inadequate social support

2. Tumor factors

a. Malignant tumor: Unresectable and/or distant metastases

b. Benign tumor: Unresectable

c. Potential morbidity unacceptable to patient

3. Surgical factors

a. Inadequate expertise

Preoperative Preparation

1. Evaluations by

a. Head and neck surgeon

b. Anesthesiology

c. Speech language pathologist

2. Discontinue antiplatelet drugs if possible

Operative Period

Anesthesia

- Nasal endotracheal tube if transparotid approach is used, as orotracheal tube may reduce access
- Avoid muscle relaxants so that cranial nerves (V3, VII, X, XI, XII) can be monitored.

Positioning

- Supine with neck extended
- Face and neck sterilized and appropriately draped

Perioperative Antibiotic Prophylaxis

- No antibiotics required unless the pharynx will be entered
- Should antibiotics be required, use
  - Clindamycin
  - Amoxicillin and clavulanate
  - Cephalosporin and metronidazole

Monitoring

- Routine anesthesia monitoring
- Patient should not be paralyzed to facilitate preserving V3, VII, X, XI, XII nerves.
- Facial nerve monitor may be used with transparotid approach.

Instruments and Equipment to Have Available

- Monopolar electrocautery
- Long bipolar electrocautery (to reach skull base)
- Standard head and neck set
- Oscillating saw, drill, and mandibular plating set if mandibulotomy planned
- Facial nerve monitor (optional)

Key Anatomic Landmarks (Depends Upon the Approach)

- Transcervical approach
  - Facial vein
  - Inferior border of submandibular gland

    - Posterior belly of digastric muscle
    - XIIn, where it descends anterior to internal jugular vein and crosses the carotid artery
    - Carotid arteries: Common, internal, and external
    - Xn
    - XIn
    - Superior laryngeal nerve
    - Transverse process of C1 (internal jugular vein and XIn immediately anterior)
    - Styloid process (VIIn crosses lateral to it; internal carotid passes medial to it)
- Transparotid approach (see Chapters 92 and 93)
- Transcervical-submandibular
    - Marginal mandibular nerve
    - Facial artery and vein
    - Digastric and stylohyoid muscles
    - Hyoid bone

FIG. 72.5 Skin incisions: *Green* for transcervical ±

submandibular approach; add *red* incision for transparotid approach.

- XIIn
- Medial pterygoid muscle

Prerequisite Skills

- Neck dissections
- Total parotidectomy
- Carotid artery repair/graft (selected cases)

Operative Risks

- Lower cranial nerve injuries VII, IX, X, XI, XII
- Horner's syndrome
- Injury to carotid arteries with cerebrovascular events
- Internal jugular vein injury

Surgical Technique

- Good surgical access is essential to expose and preserve important nerves and vessels, to achieve an adequate resection, and to control bleeding.
- Open the neck as indicated in Fig. 72.5.
- Fig. 72.6 illustrates the surgical approaches to the PPS.

Prestyloid Surgical Approaches

Masses in the prestyloid space are mostly benign, well defined, surrounded by adipose tissue, and unlike tumors of the poststyloid space, are generally not tethered to structures such as major nerves and vessels. These tumors can therefore generally be removed by careful blunt dissection along the tumor capsule. The tumors are situated

anywhere between the hyoid bone and the skull base, but generally do not extend above the level of the hard palate or pterygoid plates, and are situated on the medial aspect of the medial pterygoid muscle. They are readily accessed via a transcervical submandibular approach. Only rarely is a transoral approach ± mandibulotomy required. A large tumor may require a combined transcervical and transparotid approach.

Transcervical Submandibular Approach to Prestyloid Tumors

- Make a horizontal skin crease incision at the level of the hyoid bone.
- Identify the submandibular salivary gland (SSG) and digastric muscle.
- Ligate and divide the anterior facial vein.
- Incise the capsule of the SSG.

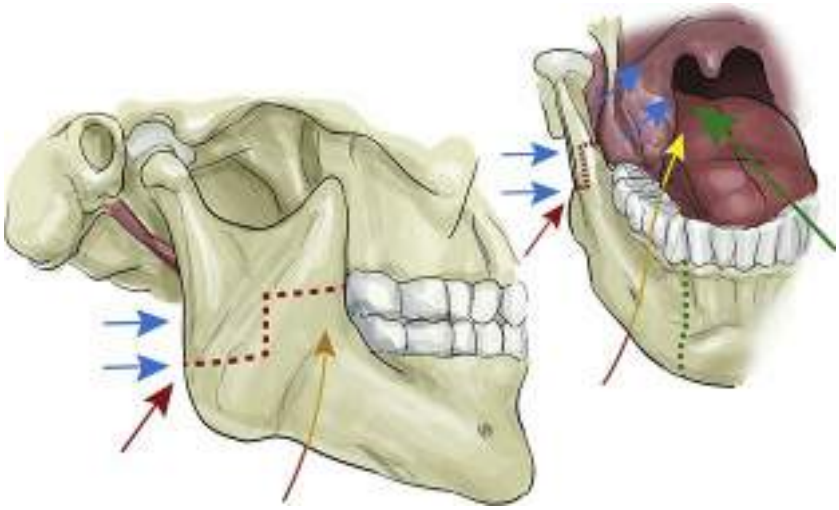

FIG. 72.6 Approaches to parapharyngeal space: transoral ± mandibulotomy *(green)*; transcervical submandibular *(yellow)*, transparotid *(blue)*, and transcervical ± mandibulotomy *(red)*.

- Mobilize the SSG in a subcapsular plane so as to protect the marginal mandibular nerve.
- Identify the facial artery posteroinferiorly to the gland where it emerges from behind the posterior belly of the digastric muscle (Fig.

72.7).

- Ligate and divide the facial artery where it emerges from behind the posterior belly of digastrics.
- Mobilize the SSG with finger dissection in a posterior-to-anterior direction, leaving the thin fascial layer over the ranine veins and the hypoglossal nerve intact (Fig. 72.8).
- Additional mobility of the SSG may be achieved (if required) by dividing the facial artery and anterior facial vein above the SSG.
- By retracting the posterior belly of digastric posteriorly, the mandible superiorly, and the SSG anteriorly, the surgeon can pass a finger/instrument directly into the prestyloid PPS and mobilize and remove the tumor.

Transoral Approach to Prestyloid Tumors

This approach is essentially the same as an extended tonsillectomy, and may include a midline or paramedian mandibulotomy for additional access. A disadvantage is that the neck is not opened and the vessels not exposed in the event of injury to the major vessels requiring proximal vascular control.

Combined Transcervical Submandibular and Transparotid Approaches to Prestyloid Tumors

Even large prestyloid tumors may be resected via a combination of transparotid and transcervical approaches. Transecting the posterior belly of the digastric muscle, the stylohyoid muscle and the sphenomandibular ligament further improve access.

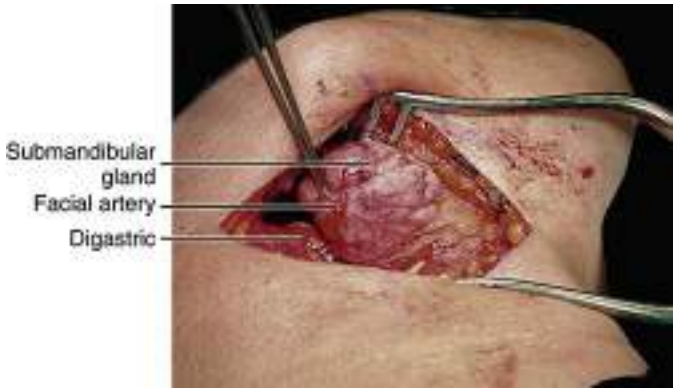

FIG. 72.7 Exposure of left submandibular gland, digastric muscle, and facial artery.

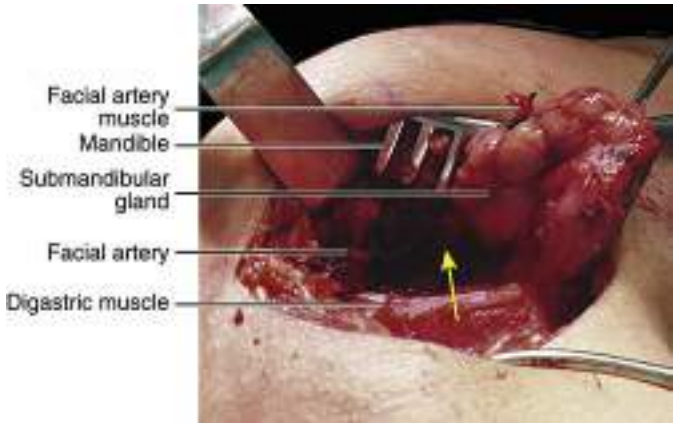

FIG. 72.8 Displacement of submandibular gland for transcervical submandibular access to prestyloid parapharyngeal space.

Poststyloid Parapharyngeal Space Surgical Approaches

The principal challenges relating to removal of a poststyloid mass are avoiding injury to the internal carotid artery, internal jugular vein, and the lower cranial and sympathetic nerves. Access is restricted by the vertical ramus of the mandible, the parotid gland, the facial nerve, and the styloid process with its muscular and ligamentous attachments. Resection requires good exposure of the mass and the major vessels and nerves via transcervical and/or transparotid approaches. Rarely a mandibulotomy of the vertical ramus is required for additional exposure.

Patients should be cautioned about the sequelae of vascular and lower cranial nerve injury, as well injury to the sympathetic trunk causing Horner's and First Bite Syndromes.

Transcervical Approach to Poststyloid Parapharyngeal Space

The transcervical approach is suitable for neural tumors, extending up to about the level of the styloid process (Fig. 72.9). The upper neck is exposed via a transverse incision in a skin crease, the X, XI, and XII nerves are identified, as are the carotid bifurcation and the internal jugular vein. The mass is then mobilized by blunt dissection and then removed. The posterior belly of the digastric muscle may either be retracted superiorly, or divided to provide additional access deep to the parotid gland.

Transparotid Approach to Poststyloid Parapharyngeal Space

A transparotid approach is required for masses situated in proximity to the skull base (Figs. 72.10 to 72.12).

- Elevate the superficial lobe of the parotid gland off the facial nerve.
- Free the nerve from the deep lobe using blunt dissection.
- Resect the deep lobe of the parotid gland.
- This exposes the styloid process.
- Immediately medial to the styloid are the contents of the poststyloid PPS.
- Access can be further improved by excising the styloid process with a bone nibbler, and retracting the mandible anteriorly (taking care to avoid excessive tension on the facial nerve) and inferiorly by dividing the posterior belly of the digastric and stylohyoid muscles.

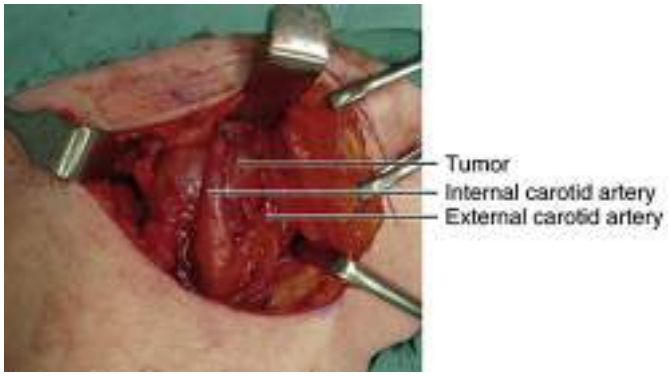

FIG. 72.9 Resection of poststyloid schwannoma via transcervical approach.

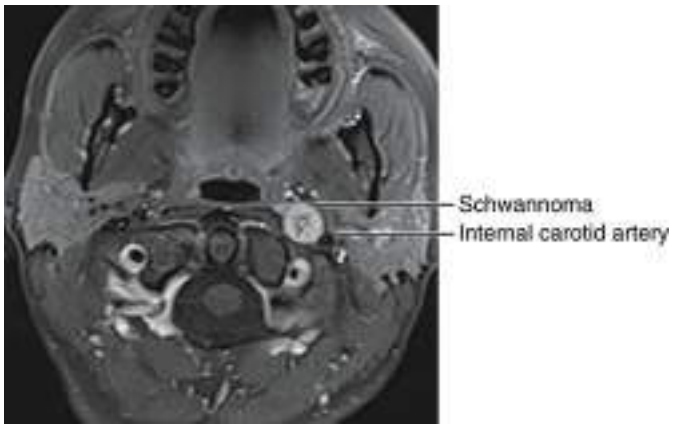

FIG. 72.10 Schwannoma of poststyloid parapharyngeal space located medial to internal carotid artery.

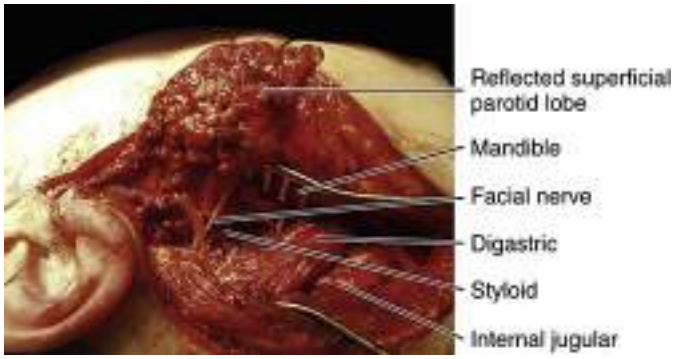

FIG. 72.11 Transparotid access to poststyloid parapharyngeal space in Fig. 72.10.

Closure

- Insert a suction drain to prevent a hematoma that could obstruct the airway.

Common Errors in Technique

- Selecting the wrong surgical approach
- Not inserting a suction drain

Postoperative Period

Postoperative Management

- Remove suction drains when less than 50 mL drainage/24 hours.
- Check that patient swallows without aspirating before introducing oral feeds.
- Speech language pathologist assists the patient if dysphagia and aspiration ensues.

Complications

- Hematoma: Return to the operating room as soon as possible and evacuate the hematoma, control the bleeding, and if necessary, perform a tracheostomy.
- Injury to one or more cranial nerves
  - Dysphagia and aspiration
  - Facial nerve paresis
- Cerebrovascular accident
- Sympathetic trunk injury
  - First bite syndrome
  - Horner's syndrome

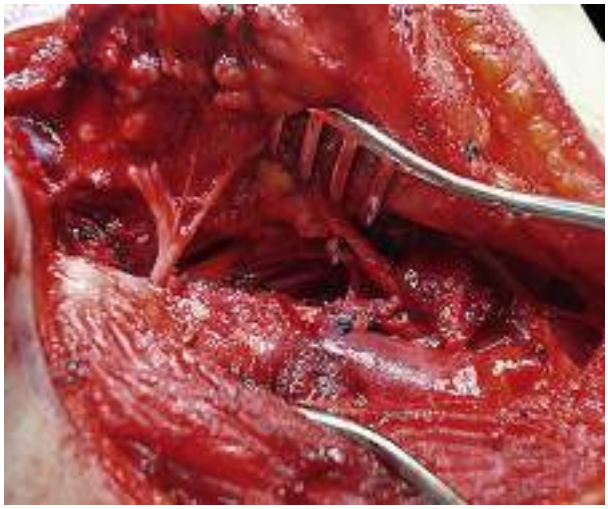

FIG. 72.12 Additional access to poststyloid parapharyngeal space by transection of digastric muscle.

TABLE 72.1

Complications Following Resection of Tumors of the Parapharyngeal Space

	Temporary (%)	Permanent (%)
Vascular injury	13	—

With permission from Carrau RL, Myers EN, Johnson JT: Management of tumors arising in the parapharyngeal space. *Laryngoscope* 1990; 100(6):583-539.

Alternative Management Plan

Always discuss nonsurgical options with patients, such as watchful waiting and radiation therapy.

Discussion

Evidence-Based Medicine Question: What

Is the Complication Rate of Surgery for Tumors in the Parapharyngeal Space?

Table 72.1 presents a summary of complications following resection of tumors of the PPS as reported by Carrau et al.[2] It does not include first bite syndrome, which can vary from mild to quite debilitating and is a result of injury to the sympathetic nerve supply to the parotid gland.[3] It manifests as cramping or spasm in the parotid area when taking the first bite of food, and diminishes with the following few bites. Linkov et al.[3] reported that it occurred in 22% of patients undergoing PPS dissection, 38% when only the deep lobe of the parotid gland was resected, and 49% when the sympathetic chain had been sacrificed; all of these variables were significant independent predictors of first bite syndrome. Although symptoms generally improve over time, few experience complete resolution of symptoms.[3]

Editorial Comment

This is a well-rounded description of approaches to the PPS; success is dependent on adequate preoperative planning, evaluation, and intraoperative surgical exposure with good proximal control of major blood vessels (internal jugular vein (IJV) and common carotid artery (CCA)) and also identification and isolation of major cranial nerves (XII, XI, X, and IX). When using the transcervical approach, exposure can be improved by dividing the stylohyoid ligament, which is felt like a cord deep to the posterior belly of the digastric muscle. This allows adequate retraction of the mandible and provides necessary exposure for removal without spillage.

Excision of Carotid Body Tumors

Eugene N. Myers, and Jason I. Kass

Introduction

Most of the tumors that originate in the poststyloid parapharyngeal space (PPS) are tumors of neural origin. Most of these are paragangliomas (PGLs), the most common of which is the carotid body tumor (CBT). It is usually possible to tell preoperatively, by imaging studies, whether these tumors are in fact CBT, glomus vagale tumors, or schwannomas. The computed tomography (CT) scan with contrast is very helpful in the differential diagnosis. The CBT is located at the bifurcation of the carotid artery, whereas the glomus vagale tumor, because of its site of origin from the vagus nerve, arises posterior to the carotid artery.

The Shamblin classification of CBT and its relationship to the carotid artery (Fig. 73.1) has proved to be very useful in the assessment of CBT.[1] The Shamblin I and Shamblin II types of tumors are amenable to surgery by dissecting the tumor off of the carotid artery using the subadventitial technique. However, the Shamblin III tumors in which the carotid artery is encased by tumor, cannot be removed safely by this technique. Not only is the artery encased in the tumor but the tumor may actually invade into the muscularis of the artery and cannot be dissected free. Further dissection then creates an opening in the wall of the carotid artery with resultant hemorrhage. Patients with Shamblin III tumors should undergo a complete resection of the artery by a vascular surgeon with reconstruction using either a vein graft or a synthetic graft (Fig. 73.2).

Although most CBTs are the result of sporadic mutations, there is a subset of PGLs that are inherited. They are referred to as the familial form (PGL1). These PGLs are multiple and usually involve the carotid

body so that there may be unilateral CBT or bilateral CBT with additional PGLs arising from unnamed arteries in the vicinity. Tumors in the familial PGL group, in addition to being multiple, are also more likely to be malignant and more likely to have an associated pheochromocytoma.

The familial form of PGL has an autosomal dominant inheritance pattern. Baysal et al. reported in *Science* the analysis of families carrying the *PGL1* gene, which revealed mutations in the succinate dehydrogenase (SDHD), a mitochondrial complex 11 gene in hereditary PGL, on chromosome 11q23.[2] In this paternal inheritance pattern, the father may pass the gene along to the son, who has a 50% chance of having a PGL, who may pass it along to successive males. However, it may also pass to the female, who may develop a tumor but cannot pass the gene to her offspring because of genetic imprinting. The families of patients who have PGL1 should undergo genetic testing. For patients who are found not to have the gene, this is reassuring, and no further testing is required. Patients who test positive should undergo magnetic resonance imaging (MRI) screening. If the MRI discloses a tumor, this should be removed. If the MRI is negative, it should be repeated annually so that if a tumor develops it may be identified at an early stage and may be removed safely.

Key Operative Learning Points

- Modern imaging techniques permit the surgeon to formulate a plan of management without a preoperative biopsy.
- Attempting to remove a Shamblin III type of CBT using a subadventitial approach will eventuate in massive bleeding due to invasion of the wall of the artery by tumor.
- Failure to evaluate for abnormal catecholamines in patients with PGL may result in intraoperative hypertensive crisis in the presence of a secreting PGL or pheochromocytoma.
- Failure to preserve the lower cranial nerves during the excision of a CBT will result in hoarseness and aspiration in the postoperative period.

Preoperative Period

History

1. History of present illness
   a. Presence of a mass in the lateral neck
   b. Labile or difficult to control hypertension
   c. Sudden flushing
   d. Palpitations
   e. Changes in voice
   f. Dysphagia
   g. Weakness of the tongue
   h. Tinnitus (may be present on the side of the tumor from the high-flow state)
2. Past medical history
   a. Prior neck surgery
   b. Comorbid medical illnesses (particularly hypertension that requires multiple medications for control)
   c. Pheochromocytoma
   d. Carotid atherosclerotic disease
   e. Transient ischemic attacks (TIAs)
3. Family history
   a. Familial PGLs
   b. Disorders of bleeding/clotting
4. Medications
   a. Antiplatelet drugs
   b. Herbal products
   c. Allergies to antibiotics

Physical Examination

1. Complete examination of the head and neck evaluating for a neck mass, which may be either unilateral or bilateral. Evaluation of cranial nerves with particular attention to involvement of the vagus or hypoglossal nerves. Assessment of any scars in the neck from prior surgery

2. Flexible fiberoptic examination

   a. Evaluation of both superior and recurrent laryngeal nerve function especially vocal fold mobility

Imaging

1. CT scan with contrast—Provides excellent resolution and the CBT will enhance intensely with contrast. The tumor will splay the internal and external carotid arteries ("Lyre sign"). The CT scan may also reveal other PGLs.

2. MR angiography

   a. T1 imaging will show an isointense or hypointense lesion when compared with muscle. Larger lesions will have a "salt and pepper" appearance representing small regions of slow blood flow (salt) and flow voids (pepper). The lesion will have intense enhancement with gadolinium contrast (Fig. 73.3).

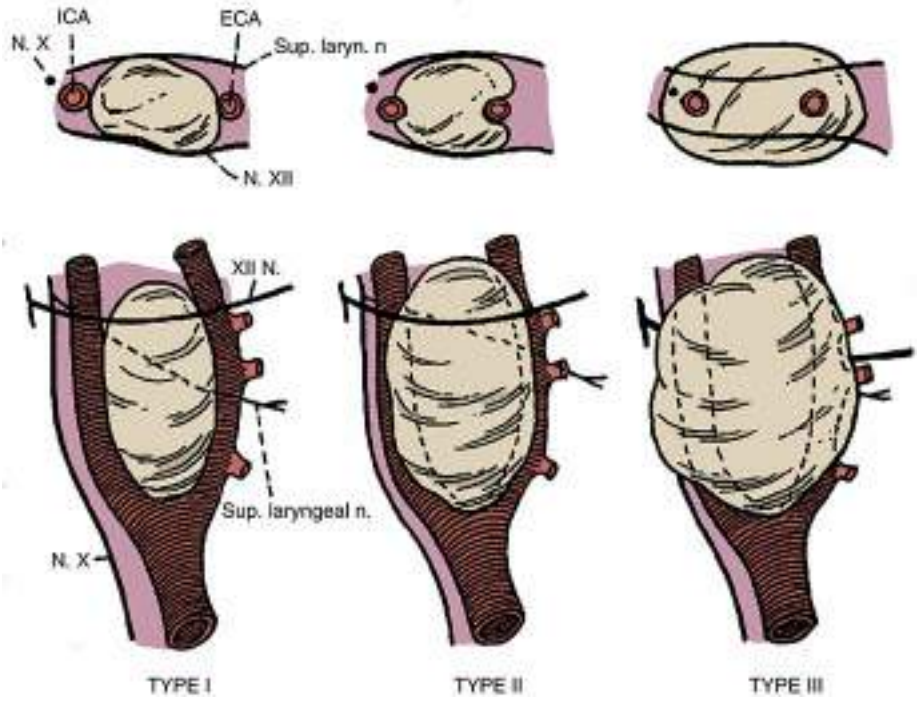

FIG. 73.1 Carotid body paragangliomas. Shamblin classification scheme: type I—small and easy to dissect, type II—medium and more intimately attached to the carotid artery, and type III—large with transmural invasion of the wall of the carotid artery requiring resection and grafting. With permission from Shamblin WR, ReMine WH, Sheps SG, et al: Carotid body tumors. Am J Surg 122:733-739, 1971.

b. T2 imaging—CBT will be hyperintense to muscle, and there will also be a speckled appearance with flow voids.

3. Transfemoral angiography—Remains the gold standard for true identification and assessment of tumor vascularity (Fig. 73.4). The senior author (ENM) has had at least one case of misdiagnosis based on history, physical examination, and a vascular blush seen on MR scanning. What was thought to be a CBT was surprisingly identified intraoperatively as an aneurysm of the internal carotid artery (Fig. 73.5).

4. Octreotide or metaiodobenzylguanidine (MIBG) scintigraphy—A sensitive but not specific test for phenochromocytoma. A variety of neuroendocrine tumors including other PGLs (glomus tumors) will enhance, as will non-neuroendocrine tumors (lymphoma, Merkel cell carcinoma). This test can be helpful when evaluating the patient for multiple lesions.

Indications

1. Small tumors that have recently been discovered should be removed, as should tumors demonstrating growth, whether accelerated or steady, with or without involvement of the lower cranial nerves. Patients who are in the Shamblin I or II classification may have this tumor removed safely.

2. Patients demonstrating neuropathy, such as vocal cord paralysis or paralysis of the tongue, should also have the tumor removed. These tumors are usually Shamblin type III and require resection and replacement of the carotid artery.

3. Secreting CBT

Contraindications

Patients who are elderly, have severe comorbidities, refuse surgery, or fail a balloon occlusion test should be considered for observation, including yearly CT scans or radiation therapy.

Preoperative Preparation

1. All patients who have the preoperative diagnosis suggestive of PGL should have examination of a 24-hour urine specimen for catecholamines (vanillylmandelic acid) before surgery. If an abnormality is identified, then an MRI of the abdomen should be performed to try to identify a pheochromocytoma. Pheochromocytomas should be removed before removing the PGL to avoid a potentially fatal intraoperative hypertensive crisis.

2. If the abnormal catecholamines are present but no pheochromocytoma is identified, it must be assumed that an unusual catecholamine-secreting PGL is present. The anesthesiologist should be consulted in advance and a program for the management of a potential hypertensive crisis planned.

3. Preoperative embolization is not required in most cases because the tumors that do not encase the carotid artery can be dissected off of the

muscularis of the carotid artery using dissection in the subadventitial plane. We believe that the preoperative embolization may induce an intense inflammatory response that may lead to obliteration of the subadventitial plane, making dissection of the tumor dangerous.

4. Discussion with a vascular surgeon is recommended in all cases. If there is an injury to the internal carotid artery during resection, vessel repair with a patch or graft should be performed. It is essential to schedule these cases on days when a vascular surgeon can be available.

Operative Period

Anesthesia

Surgery is performed under general anesthesia. In most cases the CBT does not secrete catacholamines, and no special perioperative management is required. In rare cases of catecholamine-secreting tumors, patients are typically pretreated with α- and β-receptor blockers for several weeks to prevent intraoperative hypertensive crisis, as well as circulatory collapse following tumor excision.

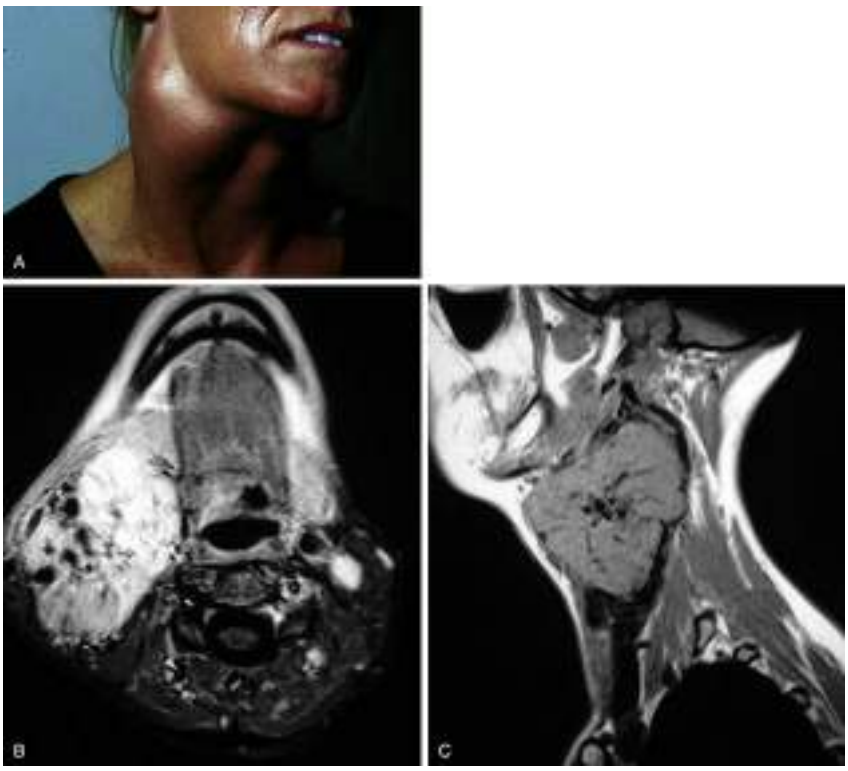

FIG. 73.2 **A,** Patient with a mass in the neck, which has increased in size over a 10-year period. **B,** Magnetic resonance imaging demonstrates a large carotid body tumor with numerous flow voids. **C,** Lateral view of mass extending to prevertebral fascia.

Positioning

The patient is placed in the supine position with a shoulder roll for neck extension.

Perioperative Antibiotic Prophylaxis

Excision of CBTs is a clean procedure and antibiotic prophylaxis is not indicated.

Monitoring

Routine anesthesia monitoring is used, generally without paralysis. An arterial line may be placed for precision monitoring of blood pressure.

Instruments and Equipment to Have Available

1. Standard head and neck instrument set

2. Vessel loops to help identify and isolate neural and vascular structure

Key Anatomic Landmarks

1. The superior border of the thyroid cartilage is the most reliable landmark for the level of the carotid bifurcation.

2. The internal carotid artery ascends in the neck lateral and posterior to the external carotid and does not have any branches prior to entering the skull base. The external branch of the carotid artery is more medial and has eight branches. The superior thyroid, ascending pharyngeal, lingual, facial, and occipital arteries are the first five branches most likely encountered during resection.

Prerequisite Skills

The surgeon should be comfortable with routine identification and isolation of the carotid artery and nearby neurovascular structures. Experience with excision of Shamblin type I tumors is recommended before excising larger and more complex tumors.

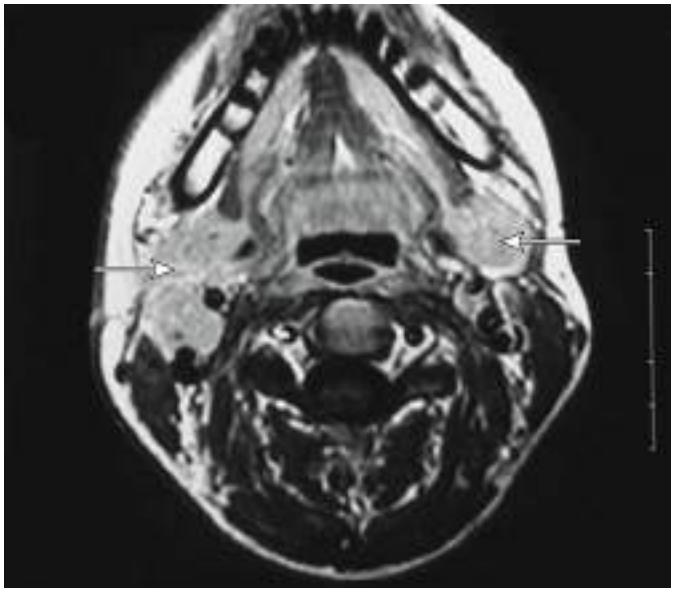

FIG. 73.3 Magnetic resonance angiogram of a 21-year-old woman with bilateral carotid body tumors *(arrows)*.

FIG. 73.4 Angiogram of the same patient demonstrates a carotid body tumor.

Operative Risks

1. Bleeding and inadvertent injury to neurovascular structures while

managing bleeding are the two key operative risks for the procedure.

2. With careful identification and protection of the hypoglossal, vagus, and superior laryngeal nerves prior to resection of the tumor, risk of neural injury is low.

3. Obtaining proximal and distal control of the carotid artery with vessel loops limits the risk of catastrophic blood loss.

FIG. 73.5 Magnetic resonance angiogram of a mass in the neck mistakenly diagnosed as a carotid body tumor. Transfemoral angiography revealed an aneurysm of the internal carotid artery.

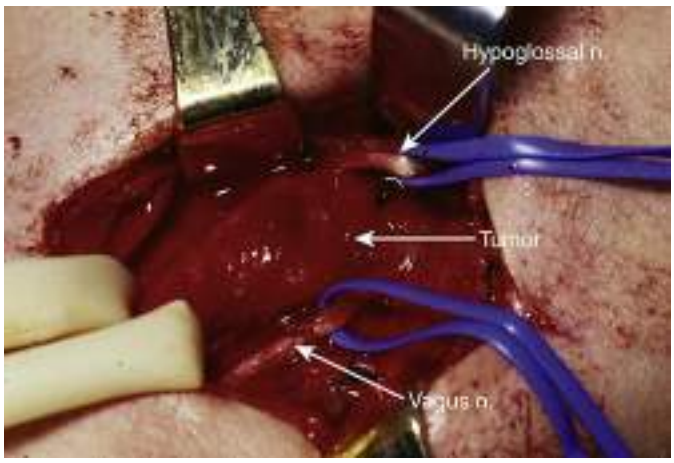

FIG. 73.6 The operative field, including tumor. The carotid artery and cranial nerves XI and XII have been identified; vessel loops are placed for safety.

Surgical Technique

CBTs are approached through a cervical incision. The incision is placed in a natural skinfold in the neck at the level of the superior border of the thyroid cartilage and carried through subcutaneous tissue and the platysma muscle. Subplatysmal skin flaps are elevated and the sternocleidomastoid muscle is identified and retracted. There is no need to dissect the submandibular triangle in this approach.

After the sternocleidomastoid muscle has been retracted, the carotid sheath will be identified. The jugular vein is then identified and dissected free of the carotid artery. The vagus and hypoglossal nerves are also skeletonized (Fig. 73.6). Arterial loops are placed around these structures for the purpose of identification and retraction. The common carotid artery is then identified and skeletonized, and a Penrose drain is placed around the artery. There is usually a large venous plexus that tracks inferiorly, approximately halfway down from the carotid bifurcation to the clavicle. At the point where the carotid artery is clear of this plexus, subadventitial dissection is begun. The dissection is carried superiorly until the bifurcation of the artery is encountered. At this time, dissection is carried superiorly along the external carotid artery approximately 1 to 2 cm above the bifurcation. The artery is then clamped, transected, and ligated with silk tie and a suture ligature (Fig. 73.7). The larger CBTs usually extend deep and may extend down to the prevertebral fascia (see

Fig. 73.2), and, if the external carotid artery is not ligated, it is very difficult to gain entry for dissection in this deep plane. Using the same plane of dissection, the tumor is then dissected off the internal carotid artery and removed. Identification and retraction of the neural structures and the jugular vein usually result in a very clean, safe, uncomplicated, and relatively bloodless removal of the tumor.

FIG. 73.7 Dissection is carried along the carotid artery in a subadventitial plane up to the bifurcation of the artery. The external carotid artery is then ligated.

Common Errors in Technique

The potential for injury to the carotid artery is minimized by preoperative evaluation to rule out the possibility of encasement of the carotid artery and invasion of the artery by the tumor. Even very precise dissection in the subadventitial plane is dangerous and should not be attempted in this setting. Failure to properly identify and preserve the vagus and hypoglossal nerves will result in functional deficits.

Postoperative Period

Postoperative Management

Patients may complain of pain in the area of the parotid gland and jaw that lasts a few seconds and is most painful with the first meal of the day.

This “first bite” syndrome may occur when the carotid sheath is violated and sympathetic deinnervation to the parotid region occurs. Many find the pain tolerable; however, botulinum toxin type A injection to the parotid can be used successfully in patients who have significant discomfort.

In special circumstance of bilateral CBT excision, patients are at risk for baroreceptor failure. With the loss of parasympathetic input, they are at risk for hypertensive crisis when the sympathetic system is triggered. These patients must be referred for blood pressure management and have been given anxiolytics to blunt a sympathetic drive.

The vast majority of CBTs are benign lesions that do not require long-term follow-up. Rarely, malignant degeneration of a CBT is identified. The benign and malignant forms have the same histologic pattern. The diagnosis of malignancy is based upon finding CBT in the cervical lymph nodes, invasion of adjacent structures, or distant metastases. These tumors should be discussed in a multidisciplinary fashion with radiation and medical oncologists, and the patients should be followed long-term for recurrent disease.

Complications

Inadvertent injury to the hypoglossal in itself is not severe; however, whenever possible a neurorrhaphy should be performed. Inadvertent transection of the vagus nerve will require evaluation and management of a paralyzed vocal fold. Although medialization is an option at the time of surgery, it is also reasonable to assess the voice quality and risk for aspiration in the immediate postoperative period. Immediate thyroplasty is discussed in detail in Chapter 6. The position of the paralyzed vocal fold may vary, and, if immobilized in the paramedian position, it may not require medialization. Patients will have substantial dysphagia and risk of aspiration if both the hypoglossal and the vagus nerve are injured.

Alternative Management Plan

Definitive radiation is an acceptable option for patients who are not good candidates for surgical resection or who demonstrate growth of CBT on CT scan or become symptomatic due to tumor-related effects, such as

cranial nerve deficits or hypertension.

Discussion

Evidence-Based Medicine Question

What is the role for preoperative embolization on CBT surgery?

The use of preoperative embolization and its effect on blood loss, operative time, and complication rate is controversial and has not been prospectively studied. In a recent review of current guidelines regarding evaluation and management of PGLs, Moore et al. do not offer criteria for when to consider preoperative embolization.[3] Litle et al. considered this question and found no benefit for tumors smaller than 5 cm.[4]

Jackson et al. recently summarized the available literature.[5] There is limited evidence to determine whether preoperative embolization has an effect on operative blood loss, operative time, or complications (including permanent cranial nerve injury). Of 2418 studies available in the literature, only 22 studies provided qualitative data and 8 provided quantitative data, which could be included in a meta-analysis. None of these studies were prospective or used patient randomization. Nonetheless, when studying blood loss, data could be extracted for 295 tumors and demonstrated significantly less estimated blood loss by more than 50%. In addition, 174 tumors were analyzed for operative time, and the authors found that the tumors excised following embolization required nearly half the time. Although there are a number of limitations to this meta-analysis, the potential effect is large. This question would best be addressed in a randomized prospective study.

Editorial Comment

Radiologists using the CT scanner introduced in the early 1980s were the ones who defined the PPS. Hugh Curtin and Peter Som were leaders in providing head and neck surgeons with invaluable information, which was a tremendous help in devising a plan of management for tumors arising in the PPS. These radiologists correlated the CT scans with surgical findings, which allowed the surgeon to predict the types of

tumors in the PPS. They divided the PPS into pre and post styloid and observed that most tumors arising in the post-styloid space were of neural origin, and most were PGLs.

This observation led to a safer way of managing the PPS tumors. The Shamblin classification of CBT, published prior to the use of CT scanners has been of great value in predicting whether a CBT could be removed safely with low morbidity.

In addition to improvements in imaging and surgical techniques, research into the molecular genetics of PGLs has been of great help in the management of patients with PGLs and their families. Bora Baysal in the Department of Human Genetics, in collaboration with members of the Department of Otolaryngology at the University of Pittsburgh, identified the relationship of the SDHD gene (an oxygen sensing gene) in the development of PGLs. Multiple PGLs in the head and neck are common in patients with SDHD mutations. Hereditary PGLs are mostly caused by mutations of the SDHD gene. These observations have allowed us to establish a website that offered screening for the presence of the SDHD gene in family members of patients who have been diagnosed with an SDHD type of PGL. This has resulted in early detection and successful removal of otherwise undetected PGLs with a low morbidity.

Eugene N. Myers

Review Questions

1. What distinguishes a Shamblin type II from a Shamblin type III carotid body tumor?

   a. Size alone

   b. Size and attachment to the carotid artery

   c. **Attachment to the carotid artery**

   d. Associated cranial neuropathy

2. In the familial form of CBT, what is the dominant type of genetic inheritance?

   a. Autosomal recessive

b. **Autosomal dominant**

c. X-linked

d. Mitochondrial

3. What is the most reliable anatomic landmark for the carotid bifurcation?

a. Hyoid bone

b. Thyroid notch

c. **Superior border of the thyroid cartilage**

d. Angle of the mandible

4. What is the laboratory test used to determine if the CBT is secreting adrenaline?

a. Blood norepinephrine and epinephrine levels

b. Urine epinephrine level

c. Urine norepinephrine/epinephrine ratio

d. **Urine vanillylmadelic acid level**

Endoscopic and Robotic Applications to Neck Surgery

Brian J. Boyce, and David M. Cognetti

Introduction

Traditional approaches for surgery of the neck involve a relatively long incision that is usually through a transverse skin crease. The length of the incision varies and depends on the procedure to be performed, but it must be of sufficient length to provide adequate exposure and removal of the desired tissue. For neck dissections, several eponymous incisions have been described such as the Crile, MacFee, and Kocher incisions. While safety and exposure are the first priorities when planning a surgical incision, providing optimal cosmesis is also an important factor for many patients.

Many recent technological advances have allowed for smaller incisions from remote locations. In the 1950s, Harold Hopkins invented the rod lens endoscope that provides superior illumination, image resolution, and magnification for minimal access surgery. The Hopkins rod lens endoscope remains the instrument of choice today for endoscopic surgeons and is frequently paired with a high-definition camera system. Robotic surgical platforms are another technology that has been used in minimal and remote access surgery. Robotic surgery allows for enhanced visualization using a three-dimensional high-definition endoscopic camera system, wristed instrumentation, and tremor reducing technology. Typically, the surgeon sits at a console that controls the robotic instrumentation, and a bedside cart contains the robotic arms and endoscope.

The initial application in head and neck surgery for minimally invasive surgery, both endoscopic and robotic, was in parathyroid and thyroid surgery.[1-4] As surgeons became more comfortable with direct incision

endoscopic techniques, the approaches expanded to include rhytidectomy and retroauricular incisions and applications expanded to include excision of the submandibular glands and neck dissections.[5] The details of thyroid and parathyroid endoscopic and robotic surgery, including transaxillary approaches, are covered in another chapter.

The first description of endoscopic excision of the submandibular gland in humans was described by Guyot, when he determined the feasibility in human cadavers.[6] While there was a 17% complication rate with damage to the facial artery and lingual nerve, both of these injuries occurred on the first cadaver dissection and were attributed to lack of training. There were no complications in many of the remaining dissections. A study was also performed on 12 patients using an incision in the midline at the hyoid bone, which did not have any complications or need to convert to an open procedure.[7] Multiple other studies have shown the efficacy of endoscopic excision of the submandibular gland without the need for gas insufflation.[8,9] Some studies have used CO_2 insufflation to maintain the working space, but complications from the insufflation including massive subcutaneous emphysema, arrhythmia, pneumothorax, hybercarbia, and death have been reported.

Robotic approach to the submandibular gland through a retroauricular incision has also been described.[10] As a natural extension of the robotic work with thyroid cancer, there has been an interest in performing central and lateral neck dissections through the same remote and minimally invasive incisions. These have been described through retroauricular incisions and transaxillary incisions. In 2012, the first study on cadavers focusing solely on lateral neck dissection was published demonstrating feasibility. The robot was then used successfully for lateral neck dissections in patients with upper aerodigestive tract malignancies with both N0 and N+ neck disease. Lastly, endoscopic and robotic approaches to benign tumors of the neck, especially second branchial cleft cysts, have been reported with good success. This chapter will focus on the rationale and technical aspects of endoscopic and robotic neck surgery.

Key Operative Learning Points

- The primary advantages of endoscopic and robotic neck surgery are a

less conspicuous and more aesthetically pleasing scar.

- The current applications for these approaches include submandibular gland excision, lateral neck dissection in early stage malignancies, and excision of the branchial cleft cysts.
- Endoscopic and robotic approaches to the neck are comparable in efficacy and safety to standard approaches but offer improved cosmesis.
- Endoscopic and robotic approaches require more operative time, but increased experience reduces the operative time.

Preoperative Period

History

- Benign tumors of the neck: onset, location, previous infections, previous treatments (incision and drainage), changes in size, and date of the last infection
- Sialadenitis: onset, duration, number of previous infections, most recent infection, pain with eating, hydration status, previous treatments
- Malignancy: onset, location, pain, otalgia, dyspnea, dysphagia, weight loss, any previous biopsies or imaging
- Past medical history
  - Medical history: previous treatment for cancer of the head and neck, carotid artery disease/TIA, bruising or bleeding easily, hypertrophic scarring or keloids, connective tissue disorders
  - Surgical history: previous surgery of the head or neck (e.g., excisional biopsy, spine surgery, carotid endarterectomy)
  - Social history: tobacco, alcohol, or use of illicit drugs
  - Family history: bleeding disorders (von Willebrand's disease, hemophilia), history of adverse reactions to anesthesia
  - Medications:

- List any anticoagulants and have a perioperative plan for managing them. This should be made in conjunction with the prescribing physician.
- Stop all herbal supplements and over-the-counter vitamins one week prior to surgery.

Physical Examination

- Head
  - Examine for any previous scars along the hairline indicating a previous cosmetic procedure, especially previous facelift.
- Oral cavity and oropharynx
  - Assess the primary site for any patient with malignancy.
  - Palpate the floor of the mouth for any submandibular calculi.
- Salivary glands
  - Palpate the parotid and submandibular glands and note any swelling, firmness, or tenderness.
  - Massage the glands and evaluate for salivary flow from Stensen's and Wharton's ducts. Note the presence or absence of saliva and consistency (purulent, turbid, normal).
- Neck
  - Note the patient's habitus/obesity and neck girth.
  - Examine neck for scars indicating previous surgery.
  - Palpate the neck for any lymphadenopathy.
  - Examine for neck mobility.
- Neurologic examination
  - Shoulder mobility and function of CN XI (ability to raise the arm above the shoulder)
  - Tongue mobility and sensation
  - Assessment of facial nerve function
- Laryngoscopy

- Evaluate the hypopharynx and larynx in patients with known cancer of the head and neck.

Imaging

- The best modality depends on the type of pathology and the surge on preferences.
- Ultrasound
  - Good initial choice to assess submandibular glands or suspected branchial cleft cysts in younger patients to avoid radiation exposure
  - Able to evaluate tissue characteristics with good resolution and real-time Doppler
  - Also good for evaluating the neck for metastases to the cervical lymph nodes and can be combined with fine-needle aspiration (FNA) biopsy
  - The biggest disadvantage is that the image acquisition is operator dependent.
- Computed tomography (CT) scan with contrast
  - Advantages include lower relative cost and excellent anatomic detail.
  - Best for evaluation of sialolithiasis and osseous detail
- Magnetic resonance imaging (MRI) with gadolinium
  - Best anatomic detail for soft tissues
  - Limited by its increased cost, susceptibility to motion artifact, and poor osseous detail

Indications

- Submandibular gland excision
  - Sialolithiasis
  - Chronic sialadenitis
  - Benign tumors of the salivary gland
- Selective neck dissection

    - Early stage primary (T1 or T2) where no microvascular reconstruction is needed
    - Early stage salivary gland malignancies (T1 or T2)
    - N0 (or N1 in select patients) neck stage
- Branchial cleft cysts or other benign masses of the neck

Contraindications

- Previous neck surgery
- Metastases to the cervical lymph nodes with evidence of extracapsular extension on imaging
- History of radiation to the neck. Some authors have performed robotic neck dissections in patients with a history of radiation to the neck, but given the longer operative times, we do not recommend it.
- Recurrent cancers of the head and neck
- Primary tumors that require microvascular reconstruction
- Significant inflammation or high degree of adhesions surrounding the submandibular gland
- Coagulopathies

Preoperative Preparation

- Review all imaging studies prior to making the incision.
- Discuss surgical options in detail with the patient including the likelihood of possible conversion to a more conventional open technique.
- Perform a system check and instrument check prior to the incision, especially when considering distant access approaches.

Operative Period

Anesthesia

- General anesthetic
- No paralytics

Positioning

- Supine
- Head turned to the contralateral side
- Neck slightly extended with shoulder roll
- For transaxillary approaches, the ipsilateral arm should be raised by 70 to 90 degrees, and no shoulder roll should be used.

Preoperative Antibiotic Prophylaxis

- None, since it is considered a clean surgery

Monitoring

- None
- Continuous nerve monitoring is not routinely used for neck dissections, submandibular gland (SMG) excisions, or excisions of branchial cleft cyst/benign neck mass.
- A hand held stimulator is helpful to confirm function of the nerves once they have been identified using standard landmarks and knowledge of anatomy.

Instruments and Equipment to Have Available

- Endoscopic
  - Four-millimeter rigid Hopkins-rod endoscope
    - Both 0- and 30-degree scopes
  - Long Debakey forceps

- Harmonic scalpel (optional)
- Endoscopic clip appliers

- Robotic
  - daVinci robotic surgical platform
  - Five-millimeter Maryland dissector
  - Eight-millimeter Prograsp forceps
  - Five-millimeter Harmonic scalpel
  - Endoscopic clip appliers
  - Lighted breast retractors
  - Chung retractor set with suspension table
  - Long vascular Debakey forceps

Key Anatomic Landmarks

- Advanced knowledge of neck anatomy is the foundation for safe and effective surgery. This is especially true for robotic and endoscopic approaches to the neck. Since these techniques approach from remote locations and unusual angles, the surgeon can easily become disoriented. It is important to know the anatomic relationships and dissection planes, so the operation can be performed effectively and safely without increased complications.
- See the neck dissection chapters (see Chapters 63, 64, 65, and 66) for detailed descriptions of the landmarks below that will provide a road map for endoscopic and robotic neck surgery.
  - Platysma
  - Sternocleidomastoid muscle (SCM)
  - Great auricular nerve
  - External jugular vein
  - Cervical rootlets
  - Carotid artery
  - Vagus nerve

- Internal jugular vein
- Marginal mandibular nerve
- Facial artery and vein
- Lingual nerve
- Hypoglossal nerve
- Spinal accessory nerve

Prerequisite Skills

- Experience with conventional neck dissections
- Experience with conventional excision of the submandibular gland
- Robotic surgery training and experience
- Familiarity with endoscopic and laparoscopic equipment can be advantageous

Operative Risks

- Neural
  - Marginal mandibular nerve weakness
  - Spinal accessory nerve damage/shoulder syndrome
  - Horner's syndrome from injury to the sympathetic chain
  - Tongue weakness or dysesthesia from injury to the hypoglossal nerve or lingual nerve
  - Numbness
- Vascular
  - Intraoperative bleeding
  - Postoperative bleeding/hematoma
  - Stroke
- Seroma
- Sialocele

- Chyle leak
- Infection
- Poor wound healing/scarring

Surgical Techniques

- Direct endoscopic excision of the submandibular gland
  - Methods using CO_2 insufflation and a gasless technique have been described. A gasless technique is preferred as it avoids potential life-threatening complications of CO_2 insufflation such as pneumothorax, subcutaneous crepitus, hypercarbia, and arrhythmias.
  - A 20- to 25-mm incision is made in a well-hidden transverse skin crease at the inferior border of the SMG. Some authors make their incision in the submental crease in the midline in an effort to better hide the scar, but this makes visualization of the lingual nerve and SMG duct deep to the mylohyoid more challenging.
  - Inject the planned incision with 1% lidocaine with 1:100,000 parts epinephrine.
  - Sharply incise through the skin and subcutaneous tissue. Divide the platysma and elevate subplatysmal flaps. Retractors are used to maintain the working space.
  - An assistant surgeon inserts either the 0-degree or 30-degree endoscope into the surgical bed to provide visualization.
  - Use either bipolar cautery or sharply incise the fascia of the SMG.
  - Bluntly dissect the fascia off the lateral surface of the gland. Staying in this plane will protect the marginal mandibular nerve as it is swept superiorly in the fascia.
  - As the superior surface of the gland is encountered, ligate the distal facial artery and vein. It is safer to ligate the entire distal facial artery instead of trying to preserve it and ligate only the branches to the SMG.
  - At the inferior border, bluntly dissect the gland away from the

digastric muscle. As dissection is carried along the posterior belly of the digastric, identify and ligate the proximal facial artery with double hemoclips.

- Dissect anteriorly to release the gland off the mylohyoid. Beware of the submental vessels that will need to be controlled.
- Retracting the gland inferiorly and the mylohyoid anteriorly, the lingual nerve, submandibular ganglion, and submandibular duct can be visualized under magnification.
- Ligate the submandibular ganglion and duct. If removing the gland for sialolithiasis, ensure that the calculus is included in the duct before ligation.
- Remove the gland.
- Irrigate the wound and ensure hemostasis.
- Sometimes the skin edges can be traumatized due to the amount of retraction needed and can be freshened to provide optimal wound healing and cosmesis.
- Place a drain (suction or Penrose) as needed.
- Close the wound in layers.

- Robotic retroauricular approach
  - This approach can be used for resection of the SMG, neck dissections, and excisions of the branchial cleft cyst. There are three steps to the surgery: elevation of the flap, bedside direct visualization, and robotic visualization.
  - Flap elevation
    - A retroauricular incision is made from the post-auricular crease and curves inferiorly into the hairline by 5 to 10 mm to hide the scar (Fig. 74.1).
    - Dissection proceeds anteriorly in a subplatysmal plane. The great auricular nerve and external jugular vein are identified and preserved. Continue dissection to the midline anteriorly, clavicle inferiorly, and inferior mandible as the upper limit. Using a lighted breast retractor can aid in visualization.
  - Bedside direct visualization

- Under direct visualization, the marginal mandibular nerve is identified at the mandibular notch and swept above the mandible for protection.

FIG. 74.1 Outline of rhytidectomy and retroauricular incision.

FIG. 74.2 Example of the exposure gained through a retroauricular incision for removal of a branchial cleft cyst that has been excised.

- Begin dissecting along the anterior border of the SCM, and identify CN XI.
- If you are excising a branchial cleft cyst, at this time dissect along the cyst wall circumferentially. If a tract is identified toward the pharynx, ligate it with 2-0 silk suture. The majority of branchial cleft cysts can be excised without robotic assistance (Fig. 74.2).
- For neck dissection, trace CN XI in a retrograde fashion until it crosses the IJV. The position of CN XI relative to the IJV is variable, but it typically crosses superficial to the IJV (detailed in Neck Dissection Chapters 63, 64, 65, and 66).
- Dissect level IIB off the trapezius muscle, and sweep it under CNXI.
- In level IIA and III, dissect through the fibroadipose tissue to identify the cervical rootlets. Dissect the fibroadipose tissue anteriorly over the deep cervical fascia and cervical rootlets.
  - The level II and III contents lateral to the IJV are then dissected off the carotid sheath.
  - If dissection of level V is required, this is also performed under direct visualization. Identify CN XI at the posterior border of the SCM approximately 1 cm above Erb's point. Trace CN XI in an anterograde fashion through level V. Dissect onto the floor of level V preserving the transverse cervical vessels and brachial plexus. Reflect the fibroadipose tissue medially around the cervical rootlets if possible until they are completely excised. If the supraclavicular nerves require sacrifice distally, make sure the proximal transection on the cervical rootlets preserves the contributions to the phrenic nerve.

- Robotic
  - At this point the robot is docked and the Maryland dissector is used in one operating arm and the Harmonic shears are used in the other.
  - For excision of the submandibular gland, begin at the posterior digastric and ligate the proximal facial artery with hemoclips. Next, retract the submandibular gland inferiorly and ligate the facial artery and vein distally at the inferior border of the

mandible. The marginal mandibular nerve should be protected at this time since it has already been identified and swept over the mandible.

- Bluntly dissect the fascia off the gland anteriorly and onto the mylohyoid.
- Retract the gland inferiorly and identify the lingual nerve, submandibular ganglion, and submandibular duct.
- Ligate the ganglion and the duct using the Harmonic shears, and remove the gland.

- If proceeding with a neck dissection, release all the fibroadipose contents containing the perifacial nodes inferiorly off the inferior aspect of the mandible to the anterior belly of the digastric.
- Sweep the anterior IB content posteriorly off the mylohyoid identifying and controlling the submental vessels with the Harmonic scalpel.
- Identify the lingual nerve, submandibular ganglion, and SMG duct. Ligate the duct and ganglion with the Harmonic shears, which will free the level IB contents.
- Using monopolar cautery, dissect level IA from between the anterior bellies of the digastric and off the mylohyoid muscle.
- For dissection of level IV, proceed by incising the fibroadipose tissue and identifying the transverse cervical vessels and cervical rootlets. Sweep the contents medially over the phrenic nerve. When dissecting medially along the carotid sheath, use the Harmonic scalpel and hemoclips to divide the tissue inferiorly to prevent a chyle leak. Dissect the contents off the carotid sheath to free it completely.

- Obtain hemostasis after irrigation.
- Place a suction drain that exits in the hairline.
- Close the incision in a layered fashion (Fig. 74.3).

- Robotic transaxillary neck dissection
  - This approach is typically used for metastatic cancer to the nodes in the lateral neck in papillary thyroid cancer, so levels IIA, III, IV, and

VB are the commonly dissected levels.

- Position the patient facing the contralateral side. The arm is abducted at least 70 to 90 degrees to provide an adequate corridor for the robot (Fig. 74.4).
- Make a 10-cm incision along the anterior axillary crease. Dissect in a suprafascial plane above the pectoralis major muscle to the sternal notch and clavicle.

FIG. 74.3 Example of an inconspicuous healed retroauricular incision at 3 months postoperative.

FIG. 74.4 Positioning for the robotic transaxillary approach for thyroidectomy or neck dissection. Incision is planned on the anterior axillary crease.

- Once over the clavicle, dissect in a subplatysmal plane to the midline and superiorly to the submandibular gland. CN XI is identified in level V and traced retrograde to the SCM. The external jugular vein is ligated as it crosses the posterior border of the SCM. Identify and preserve the great auricular nerve.
- Dissect deep to the SCM, and divide the clavicular head of the SCM.
- Insert the Chung retractor under the SCM and place it in suspension (Fig. 74.5).
- The docking of the robot is the next step in the procedure, and it should be performed conscientiously. If the necessary time and attention to detail are not allowed to ensure proper placement of the robotic arms, it will cause collisions and more time spent adjusting the robot later.

FIG. 74.5 Placement of the Chung retractor under the SCM through the transaxillary incision.

- Place the 30-degree camera facing down in the center of the axillary incision. The ProGrasp forcep should be placed just to the right of the camera but at the superior-most portion of the working space. The Maryland dissector is placed as far to the left of the camera as possible and the Harmonic shears are as far to the right of the camera as possible.
- Divide the omohyoid at the level of the thyroid cartilage.
- The ProGrasp forcep is used to grasp the IJV and pull it superomedially.
- Dissection begins in level III and IV as the plane is developed between the IJV and fibroadipose tissue laterally. Once this plane is developed, the fibroadipose tissue can be dissected off the carotid sheath in a medial to lateral fashion. In level IV on the right side, it might be necessary to switch the Maryland dissector to the right hand and the Harmonic to the left in order to reach in lower level IV under the clavicle. Take care not to damage the thoracic duct, phrenic nerve, and transverse cervical vessels.
- Continue dissection into level VB over the deep cervical fascia and brachial plexus. Divide the omohyoid near the scapula origin. CN XI should already have been exposed in the initial step of the surgery to create a working corridor.
- In order to access level IIA, the Chung retractor will have to be re-

inserted more cranially.

- The Maryland is used to pull the fibroadipose contents inferior and lateral, and it is released from the submandibular gland. Dissection proceeds over the carotid sheath medially and cervical rootlets laterally.
- The entire specimen can be removed en bloc.
- Irrigate the surgical bed and obtain hemostasis.
- Place a suction drain.
- Close the incision in a layered fashion.

- Direct incision endoscopic branchial cleft cyst excision
  - Identify a transverse skin crease over the cyst.
  - A two-centimeter incision is placed over the cyst regardless of the size of the cyst.
  - Incise the skin and platysma.
  - Elevate subplatysmal flaps.
  - Dissect along the anterior border of the SCM around the cyst.
  - A 25 G needle is inserted into the cyst to partially decompress it. A hemostat clamp is placed over the puncture site to prevent further leakage and to assist with manipulation of the cyst.
  - Dissect along the cyst wall circumferentially under endoscopic magnification.
  - If a tract to the pharynx is encountered, be sure that it is ligated before complete excision of the cyst.
  - Obtain hemostasis after irrigation.
  - A drain is not typically needed.
  - Close the skin in a layered fashion.

Common Errors in Technique

- Not converting to open approach if significant bleeding or if significant inflammation/adhesions are encountered

Postoperative Period

Postoperative Management

- Regular diet
- Pain control regimen
- Drains may be removed once output is less than 30 to 50 cc/day

Complications

- See neck dissection and submandibular gland excision chapters.
- It is important to mention that with transaxillary approaches, there is a possibility of brachial plexus neuropathy due to the arm positioning as well as due to surgical dissection in the neck.

Alternative Management Plan

- Conventional open neck surgery

Discussion

Evidence-Based Medicine Question

Are robotic lateral neck dissections as effective and safe as traditional approaches to the neck?

While there have not been any randomized controlled studies that address this question, several manuscripts have retrospectively compared the two approaches. A study by Kang et al. compared the results of 56 patients who had a robotic neck dissection with 109 patients who had a conventional neck dissection for papillary thyroid cancer. There was no significant difference in the total number of lymph nodes retrieved or in the rates of complications. Another study compared the two approaches retrospectively in patients with oral cavity cancer. This again demonstrated no difference in the complication rate or number of

lymph nodes removed. Neither group had any evidence of regional recurrence, but the follow-up time was limited to 6 months. Lastly, a North American–based group reported on their experience with robotic lateral neck dissection in patients with head and neck mucosal malignancies. This study did not find any significant differences in lymph nodes removed or compilations. In all the studies listed above, the robotic approach was associated with significantly longer operative times than the traditional approach.

Editorial Comment

Distant access surgery provides an option for surgical access for patients seeking a more cosmetic option for a visible scar on the neck. While distant access neck surgery (endoscopic and robotic) have been proven to be safe, these procedures are longer and require expertise available in few centers. In addition, certain complications are introduced to the conventional procedure that are unique to distant access surgery, such as conversions to open approaches, brachial plexus neuropathy due to arm position for transaxillary surgery and hypercarbia, and subcutaneous emphysema associated with insufflation techniques. The surgical anatomy and approach for these procedures can be challenging for even experienced head and neck surgeons. Consequently, although feasible, distant access surgery must be offered at centers where expertise in these procedures is available; moreover, case selection must performed carefully, taking into consideration patient factors (cosmesis, patients anatomy, BMI, comorbidities), surgical factors (surgeon experience and comfort level with surgical anatomy), and institutional factors (availability of equipment and trained staff).

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. What is the primary benefit of robotic and endoscopic approaches to the neck?

a. Fewer complications because of the magnified field

b. Shorter hospital stay

c. **Improved cosmesis and less conspicuous scar**

d. Improved postoperative pain scores

2. Which of the following is a contraindication to robotic and endoscopic neck surgery?

a. BMI >30

b. N1 nodal disease

c. **Lymph node with ECS**

d. Allergy to latex

3. All of the following are drawbacks to robotic neck surgery, except

a. **Increased rate of complications**

b. Longer operative times

c. Increased cost

Management of Traumatic Soft Tissue and Vascular Injuries to the Neck

Richard A. Goldman, and David M. Cognetti

Introduction

Patients with evidence of vascular or soft tissue trauma must be approached in a similar fashion as all trauma patients. Primary and secondary surveys initially screen for any imminently life-threatening injuries and guide the acute workup. Occasionally, that survey reveals a vascular injury to the neck requiring immediate surgical exploration, but in most cases, soft tissue injuries are addressed following initial evaluation and stabilization.

Fractures of the facial skeleton, injury of the orbit, pharyngoesophageal perforation, and laryngotracheal trauma must be considered and incorporated into the comprehensive approach to the trauma patient, but the details of the specific management of these injuries are addressed elsewhere in this textbook. Here we focus on the repair of mucosal and cutaneous injury, as well as the evaluation and management of vascular trauma.

Key Operative Learning Points

1. A comprehensive knowledge of head and neck anatomy is essential in order to approach the wide variety of traumatic injuries.

2. Soft tissue repair requires meticulous attention to anatomic re-approximation with wound eversion and tension-free closure.

3. Management of vascular trauma should follow a systematic approach and appropriate application of diagnostic and therapeutic interventions.

4. The management of certain vascular and soft tissue injuries may require experience and techniques beyond the scope of practice of many head and neck surgeons, and consultation with additional specialists may be required.

Preoperative Period

History

1. History of present illness

   a. Mechanism of injury: This is the single most important piece of historical information and will guide further history taking, physical examination, and workup.

      1) Determining the type of trauma allows an estimation of forces involved and potential severity of the injury.

         a) Types of blunt trauma: motor vehicle accident, fall, or assault

         b) Types of penetrating trauma: impalement, stab wound, projectile trauma, or gunshot wounds.The type of firearm and projectile should be investigated when possible to estimate the energy transmitted with the injury. A high-power rifle wound, for instance, will cause a greater degree of injury out of the immediate path of the projectile due to concussion and cavitation. Such injuries can be missed on initial evaluation and can result in delayed soft tissue necrosis.

   b. Timing of the injury: Prolonged delay will increase the risk of infection following primary closure.

   c. Additional historical considerations

      1) Memory of event/loss of consciousness

      2) High-volume or pulsatile bleeding prior to presentation

      3) Restrained or unrestrained, airbag deployment, and the use of a helmet

   d. Symptoms that may suggest additional injuries

1) Dyspnea

2) Dysphonia

3) Nasal obstruction

4) Changes in vision

5) Malocclusion

6) Epistaxis/rhinorrhea

2. Past medical history

a. Medical illness

1) Disease states that may affect wound healing or infection risk (e.g., diabetes, immunocompromised states)

b. Prior surgery and anesthesia

c. Family history: bleeding disorders

d. Medications

1) Anticoagulants

e. Allergies

1) Antibiotics

2) Local anesthetics

Physical Examination

1. Primary and secondary trauma surveys

2. "Hard signs" of penetrating trauma

3. Neurologic examination

4. Signs of skull base injury

5. Types of soft tissue trauma

a. Lacerations

1) Simple, stellate, flap

b. Abrasions

c. Avulsions

d. Burns

e. Bite wounds—human/animal

f. Gunshot and stab wounds

6. Specific anatomic evaluations

a. Facial skeleton, projection, occlusion

b. Facial nerve function

c. Globe, pupillary response, orbit, eyelid, and lacrimal apparatus

d. Lip, oral cavity, and pharynx

e. Scalp

f. Nasal deformity, septal hematoma

g. Ear

Imaging

None

For simple soft tissue trauma with no evidence of more serious injury and low suspicion based on mechanism of injury, no imaging is required.

Computed Tomography

Computed tomography (CT) imaging is the mainstay of the trauma evaluation. In addition to the standard trauma head and cervical spine CT, noncontrast maxillofacial scans should be considered in patients with evidence of significant soft tissue injury (facial edema and ecchymosis) to evaluate for underlying trauma to the facial skeleton or skull base. A CT scan of the neck with contrast may help to evaluate injury to the upper aerodigestive tract. These studies may also identify orbital hematoma and injuries to the globe.

Computed Tomography Angiography

CT angiography (CTA) should be considered when initial studies have demonstrated evidence of skull base fractures extending close to the

carotid canal. It has also become the dominant imaging modality in the evaluation of penetrating trauma of the neck.

Magnetic Resonance Imaging

While magnetic resonance imaging (MRI) may have some value in delayed evaluation of traumatic vascular and soft tissue injuries of the head and neck, its role is limited in the acute and preoperative setting.

Angiography

Four-vessel digital subtraction angiography is the generally accepted modality used in the evaluation of suspected vascular injury to the neck. Traditionally, it was a key part of the classical algorithms for management of penetrating trauma based on anatomic zones of injury. While somewhat controversial, its role in that respect has decreased in favor of more selective use. Over time, endovascular techniques have improved, and angiography as a diagnostic study can be combined with a variety of therapeutic interventions, including embolization and stenting, instead of open surgical exploration.

Duplex Ultrasonography

This modality may be used in the evaluation of the carotid arteries, but subtle signs of injury may be missed, and there is a high degree of interoperator variability.

Indications

1. Indications for immediate surgical exploration after penetrating trauma; "Hard signs"[1]

   a. Shock

   b. Pulsatile bleeding

   c. Expanding hematoma

   d. Unilateral pulse deficit

   e. Signs of stroke/cerebral ischemia

f. Bruit or thrill

g. Stridor, hoarseness

h. Extensive subcutaneous air or wound bubbling

2. Indications for additional evaluation and possible exploration; "Soft signs"

a. History of heavy or pulsatile bleeding

b. Presence of clot

c. Findings on angiography or CTA

3. Lacerations: P - capitalize to be consistentrimary closure usually indicated

4. Burns: Operative débridement may be required acutely.

5. Avulsions and abrasions: initial management usually limited to wound care

6. Penetrating trauma: Usually left open but partial closure of large wounds may be considered.

Contraindications

1. Other immediately life-threatening injury

2. Hemodynamic instability

3. Contaminated wounds open greater than 24 hours and penetrating wounds

Relative contraindication: Primary closure can be considered, but infection risk is increased. Antibiotics and drains may be appropriate.

Preoperative Preparation

1. Airway: Evaluate and secure when appropriate.

2. Control of hemorrhage: Active bleeding should be controlled in the trauma bay or emergency department.

a. For suspected injury to the carotid artery, an assistant may need to

maintain manual pressure to prevent exsanguination while proceeding emergently to the operating room. A balance must be struck between adequate pressure to control hemorrhage and the need to maintain cerebral perfusion.

b. Hemorrhage from other soft tissue trauma should be controlled with pressure and dressings. Nasal packing can be used judiciously but with caution if there is concern for skull base injury. If the airway has been controlled, oral and pharyngeal bleeding can generally be controlled with packing. Scalp wounds can result in clinically significant blood loss. Hemostasis can be achieved with pressure dressing or temporary closure with staples or suture until definitive repair is performed.

3. Trauma resuscitation

4. Laboratory evaluation

   a. Hemoglobin/hematocrit

   b. Type and screen

   c. Toxicology

Operative Period

Anesthesia

General Anesthesia

Emergent exploration of the neck requires a definitive airway and general anesthesia. Transnasal intubation might improve access to the high carotid by allowing increased subluxation and anterior displacement of the mandible. Transnasal intubation should not be performed if there is suspicion for skull base injury.

General anesthesia is also preferable for extensive soft tissue injuries, which will require extensive débridement and a lengthy repair. Long-acting paralytics should be avoided if nerve dissection and stimulation are required, as in facial nerve exploration and repair.

Sedation

Intravenous sedation may be an option if general anesthesia is contraindicated or if inadequate resources are available in a timely manner, since it can be administered outside of the operating room and without an anesthesiologist. The patient, however, must be continuously monitored, and a separate physician should be dedicated to that role. Sedation is often a good option in the pediatric population when general anesthesia is not required, but cooperation is inadequate to permit local anesthesia alone.

Local Anesthesia

The majority of minor soft tissue trauma can be repaired using local anesthesia alone. Knowledge of sensory neuroanatomy and regional blocks can be extremely useful. These techniques allow excellent anesthesia with a lower total dose of anesthetic, and they avoid further distortion of the anatomy by local infiltration. Even if some local infiltration is needed or desired for hemostasis, blocking the area first will significantly improve patient comfort. Some of the simplest and most useful blocks include the inferior alveolar, mental, infraorbital, supraorbital, and supratrochlear.

Positioning

Positioning will vary depending on the specific procedure performed. For exploration of the neck, the patient is positioned supine with some degree of extension of the head and neck. The patient's arms should be secured at the sides so that access to the chest is maintained. The chest should also be prepared and included in the surgical field in the event that vascular access requires removal of the clavicle or a median sternotomy. Turning the bed 90 or 180 degrees may be helpful.

For soft tissue repairs, the patient should be positioned and prepped to afford access to all injuries including the scalp. For facial wounds, both sides of the face should remain in the field to evaluate symmetry. In awake and sedated procedures, semirecumbent positioning will improve the patient's comfort and help him or her to maintain his or her airway.

Perioperative Antibiotic Prophylaxis

Operative primary closure of open wounds of the head and neck could be considered clean-contaminated or infected surgery, and, therefore, prophylactic antibiotic therapy would be indicated, according to clinical practice guidelines for surgery.[2] The use of antibiotics for simple wound repair, however, has been investigated with multiple clinical trials and a definite benefit has not been demonstrated.

Prophylactic antibiotics are, therefore, reserved for extensive injury or contamination and bite wounds, where a benefit has been demonstrated.[3]

First line: cefazolin + metronidazole, cefuroxime + metronidazole, or ampicillin-sulbactam

Second line: clindamycin

For bite wounds:

Prophylactic antibiotics for 3 to 5 days are indicated for repaired human or animal bite wounds to the head and face.

First-line treatment: amoxicillin-clavulanate

Second line:

- Moxifloxacin
- Doxycycline
- Cefuroxime + clindamycin or metronidazole
- Trimethoprim-sulfamethoxazole + metronidazole or clindamycin

Tetanus toxoid should also be administered if not previously received within 10 years or if unknown.

Monitoring

Routine general or sedation anesthesia monitoring.

EMG: Multichannel electromyography is essential in patients undergoing facial nerve exploration and repair.

EMG/EEG: Electromyography and electroencephalography can be used

to evaluate for cerebral ischemia during routine carotid surgery but are not typically available in emergency surgery.

Pressure transduction: Backflow pressure of the distal carotid stump after clamping can be used to assess cerebral perfusion. Pressures below 50 mmHg indicate inadequate collateral flow and necessitate shunting.[4]

Instruments and Equipment to Have Available

Available equipment should be appropriate for the intended procedure and any contingency. This may include:

1. Basic plastic and eyelid instruments, hooks, and retractors
2. Intraoral retractors (Obwegeser, Minnesota, Weider [sweetheart])
3. Monopolar and fine bipolar cautery
4. EMG/nerve stimulation and monitoring system
5. Microsurgical instrumentation for nerve repair or revascularization
6. Vascular instruments and clamps
7. Specialty vascular supplies (shunts, balloon catheters)

Prerequisite Skills

1. Soft tissue handling and basic reconstructive technique
2. Oculoplastic experience in the management of major eyelid and lacrimal apparatus injuries
3. Microsurgical skill for neurorrhaphy and revascularization of amputated tissue segments
4. Neck dissection skills and management of the great vessels of the neck
5. Vascular techniques for carotid repair and revascularization

Operative Risks

1. Orbital injury
2. Facial nerve injury
3. Salivary duct obstruction
4. Lacrimal/canalicular obstruction
5. Skin ischemia
6. Massive hemorrhage/death
7. Stroke

Surgical Techniques

Wound Preparation

Irrigation

- Open wounds should be copiously irrigated with saline. For large and heavily soiled wounds, pulsatile irrigation systems can help to efficiently cleanse the wound. Dried blood, clots, and foreign material should be removed, and the wounds should be carefully inspected to fully appreciate all injuries. When included in the field, the eye should be protected with a scleral shield or tarsorrhaphy.

Débridement

- Foreign material that is not rinsed from the wound should be removed mechanically. Most large pieces of debris can be removed with agitation with a sponge or forceps. Implanted projectiles and glass may need to be gently dissected from the wounds. Small imbedded foreign bodies that are retained will result in tattooing so attempts should be made to remove them with mechanical débridement or dermabrasion. This can be done carefully with a scalpel in a scraping rather than cutting motion.
- Devitalized tissue should be sharply excised. Severely contused wound edges can be débrided to facilitate closure between healthier tissues. Rough and irregular wound edges can also be débrided to facilitate simple linear or curvilinear re-approximation.

Re-approximation and Adjacent Tissue Rearrangement

Low tension closure: Deeper layers should be closed such that the epidermis can be aligned and closed without tension. Some degree of undermining and local flap advancement can help to reduce tension, but careful placement of the sutures is probably most important. It is critical to close the deeper fascia (platysma, superficial musculoaponeurotic system, galea) whenever possible to provide strength and take tension off of the superficial tissues. If it is not possible or that layer is intact, deep dermal sutures should be used instead. We typically use 3-0 and 4-0 braided synthetic absorbable suture (Vicryl, Ethicon, Inc., Somerville, New Jersey). In the galea, 2-0 suture may be more appropriate, and 5-0 may be better in the thinner nasal and periorbital tissue.

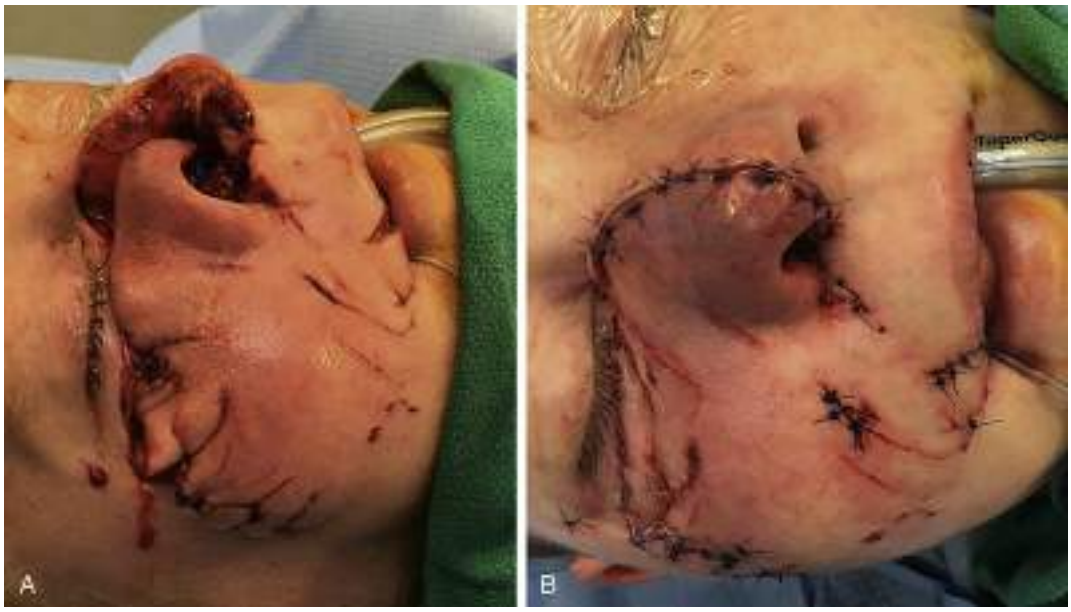

FIG. 75.1 **A,** Multiple lacerations from a dog bite. **B,** Nasal injury repaired in layers and mattress sutures used to provide adequate eversion.

Eversion: In the deep layers, precise suture placement set back from the leading wound edge will result in eversion when the tie is made. It also thereby removes all tension from more superficial layers. If eversion

from the deeper closure is inadequate, vertical or horizontal mattress sutures should be employed (Fig. 75.1). These techniques provide reliable eversion and remove tension from the healing edge.

Skin closure: A variety of techniques and materials are available, and the specific choice of material will depend on a variety of factors including preference. Fine nylon or fast-absorbing gut suture is frequently used on the face. While some might advocate for a permanent nylon suture, removal within 5 days is required, or the result is certainly worse than with a rapidly dissolving gut suture. Alternatives include tissue adhesives such as Dermabond (Ethicon, Inc., Somerville, New Jersey) or taping. Staples are a good option for the scalp and are easier to remove.

Alignment and soft tissue handling: Meticulous technique will improve the ultimate aesthetic outcome. Accurate placement of the sutures is critical to realign skin edges. The tissue depth of the course of the needle and suture should be symmetric on each side of the wound edge. Further tissue trauma can be minimized with the use of skin hooks and fine-toothed forceps. The skin should be manipulated by grasping the deeper tissues instead of the epidermis wherever possible. Closure may proceed in a running or interrupted fashion. A corner stitch or Gillies stitch may be helpful with acute angles and trifurcations. A combination of the above techniques is routinely used for complex lacerations (Fig. 75.2).

Lip and Intraoral Wounds

A large percentage of intraoral wounds will not require closure and can be left open to heal by second invention. Larger and deeper injuries, however, should be addressed. These include lacerations through the full thickness of the lip or vestibule from skin to mucosa, as well as tongue and oropharyngeal lacerations, which extend through the underlying musculature.

Tongue and soft palate musculature should be re-approximated. Mucosal or musculo-mucosal sutures can then be used to loosely re-approximate the superficial wound, but wide spacing should be maintained and watertight closure should be avoided.

Full-thickness lip and vestibule injuries should be repaired following the same principles as above. The deeper muscle (orbicularis, buccinator) is closed, followed by plastic repair of the skin. The key maneuver is the deep suture, which reestablishes continuity of the orbicularis muscle. The skin and vermillion border should be roughly realigned with some eversion or redundancy. It is worthwhile to cut and revise this suture if the initial attempt is imperfect. Excessive local anesthetic infiltration should be avoided, as it will distort tissue and hamper precise realignment. The white roll and vermillion border must be precisely realigned when closing the skin and vermillion. The mucosal closure should be relatively loose.

Nose and Auricle

The principles of layered closure and precise realignment apply. In this case the cartilaginous framework provides the deep strength layer.

In the nose, a mucosal closure should be achieved whenever possible. If any pedicle is maintained, an avulsed auricular or nasal segment generally should be reattached. The nonviable portions can be débrided in a delayed fashion if required at all. In the event of complete amputation, delayed reconstruction or use of a prosthetic is often the best option. Microvascular replantation has been described for facial segments. Ear cartilage can also be de-epithelialized and used as a free graft. Primary reconstruction with that cartilage, a temporoparietal fascia flap, and skin grafting could be considered. In delayed reconstruction the cartilage is buried under the dermis for preservation. Cosmetic results from cartilage grafting, however, are frequently inferior to prosthetics or reconstruction using a porous polyethylene implant.

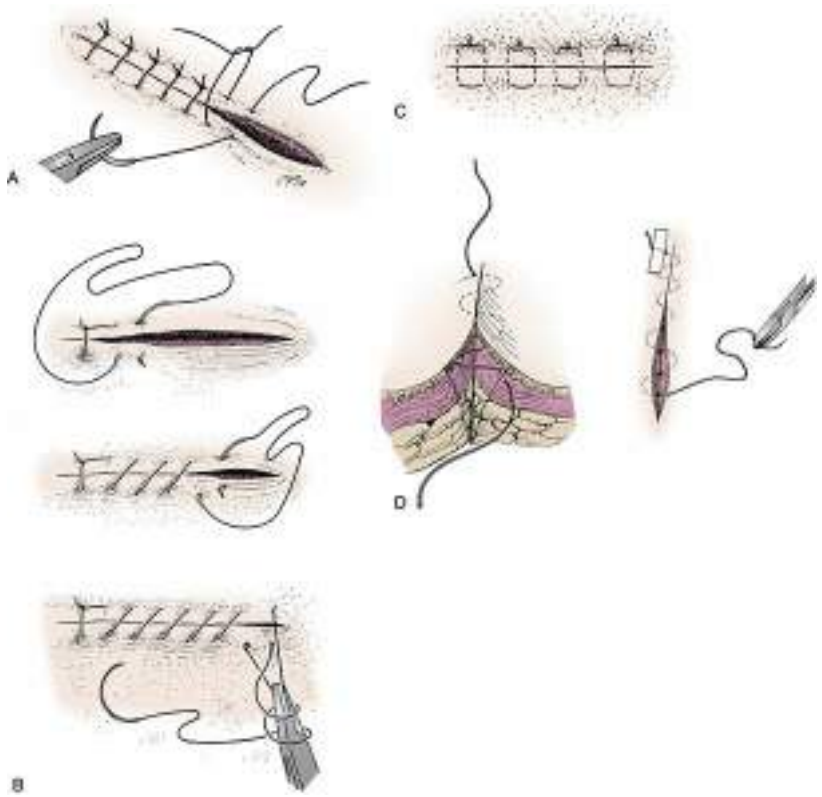

FIG. 75.2 **A,** Simple interrupted sutures should be placed evenly and far enough away from the laceration edge that eversion of the skin edge is achieved. **B,** A simple continuous suture may be used for lacerations that are easily approximated. **C,** Horizontal mattress sutures are rarely used on skin but may be used for wounds that require extra strength, such as avulsions or gunshot wounds, and are expected to require revision. The surgeon must remember to avoid tying the sutures too tight or the blood supply to the margins of the laceration will be constricted. **D,** Running subcuticular sutures may be used in wounds that are well approximated and cleanly lacerated. A very aesthetic closure can be achieved if the wound edges are everted appropriately. Redrawn from Laskin DM (ed). Oral and Maxillofacial Surgery, vol 1. St Louis: CV Mosby; 1980, pp 277-280.

Due to the multiple sensory nerve contributions, peripheral blockade can be challenging, and additional local infiltration is often required.

Auricular hematoma: These are typically the result of blunt trauma and

should be drained acutely to prevent cauliflower ear deformity. Incision and drainage is superior to aspiration to ensure that the consolidated clot is evacuated. A bolster and or bolstering sutures should be used to prevent re-accumulation. We prefer to mold petroleum gauze into the scaphoid fossa and secure it with a mattress suture through the full thickness of the auricle.

Scalp

Large scalp wounds that result in a large scalp flap can be quite impressive on examination and can result in significant bleeding, but repair is generally straightforward. A large sub-galeal space may be opened and should be carefully cleansed (Fig. 75.3A).

FIG. 75.3 **A,** Complex injuries of the face, scalp, and periorbital from motor vehicle crash. **B,** Scalp flap replaced and closed over a suction drain.

Advancement to cover any avulsed area can be challenging. The scalp is very inelastic, and any rearrangement requires wide undermining. Parallel incisions in the galea made perpendicular to the line of advancement can improve the stretch of a scalp flap. Care must be taken to avoid any vessels in the skin flap just superficial to the fascia.

Undermining should not extend beyond the temporal line anteriorly in

order to avoid the frontal branch of the facial nerve.

Suction drains may be considered for large potential spaces and contaminated wounds. Infection and hematoma risk is low, but the morbidity of a drain is also quite low (see Fig. 75.3B).

Periorbital Injuries

While most eyelid lacerations may be approached with confidence by the facial surgeon, a comprehensive discussion of oculoplastic techniques is beyond the scope of this chapter. Here we provide a basic overview of the approach to periorbital trauma.

Similar to other facial units, periorbital tissues must be repaired with meticulous attention to the approximation of the native anatomy in layers. In the eyelid this includes the tarsal plate, orbicularis muscle, lid margin, and eyelash line. The deeper layers may be closed with 6-0 Vicryl and the skin with 6-0 nylon or fast-absorbing gut. The conjunctiva can frequently be left open or closed partially with a few 6-0 fast-absorbing gut sutures with a buried knot. The canthi must be resuspended, if disrupted. Suture tails at the margins should be left long and then held down by adjacent knots to avoid corneal abrasion (see Fig. 75.3B).

Special attention must be given to inspection of the lacrimal apparatus. If a laceration extends near or through the puncta, then the canaliculi should be examined with probing and potentially stented for a prolonged period.

In the event of significant loss of tissue, the lid can be reconstructed with primary closure or with small advancement flaps for defects up to 50% of the upper or lower lid (e.g., Tenzel flap). Larger defects will require more extensive reconstruction.

For the above more complex injuries, oculoplastic expertise should be sought when possible.

Salivary Duct Injury

Significant injury to Stensen duct and Wharton's duct fortunately is uncommon. Failure to identify and manage such an injury may result

in obstruction, sialocele, sialadenitis, or salivary fistula.

Exploration using lacrimal probes or sialendoscopy along with massage of the gland may help to identify a ductal injury.

Ducts may be repaired with diversion and sialodochoplasty or reanastomosis over a stent. A large angiocatheter may be used in this capacity and sutured in place for a matter of weeks. Alternatively, the proximal duct may be ligated. In this case, botulinum toxin injection of the gland may help to decrease obstructive symptoms.

Facial Nerve Injury

Injury to the facial nerve should be suspected based on the type and location of trauma and confirmed by physical examination. Detection of a nerve injury may be difficult in patients with decreased mental status who cannot attempt voluntary movements on examination. While older patients may demonstrate a loss of facial tone immediately following a nerve injury, younger patients may demonstrate near normal tone in the acute setting despite a totally severed nerve.

Wounds should be explored within three days of injury while the severed distal nerve branches can still be stimulated. Even if the repair is not done at that point, the distal segments can be confirmed with stimulation and then marked with clips or suture for future reconstruction.

Depending on the location of the injury, wounds can be explored locally (Fig. 75.4A and B) or with a parotidectomy approach. Injuries medial to the lateral canthus typically do not warrant exploration and repair. Due to distal branching and decussating fibers, innervation tends to be redundant, especially in the midface. The small size of the distal branches also makes neurorrhaphy challenging.

Nerve repair can be done primarily (see Fig. 75.4C) or with interposition nerve grafts, most commonly using the great auricular or sural nerve. An additional option is the use of conduit grafts in which the nerve segments are held in opposition by suturing to and within a conduit, such as a small sleeve from a vein graft or a commercially available conduit graft. The use of loupe or microscope magnification is beneficial.

Parotidectomy, soft tissue dissection, and use of grafts will facilitate a tension-free repair, which is the key to success.

Neck Exploration for Penetrating Trauma

Incision: endarterectomy-type incision along the anterior sternocleidomastoid or a transverse incision as in neck dissection

- The transverse incision requires additional elevation of subplatysmal flaps but offers excellent exposure to structures in the neck beyond the carotid sheath.

Carotid sheath exposure: Dissection continues deep to the sternocleidomastoid muscle.

- The internal jugular vein is identified first. The omohyoid may be divided or retracted to improve exposure. The internal jugular vein should be mobilized with blunt dissection, and circumferential control should be obtained above and below any site of injury.

FIG. 75.4 **A,** Deep preauricular laceration with upper paralysis of the face. **B,** Wound explored demonstrating transection of the main trunk of the facial nerve. **C,** End-to-end repair of the nerve conducted under binocular microscopy. Cut ends are held in tension-free opposition with 9-0 nylon suture through the epineurium. Fibrin glue can also be used in addition to or instead of suture.

- The internal jugular vein is a low-pressure but high-volume vessel, and massive hemorrhage can occur with injury, including iatrogenic injury during exploration. The clot should be left in place until distal and proximal control is achieved. Active hemorrhage can be arrested with relatively light pressure while control is established. Vessel loops or a variety of vascular clamps can be used.
- A laceration of the veins can be repaired primarily, or larger defects can be patched with vein graft. The vessel may also be ligated with relatively low morbidity.
- The carotid artery may be approached anteriorly or posteriorly to the jugular vein. The anterior approach requires division of the common facial vein and any other anterior branches but affords better exposure to the external carotid system and the hypoglossal nerve.

The course of the common and internal carotid arteries is then dissected.

- Vagus and hypoglossal nerves are identified and preserved
- The posterior belly of the digastric muscle can be divided to improve superior exposure.
- The mandible should be subluxed and retracted anteriorly.
- The descending ansa cerivcalis can be divided and even used to help retract the hypoglossal nerve superiorly.
- The external carotid artery will course medially and anteriorly to the internal. It can be ligated and divided when necessary, but multiple branches should be seen prior to ligation to ensure appropriate identification. The external system can also be used to bypass a damaged internal carotid segment, so it should only be divided if necessary.

Management of carotid artery trauma[4]

- Ligation for impending exsanguination or if neurologic injury has already occurred
- Ligation or occlusion of inaccessible injury, use of balloon catheter to occlude the distal segment at the skull base
- Revascularization preferable
- Distal and proximal control with vessel loops: distal clamp first to avoid embolus
- Cerebral perfusion assessment and shunting when possible
- Suture or patch repair
- Resection with end-to-end anastomosis
- Interposition graft with reversed saphenous or superficial femoral vein
- External carotid transposition

The techniques required to revascularize a damaged carotid artery are beyond the scope of practice for most head and neck surgeons. Emergent consultation and assistance from a vascular surgeon or neurosurgeon are always indicated.

Common Errors in Technique

1. Inadequate débridement and undermining
2. Lack of wound edge eversion
3. High tension closure or anastomosis
4. Tight closure of intraoral wounds or penetrating trauma
5. Inadequate exposure and vessel control

Postoperative Period

Postoperative Management

1. Neurologic monitoring and intensive care management for suspected vascular injuries

2. Continued trauma resuscitation

3. Wound cleansing with dilute peroxide or soap and water at 48 hours

4. Petroleum-based ointment (avoid neomycin-containing preparations)

5. Sun protection

6. Remove sutures from facial wounds within 5 days.

7. Massage scar after initial healing.

Complications

1. Infection

Exploration and drainage

2. Seroma, hematoma

Aspiration versus drainage, pressure dressing

3. Corneal abrasion

Ophthalmologic consultation, ophthalmic ointment

4. Skin flap ischemia and necrosis

Delayed débridement when necessary

5. Sialocele, salivary fistula, or duct obstruction

Aspiration, pressure dressing, anticholinergics, Botox

6. Unfavorable scar: hypertrophic or prominent

Steroid injection, dermabrasion, other resurfacing techniques, and scar revision

7. Cranial nerve injuries (VII, IX, X, XI, XII)

8. Hemorrhage

9. Stroke

10. Death

Alternative Management Plan

1. Wound care with delayed closure and/or reconstruction

2. Angiography with endovascular management of carotid and vertebral injuries

Discussion

Evidence-Based Medicine Question

What is the benefit of immediate surgical exploration of penetrating zone 2 injuries in stable patients?

Traditionally, the approach to penetrating trauma to the neck was based on anatomic zones of injury (Table 75.1). The proposed algorithms developed in the 1970s recommended immediate surgical exploration for the more accessible zone 2 injuries. The less accessible zone 1 and 3 injuries were assessed with angiography and endoscopy. The most apparent shortcoming of this system is the unreliability of external wounds to predict internal injuries. An additional problem was the very high rate of negative findings on immediate exploration, resulting in significant morbidity.

In a 2013 review, Shiroff and colleagues proposed a "no zone" approach based on available evidence, whereby patients with hard signs are managed with immediate surgery, and stable patients without concerning findings on physical examination are evaluated with CTA initially.[1] Findings on imaging then direct subsequent management with surgery, diagnostic or therapeutic angiography, and observation (Fig. 75.5). Physical examination alone has been shown to be sensitive for identifying vascular injuries, which require repair. Observation following initial examination requires intensive monitoring and serial examinations. It - break up sentence for clarification may miss tracheal and pharyngoesophageal injuries.

TABLE 75.1

Zones of the Neck

Zone 1	Clavicle/sternal notch to cricoid cartilage
Zone 2	Cricoid cartilage to angle of mandible
Zone 3	Angle of mandible to skull base

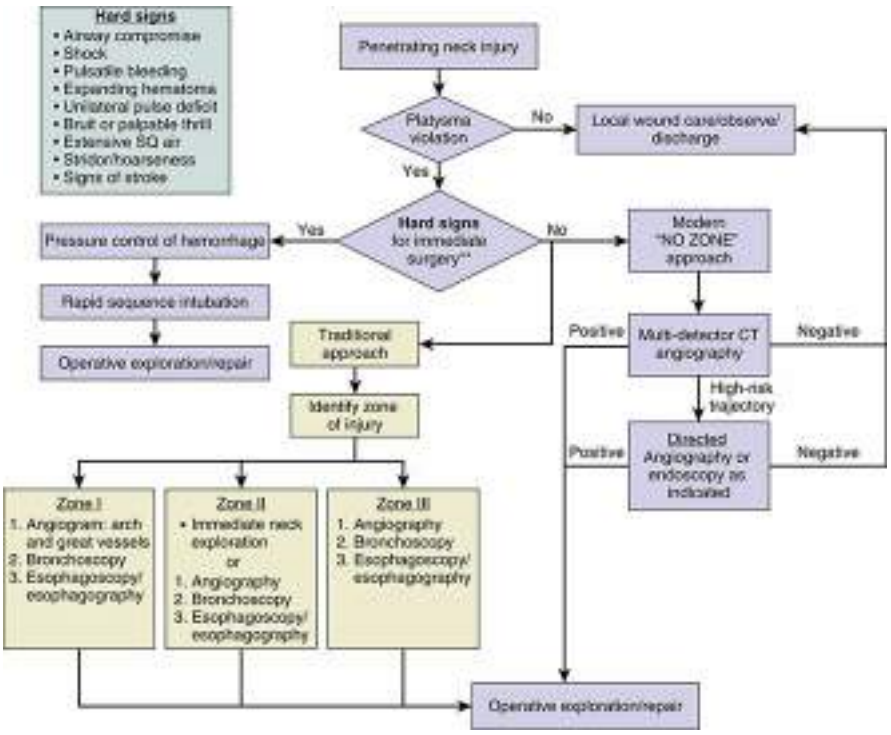

FIG. 75.5 Algorithm for the modern management of penetrating neck.

From Shiroff AM, Gale SC, Martin, ND, et al. Penetrating neck trauma: a review of management strategies and discussion of the 'No Zone' approach. Am Surg 79(1):23-29. 2013.

CTA provides additional triage capability and has been found to be highly sensitive for the detection of vascular injury. Given advances in imaging technology in the modern era and the available evidence, a transition to the above approach from the older and more invasive zone-based approaches should be considered in the evaluation and management of penetrating neck trauma.

Editorial Comment

Traumatic injuries to the soft tissues and vascular structures in the neck need a protocol-based intervention to maintain effective and efficient interventions in what tend to be high-stress situations. Involvement of additional expertise such as vascular surgery, intensive care team, or reconstructive surgery at appropriate times is key to successful outcomes in terms of function, cosmesis, and long-term sequelae.

Review Questions

1. Which of the following is NOT recommended as monotherapy for prophylaxis after bite wound?

   a. Moxifloxacin

   b. Amoxicillin-clavulanate

   c. Doxycycline

   d. **Clindamycin**

2. Benefits of computed tomography angiography (CTA) in the assessment of penetrating trauma compared to angiography include all of the following, except

   a. Rapid availability and widespread accessibility

   b. Lower rates of negative exploration following positive findings

   c. **Less effect of movement or metallic foreign body artifacts**

   d. Lower morbidity/less invasive

3. Suspected facial nerve transection should be explored within

   a. 24 hours

   b. **3 days**

   c. 7 days

   d. 2 weeks

Deep Neck Abscesses

Lisa Galati

Introduction

The potential for a seemingly benign entity like an infected tooth, tonsil, or skin lesion to cause life-threatening illness is due to the complex relationship between the spaces of the neck. Deep neck infection (DNI) may result from any of the above and can extend into the mediastinum and beyond when these spaces are involved. Aggressive bacterial species, inadequate host defenses, and access to medical care all contribute to the development of deep neck infections and make management difficult. Understanding the relationship of the potential spaces of the neck to each other, as well as the most common pathogens, is key to successful treatment of this problem.

Key Operative Learning Points

- Knowledge of the anatomy and relationships between the deep neck spaces is necessary to adequately drain the neck during incision and drainage (I&D).
- Failure to drain pockets of infection will prolong recovery or lead to complications.
- Deep neck abscesses are often fulminating and can lead to rapid changes in status by causing airway obstruction, vascular compromise, or sepsis and need to be treated in an urgent manner.
- Tracheostomy is often required for safe airway management.

Preoperative Period

Patients with DNI typically have localized pain and swelling, fever, and an elevated white blood cell counts. All patients undergo a computed tomography (CT) scan to assess the extent of disease, unless airway compromise dictates otherwise. If an aspirate is available for Gram stain analysis, this is helpful in identifying pathogens before empiric antibiotics are administered. Otherwise, intravenous antibiotics should be administered and chosen on the presumed site of origin. Oropharyngeal abscess requires coverage of beta-lactamase producing streptococcal and staphylococcal organisms; oral infections require coverage of anaerobic bacteria. Use of antibiotics with coverage of anaerobes and beta-lactamase–producing microbes provides good broad-spectrum coverage for most cases.

History

1. History of present illness
   a. Duration of symptoms
   b. Odynophagia or dysphagia
   c. Dental history—periodontal disease, fractured teeth, periapical abscess, carious teeth
   d. Preceding upper respiratory tract infection or trauma
2. Past medical history
   a. Diabetes mellitus
   b. Other forms of immunocompromised states—HIV, iatrogenic (chemotherapy)
3. Medications
   a. Antibiotics
   b. Anticoagulants

Physical Examination

1. Airway
   a. Flexible fiberoptic laryngoscopy to assess for pa-tency

b. Presence of swelling of the posterior pharyngeal wall

2. Neck

a. Extent and location of edema

b. Presence of fluctuance, tenderness, erythema

3. Oral cavity

a. Gingival swelling and erythema, purulent discharge near carious teeth

b. Edema of the floor of the mouth with retrodisplacement of the tongue

4. Oropharynx

a. Bulging of the soft palate/tonsil

b. Trismus

Imaging

CT

1. Preferred for rapid procurement of images (over MRI)

2. Contraindicated if the airway is unstable

3. Recommend use of contrast

4. Standard 3-mm cuts

Indications

- Abscess with airway compromise
- Sepsis
- Smaller abscess with lack of response to IV antibiotics
- Lack of resolution that will require revision surgery

Contraindications

- Hemodynamic instability

Preoperative preparation

1. Evaluate imaging to determine the extent of the abscess

2. Culture–If the patient is stable, obtain an aspirate at the bedside to initiate Gram stain and culture studies.

3. Antibiotics–Empiric administration of intravenous antibiotics that provide aerobic and anaerobic coverage

4. Manage any airway compromise

Operative Period

Anesthesia

- Management of impending airway collapse in the patient with a deep neck abscess takes precedence over all other considerations.
- Tracheotomy is achieved with the patient awake with the anesthesiologist prepared to administer general anesthesia once the airway is secured.
- Sedation is contraindicated as it may lead to further collapse of the airway.

Positioning

- The patient is placed in the supine position with a shoulder roll used to gently extend the neck.

Perioperative Antibiotic Prophylaxis

- Antibiotics that provide coverage of aerobes and anaerobes are administered intravenously perioperatively.

Monitoring

- Paralytic agents should not be used in order to avoid injury to the cranial nerves.

Instruments and Equipment to Have Available

- Head and neck instrument set

Key Anatomic Landmarks

Management of deep neck space infections mandates a thorough understanding of the anatomy of deep neck spaces, etiology of the abscess, and knowledge of the pathogens involved.

Anatomy

Anatomic structures and fascial layers delineate the spaces of the neck. Fascial layers envelope muscles, bone, and viscera in the neck and are coalescent in some areas, dehiscent in others. Where multiple layers come together, it is very unlikely that infection will spread beyond as in the inferior limit of the retropharyngeal space. In regions where the fascia is thin, deep neck abscesses are able to spread to neighboring spaces if left untreated.

There are two layers of cervical fascia: superficial and deep. The superficial layer lies superficial to the platysma and extends from the upper chest to the zygoma. DNI only involves the spaces formed by the three layers of deep cervical fascia—superficial, middle, and deep—which create a potential "highway" from the neck, allowing infection to spread as far as the sacral spine.

The superficial layer of deep cervical fascia encircles the neck like a drum. It lies on the submandibular gland (and the marginal mandibular division of the facial nerve runs within it) and sternocleidomastoid (SCM), omohyoid, and trapezius muscles. The superior or "investing" fascia attaches inferiorly to the sternum, clavicle, and first rib, superiorly to the mandible, mastoid, and occipital bone. The lateral portion of the carotid sheath and the stylomandibular ligament are formed by this

layer. The submandibular and sublingual spaces lie deep to this fascial layer, which is bordered by the digastric muscle inferiorly, mandible laterally, hyoglossus muscle medially, and sublingual gland superiorly. The masticator space is bounded medially and laterally by the superficial layer as it splits above the jaw and extends up to the skull base and zygomatic arch.

Infections of the sublingual space are most often odontogenic, with the first molar being the usual source. The patient presents with edema of the floor of the mouth, dysarthria, pain, and fever. Transoral drainage is helpful, but dental consultation is paramount in avoiding recurrent infection. If the swelling is due to a periapical abscess, the latter must be drained. Infection of the second molar leads to swelling of the submandibular space, as this tooth lies posterior to the insertion of the mylohyoid muscle (Fig. 76.1). An abscess of the submandibular space should be drained via a transcutaneous route. Ludwig's angina is an infection of both spaces that often manifests as significant retrodisplacement of the tongue, edema of the floor of the mouth, and impending airway collapse (Fig. 76.2). Management often requires awake tracheostomy because intubation is not feasible due to the edema and the position of the tongue. Incision and drainage is done through an incision in the neck and often yields a thin, watery discharge. Wounds are drained and left open; both surgical drains and the tracheostomy are removed once the edema has subsided and the infection has resolved.

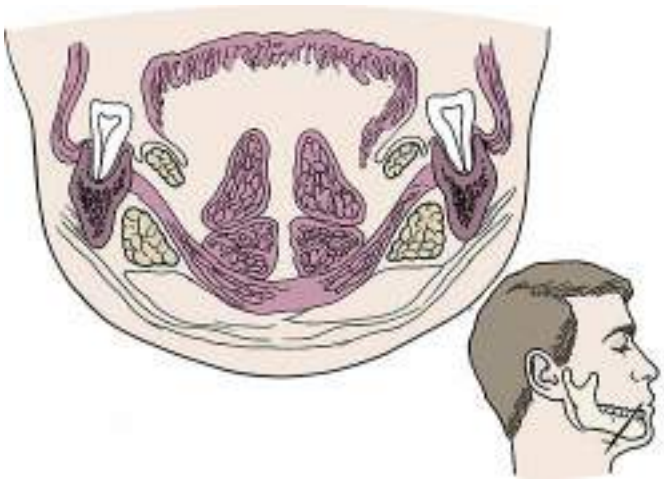

FIG. 76.1 The mylohyoid sling divides the submental space into two relatively independent sites. The plane of

this schematic is depicted in the *inset*.

The middle layer of the deep cervical fascia, also known as the visceral layer, contributes to the carotid sheath (which is formed by all three layers). The middle layer envelops the thyroid, esophagus, constrictor muscles, and trachea. The superior portion of the middle layer, the buccopharyngeal fascia, envelops the constrictors and buccinator muscle. As it courses behind the pharynx, it forms the anterior boundary of the retropharyngeal space. A midline raphe attaches to the alar layer component of the deep layer of the deep cervical fascia, which is responsible for the hallmark finding of a unilateral retropharyngeal abscess, which differentiates it from an abscess in either the danger or prevertebral space (Fig. 76.3). However, the converse is not true—a midline abscess does not necessarily exclude a retropharyngeal location. The midline raphe is often breached, resulting in a midline, retropharyngeal abscess. The retropharyngeal space extends to the thoracic spine (T1 to T6), and infection may descend into the mediastinum, a potentially fatal complication.

Retropharyngeal abscesses usually result from sinonasal or nasopharyngeal infection (adenoiditis). Odynophagia, meningismus, and a muffled quality of the voice are common findings. Although a radiograph of the lateral neck is an easy way to assess the retropharynx, all patients require CT imaging prior to definitive treatment. On lateral radiographs of the neck, the retropharyngeal soft tissues near C2 should be about 4 mm in thickness—over 7 mm is considered pathologic. At the level of C6, the retropharyngeal depth is thicker—up to 14 mm for children and 22 mm in adults are considered normal.

The deep layer of the deep cervical fascia consists of alar and prevertebral layers, which define the danger and prevertebral spaces. The posterior boundary of the retropharyngeal space is formed by the alar layer. Posterior to the alar layer lies the "danger zone" of the neck, as infections here can spread as for inferior as the abdomen, where the fascia terminates. The prevertebral space lies deep to the fascia of the same name and extends from skull base to sacrum. Infections in this area are most often caused by infections of the spine (either iatrogenic or, less commonly, tuberculous), but fulminant infections from neighboring spaces can also affect the prevertebral space.

FIG. 76.2 The classic appearance of a patient with Ludwig's angina.

Note **A,** upward displacement of the tongue and the erythema, and **B,** edema of the submental skin.

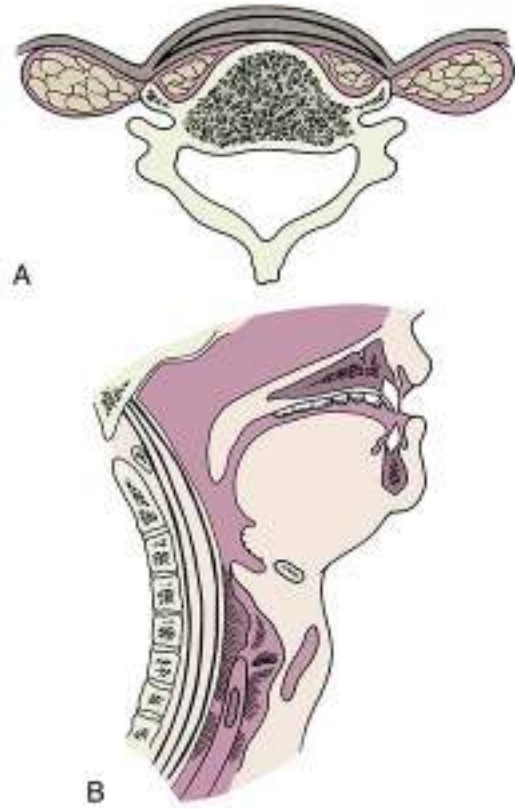

FIG. 76.3 **A,** Axial schematic of the relationship of the potential space anterior to the vertebral bodies. The alar fascia separates the prevertebral space from the retropharyngeal space. **B,** Sagittal drawing depicting the relationship between the retropharyngeal and prevertebral spaces.

The parapharyngeal space is important because of its central location and proximity to other deep neck spaces. The middle layer of deep cervical fascia forms its medial border as it envelops the superior constrictor. Posteriorly, the prevertebral fascia and two other spaces border it. Laterally, it abuts the masticator space and, inferiorly, the submandibular. The inverted pyramidal space extends from the skull base to the hyoid bone and is most often involved due to tonsillitis, but given its central location, abscesses here can extend into any of these other spaces. Peritonsillar abscess starts out confined by the constrictor muscle and fascia but if untreated can gain access to the parapharyngeal space. Patients present with trismus, drooling, and swelling in the neck. Parapharyngeal space abscesses require external drainage, as transoral I&D is inadequate to drain the inferior extent.

Pathogenesis

- The most common source of DNI is the teeth.
- Infections of the upper aerodigestive tract, illicit intravenous drug use, and surgical complications are responsible for some cases.
- The cause is never identified in approximately 50% of cases.
- Delay in treatment, immunocompromised status, and antibiotic resistance also play a role in the transformation of a common infection into a life-threatening illness.

Pathogens

- Anaerobic bacteria are causative in odontogenic infection.
- In pediatric patients aerobic infection is most common.[1]

- The most common aerobes are *Streptococcus pyogenes* and *Staphylococcus aureus.*
- Anaerobes are more common in adults and non-diabetics.
- *Prevotella,* proprionobacter, and *Peptostreptococcus* are the most common anaerobes in deep neck infection. *Fusobacterium, Porphyromonas,* and *Bacteroides* are other common anaerobes involved in DNI stemming from an oral source.
- Polymicrobial culture results (both aerobes and anaerobes) occur in 30% to 40% of cases.

Increasing drug resistance and difficulty in obtaining accurate anaerobic cultures contribute to the prevalence of these potentially life-threatening infections. Anaerobic cultures must be carefully collected, transported, and cultivated without exposure to air to properly identify flora. Beta-lactamase-producing bacteria (BLPB) render beta-lactam antibiotics ineffective and can shield non-BLPB from these drugs as well.[2] Both aerobes (*S. aureus, Haemophilus influenzae, Moraxella catarrhalis*) and anaerobes (prevotella and porphyromonas) are capable of producing beta-lactamase.

Prerequisite Skills

- Experience with neck dissection and surgery of the parapharyngeal and retropharyngeal spaces
- Experience with tracheostomy

Operative Risks

- Recurrent/persistent deep neck infection
- Cranial nerve injury
- Vascular injury

Surgical Technique: Incision and Drainage

- Perform through an external incision, which is planned, based on the

location of the abscess.

- Ludwig's angina is drained through a submental incision.
- Parapharyngeal space abscess is best approached through an incision at the level of the hyoid, which allows access to the posterior belly of the digastric. The muscle is retracted superiorly, and blunt dissection here allows access to the parapharyngeal space and drainage of the abscess (Fig. 76.4).
- Retropharyngeal abscess drainage should be planned at a level appropriate to reach loculations and the abscess cavity. The surgeon must consider that abscesses in this space may extend into the mediastinum, and an incision at one or two fingerbreadths above the clavicle may be very advantageous. This is often helpful in cases in which thyroiditis also exists. Third or fourth branchial cleft cyst abscess is associated with thyroiditis and can extend down into the mediastinum. Management includes thyroid lobectomy and tracing the tract up to its origin in the piriform sinus. Dissection deep and medial to the carotid sheath provides access to the retropharyngeal space.
- Abscesses involving multiple spaces may require several separate "stair-stepped" incisions (horizontal to each other) for drainage of all loculations. Occasionally, bilateral incisions are required for adequate drainage.

FIG. 76.4 Surgical approach to the parapharyngeal space.

- Once purulent exudate is encountered, specimens are gathered for Gram stain and aerobic, anaerobic, and fungal cultures.
- Using the CT scan as a "map" to identify all loculations is helpful, but gentle palpation within the abscess cavity may also uncover areas of infection.
- After the wound has been thoroughly examined, it should be irrigated with copious amounts of sterile saline until no further turbidity is noted. Large (half-inch) Penrose drains are inserted into each incision and sutured to the skin to prevent dislodgement. An absorbent dressing is applied to help contain discharge and to prevent maceration of the surrounding skin.

Common Errors in Technique

- Failure to adequately drain all abscess loculations
- Injury to cranial nerves

Postoperative Period

Postoperative Management

Monitoring

- Intensive care unit placement for
    a. Ventilatory requirements
    b. Hemodynamic instability due to sepsis
    c. Adequate pain control and sedation

Wound Care

- Multiple dressing changes each day until the discharge decreases

- Frequent checks on microbiology reports are crucial to determine if antibiotic coverage needs to be altered.
- Penrose drains are maintained until drainage decreases and then are slowly backed out of the wound.
- Wounds are allowed to close by secondary intention.
- Repeat lavage is indicated for wounds that produce copious amounts of purulent discharge.
- In cases of necrotizing fasciitis (NF), revision surgery may be required if the patient's condition does not improve and further necrotic tissue is identified.

Complications and Other Considerations

- Persistent signs of infection—elevated WBC, fever, sepsis, and abnormal CT
- In odontogenic cases the offending tooth/teeth must be extracted.
- Consider reoperation if scans indicate an abscess.
- Infectious diseases consult to adjust antibiotic coverage.
- Minimally invasive trends continue to develop, but abscesses that are multiloculated, occur in the critically ill, threaten airway patency, or have failed conservative management *must* be drained through an external incision.
- Dysphagia may result from dissection of the retro- or parapharyngeal space or edema of the airway. It is particularly important to assess this in geriatric patients due to the high incidence of pre-existing dysphagia in this population. Management of dysphagia requires speech pathology consultation and nutritional support via a nasogastric tube or percutaneous endoscopic gastrostomy tube

Lemierre Syndrome

Lemierre syndrome is a life-threatening complication of deep neck infection. Thrombosis of the internal jugular vein and bacterial emboli

are the hallmarks of this disease (Fig. 76.5). Spiking fevers ("picket fence"), dyspnea, and an oropharyngeal or dental source are common. The most common pathogen is fusobacterium, a gram-negative anaerobe (*Fusobacterium necrophorum* is most common), but bacteroides, prevotella, and peptostreptococcus may also be identified. Hemagglutinin produced by these microbes leads to platelet aggregation and thrombus formation. Prior to the antibiotic era, such cases would most likely end in death, and the only treatment available was ligation of the vein. Currently, ligation of the vein is not routinely indicated. Anticoagulation is frequently used in this disease although consistent evidence for this strategy is lacking (see Fig. 76.5A and B).

Necrotizing Fasciitis (NF)

Perhaps the most dreaded of all neck infections, NF is a fulminant infection involving the superficial fascial layers. In the head and neck, odontogenic sources are also most common, but simple skin disruption from minor trauma (insect bites have been reported as the seminal event in some cases) may be enough to introduce the virulent streptococcus and bacteroides most often implicated in this disease.[3] Infection leads to liquefaction of subcutaneous tissues, venous thrombosis,[4] and endarteritis obliterans. Risks include lack of immunocompetency (diabetes being most common), alcoholism, obesity, advanced age, or peripheral vascular disease. Presenting signs may mimic deep neck abscess, but presence of subcutaneous air, skin anesthesia, and duskiness should raise concerns for NF.

Surgical management includes drainage of the thin, gray, foul-smelling fluid that is typical in NF and débridement of necrotic tissue. This often involves removal of significant amounts of soft tissue, as exposure of healthy bleeding tissue is the goal of an adequate operation. Wounds are never closed at the time of débridement. Reconstruction is performed after signs of infection have resolved. The use of hyperbaric oxygen has been shown to improve healing in some studies but is not a standard recommendation.[4] Mortality rates of 23% have been reported and increase to more than 40% if the process extends into the mediastinum.

Longus Colli Tendinitis

This unusual condition is seen at our institution several times each year. Described in 1964 by Hartley, retropharyngeal calcific tendinitis is an acute inflammation of calcium crystal deposits in the longus colli tendon as it inserts into the muscle. Therefore, these calcifications are always seen at the level of C1, occasionally C2, and the surrounding edema can mimic a phlegmon, leading to erroneous consultation for retropharyngeal abscess or, worse, unnecessary surgery.

Calcific tendinitis is characterized by severe neck pain and stiffness as well as odynophagia. Physical findings include erythema and edema of the posterior nasopharyngeal wall. Fever and elevated WBC are not part of the presentation, but elevated sedimentation rate and C-reactive protein may be. CT is the recommended imaging, revealing calcifications and retropharyngeal edema that may extend to the lower cervical vertebral level. The calcifications are pathognomonic, but it is important to remember that lack of reactive lymphadenopathy also differentiates this from an infectious process. Nonsteroidal anti-inflammatory drugs are the treatment of choice,[5] although steroids may also be used, and complete resolution is expected in 1 to 2 weeks (Fig. 76.6A and B).

Vascular Rupture

Hemodynamic instability is most often due to sepsis, but in some cases of deep neck infection, it may be a sign of vascular rupture. Patients with neck ecchymosis, rapid swelling, and hypotension may have suffered a catastrophic injury to the carotid due to exotoxins produce by virulent bacteria. If during the I&D of the abscess, the surgeon encounters a blood clot in proximity to the artery, intraoperative vascular consultation should be obtained immediately.

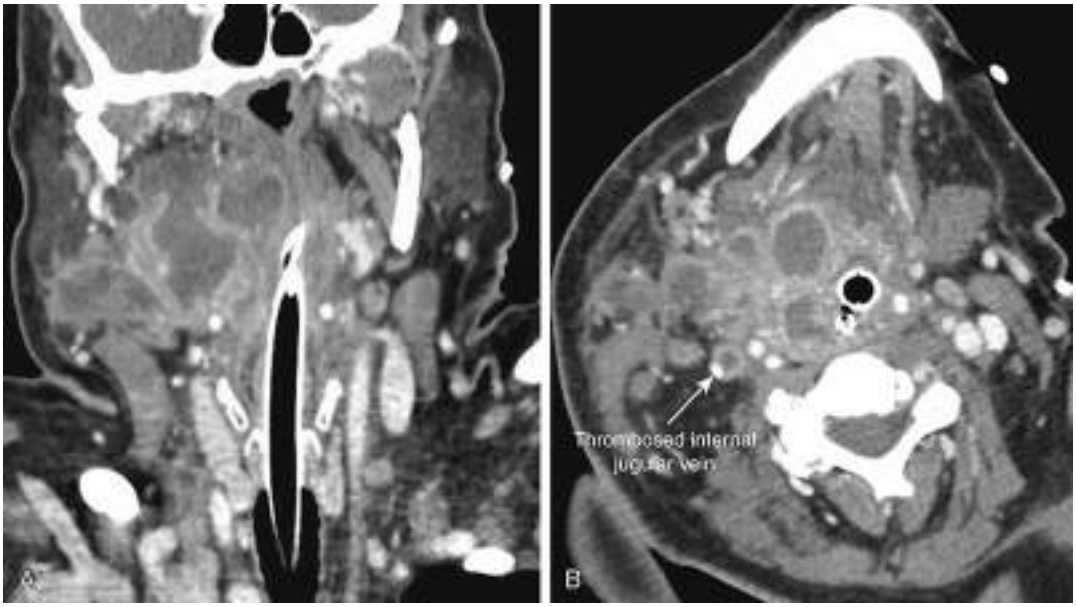

FIG. 76.5 **A,** Computed tomography (CT) scan from a 62-year-old diabetic woman who presented with thrombosis of the internal jugular vein (IJV) that resulted from an untreated peritonsillar abscess. She was also noted to have multiple fractured carious teeth. **B,** CT scan demonstrating large multiloculated right parapharyngeal space abscess. Image on right shows classic "O" sign of IJV thrombosis *(arrow).* Cultures grew strep anginosus. The patient was successfully treated with intravenous antibiotic therapy and incision and drainage and did not require tracheostomy.

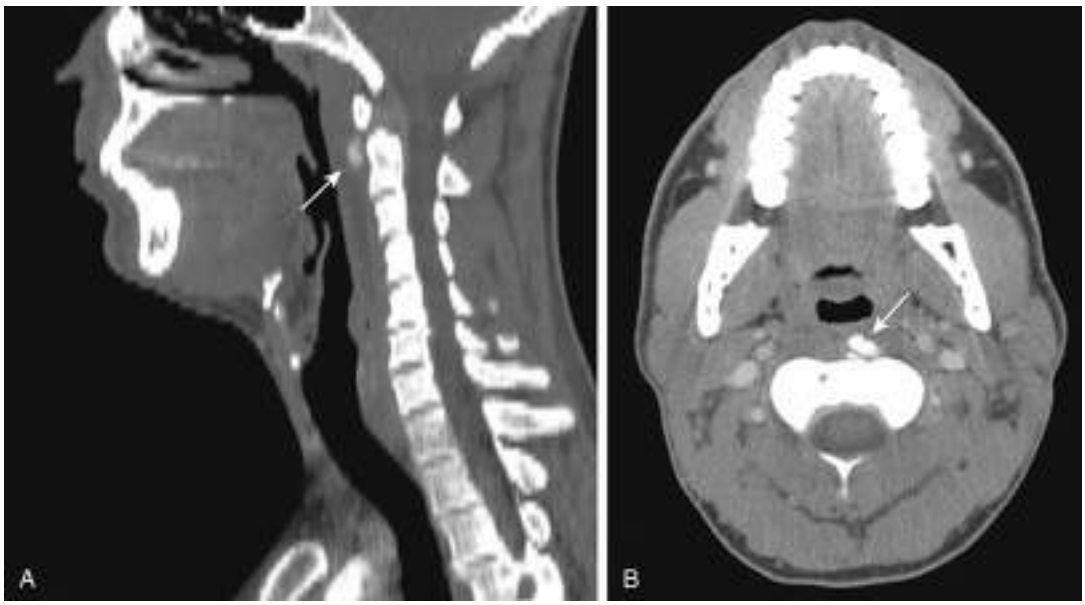

FIG. 76.6 **A,** A reconstructed lateral neck CT scout film of a patient with longus colli tendinitis. The retropharyngeal soft tissue is thickened at C1 to C2 and measures 8 mm (*arrow*). **B,** The hallmark calcifications near C1 (*arrow*). Note the hypodensity as well; this inflammatory change is sometimes misinterpreted as a phlegmon or abscess.

Alternative Management Plan

A recent report[6] of ultrasound-guided aspiration has shown good results in selected cases of deep neck abscess. Patients with well-defined, unilocular abscesses are candidates for this approach. No recurrences were noted, and hospital stays were shorter. It is unclear if this technique is an option for immunocompromised patients (diabetics).

Transoral drainage of retropharyngeal abscess is indicated for pediatric patients or small abscesses limited to this space. It should not be used for infections that extend out laterally to the parapharyngeal space or if revision surgery is necessary for persistent infection.

Discussion

Evidence-Based Medicine Question

How are outcomes affected by conservative management and delay of surgery in deep neck abscesses?

Conservative management of deep neck abscess with intravenous antibiotics, with or without needle aspiration, is used more often in the pediatric population. In a recent study by Cramer et al.,[7] adult patients had significantly higher risk of morbidity and mortality if surgery was delayed (11.5% day 0, 17.3% day 1 to 2; P = .02). The risk increased 2.4-fold if surgery occurred after day 2. The authors found that delay of surgery did not affect the risk of morbidity and mortality in pediatric patients. Despite this, there appears to be a subset of pediatric patients who require immediate surgical intervention. Lawrence and Batemen[8] describe the controversies involved in treating deep neck abscess in the pediatric age group and concluded that airway compromise, complications (Lemierre syndrome, cranial nerve palsy, septicemia), abscess >2.2 cm, age <4, and ICU admission are reasonable criteria for surgery.

Editorial Comment

Clinical evaluation, appropriate imaging, and active aggressive management are vital to successful outcomes for DNI. Usually the origins of the DNI are evident from clinical and radiologic examination. However, efforts must be made to identify the source of infection, and this must be treated synchronously or in an elective fashion. Although the majority of deep neck abscesses are due to infectious sources such dental or oropharyngeal infections, the possibility of a malignant fistula must be considered, especially in patients who have a prior history of head and neck cancer.

Review Questions

1. Which of the following is true?

   a. **Most deep neck abscesses that occur in adults are caused by mixed aerobes and anaerobes.**

b. Upper respiratory tract infection is the most common cause of DNI.

c. Pediatric DNIs are most often anaerobic.

d. Streptococcal species are responsible for most abscesses of dental origin.

2. The boundaries of the masticator space include all of the following, except

a. The mandible

b. Buccinator, masseter, and orbicularis muscles

c. **Deep layer of the deep cervical fascia**

d. Zygomatic arch

3. A patient presents to the ER with 2 days of increasing pain in the neck and stiffness. Which of the following is indicative of an abscess?

a. Elevated sedimentation rate

b. **Elevated WBC and erythematous swelling of the submandibular triangle**

c. CT showing phlegmon of retropharyngeal space and calcifications near C1

d. History of URI

Anterior Transcervical Approach to the Cervical Spine

Carl H. Snyderman

Introduction

The otolaryngologist is often involved in surgery to provide access to the cervical spine. This is usually for the treatment of cervical spondylosis by the orthopedic or neurologic surgeon. Rarely the head and neck surgeon will be involved in the treatment of pathology involving the spine, such as infection or primary and metastatic neoplasms. Potential benefits for the primary surgeon of the participation of the otolaryngologist include increased efficiency, decreased risk of injury to the vagus nerve or esophagus, decreased medicolegal risk, and follow-up care of voice and swallowing problems.

Familiarity with these approaches is also important for the treatment of conditions that do not involve the spine, such as deep neck infections, retropharyngeal lymph node metastases, and cricopharyngeal achalasia with Zenker's diverticulum. Surgical approaches to the cervical spine can be categorized as anterior cervical, lateral cervical, transoral, and transnasal approaches. This chapter will focus on anterior transcervical approaches to the cervical spine. Transoral and transnasal approaches to the upper cervical spine are included in Chapter 123.

Key Operative Learning Points

- C1 and C2 are at or above the level of the body of the mandible. C3 and C4 are at the level of the hyoid bone and the superior aspect of the thyroid cartilage. C5 and C6 are at the level of the posterior cricoid cartilage. C7 is at the lower limit of the neck and may be below the level of the clavicle in some patients.

- The anterior cervical spine is approached medial to the carotid sheath and lateral to the strap muscles.
- The superior laryngeal nerve courses across the neck deep to the carotid artery at the level of the thyrohyoid membrane and is in close association with the superior thyroid artery.
- The recurrent laryngeal nerve is situated in the tracheoesophageal groove superficial to the plane of the prevertebral fascia and enters the larynx at the cricothyroid joint.
- Injury to the recurrent laryngeal nerve can be avoided by maintaining a plane of dissection deep to the nerve.
- In revision surgeries, the carotid artery is medially displaced due to scar contracture and at greater risk of injury.
- Lateral to the vertebral bodies, the vertebral artery courses within the vertebral canal of the lateral processes.
- The lateral retropharyngeal lymph nodes (nodes of Rouviere) are situated just medial to the internal carotid artery at the level of the transverse process of the first cervical vertebra (atlas).[1]

Preoperative Period

History

1. History of present illness

- Pain

  Patients may have pain in the neck or shoulders from nerve root compression from cervical spondylosis; it may radiate to the upper extremities. Pain may also be exacerbated by movement of the neck.

- Neurologic dysfunction

  Patients may have sensory and motor loss from spinal cord compression. Patients should be questioned about sensory loss or weakness of the extremities (decreased grip strength, difficulty ambulating).

- Hoarseness

Patients who have had prior cervical surgery should be questioned about hoarseness following prior surgery. Hoarseness may signal vocal cord paresis from injury to the recurrent laryngeal nerve. Decreased vocal range with coughing due to aspiration may be associated with injury to the superior laryngeal nerve.

- Dysphagia

Dysphagia is often multifactorial. Large osteophytes can cause compression of the esophagus with dysphagia for solids. Dysphagia with regurgitation of undigested food is suggestive of a Zenker's diverticulum.

2. Past medical history

- Prior cervical spine surgery

In patients with a prior history of cervical spine surgery, it is important to inquire about the indications for the previous surgery, the operated spine levels, postoperative complications, and the duration of postoperative symptoms. Prolonged hoarseness after surgery may indicate injury to the recurrent laryngeal nerve.

- Other neck surgery or trauma to the cervical spine

Other operations in the cervical region such as thyroidectomy should be noted.

Physical Examination

- Inflammation

Inflammatory conditions such as osteomyelitis or retropharyngeal abscess can result in erythema and edema of the soft tissues. Rarely, crepitus from subcutaneous air is palpable if there is communication with the pharynx or esophagus.

- Range of motion

Cervical osteophytes may limit the range of motion of the neck (flexion, extension, rotation). Patients with Forestier's disease or diffuse idiopathic skeletal hyperostosis (DISH) often have limited flexion/extension due to extensive calcification of the anterior longitudinal ligaments.[2]

- Mass in the neck

  A mass in the neck may be inflammatory or neoplastic. A large Zenker's diverticulum is rarely palpable. A large thyroid goiter may interfere with a low cervical approach.

- Evidence of prior surgery

  The side and level of prior surgical approaches to the cervical spine should be noted, since this may have an impact on the surgical approach. If a new level is targeted, it may not be possible to use the same incision.

- Upper airway

  The upper airway should be examined by endoscopy to assess the safety of the airway for intubation. Large osteophytes posterior to the pharyngeal mucosa may limit access to the airway.

- Neurologic function

  The function of the larynx should be assessed by laryngoscopy. If there is paresis of a vocal cord, this should be clearly documented.

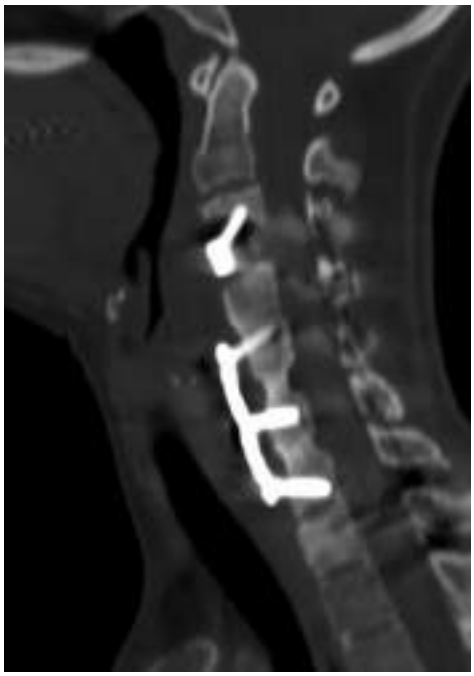

FIG. 77.1 Sagittal plane computed tomography scan demonstrates position of cervical hardware as well as

relationships of laryngeal landmarks to cervical spine levels. In this patient, there is compression of the esophagus by the hardware.

Imaging

- Lateral plane radiograph

  Anterior-posterior and lateral spine radiographs provide basic details of bone anatomy and are good for visualization of spinal hardware. The optimal placement of the skin incision can be determined based on the relationship of the cervical spine level to the bony/cartilaginous landmarks of the hyoid bone and thyroid cartilage.

- Esophagram

  If there is suspected perforation of the esophagus, an esophagram is obtained using a water-soluble contrast agent. An esophagram or modified barium swallow is also helpful in assessing the severity and contribution of osteophytes to dysphagia.

- Computed tomography (CT)

  A CT scan with contrast should be considered in patients with associated symptoms or physical findings suggestive of a neoplasm or osteomyelitis. A sagittal view provides optimal viewing of cervical hardware: cervical spine levels, displaced hardware, compression of esophagus (Fig. 77.1).

- Magnetic resonance imaging (MRI)

  MRI is superior for delineating the level of cord compression from a herniated disc (Fig. 77.2).

Indications

1. Cervical spondylosis

The most common indication for an anterior approach to the cervical spine is cervical spondylosis (Fig. 77.2). Revision surgery is sometimes necessary when there is infection or displacement of plating hardware. Bulky hardware may also contribute to postoperative dysphagia and

may be removed electively to improve swallowing function. Large osteophytes occur most commonly at the C4-C6 levels in approximately 12% to 30% of the elderly and may be associated with symptomatic dysphagia and aspiration. It can be difficult to demonstrate that the patient's symptoms are due to the osteophyte, however, since dysphagia is frequently multifactorial in these patients. Patients with Forestier's disease or DISH can develop extensive calcification of the anterior longitudinal ligaments with resultant dysphagia (Fig. 77.3).[2] The calcifications usually span multiple levels.

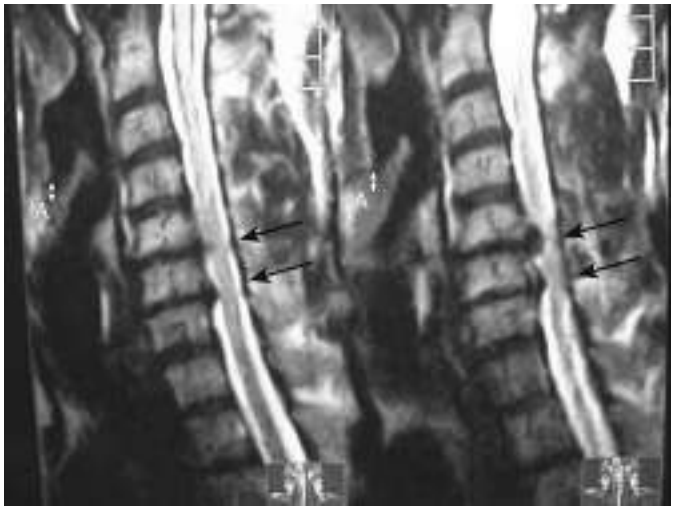

FIG. 77.2 Preoperative magnetic resonance image (sagittal plane) demonstrating the relationships of the cervical vertebrae to palpable laryngeal landmarks, as well as significant spinal cord compression at the C5-C6 and C6-C7 levels due to cervical spondylosis *(arrows)* (A = anterior).

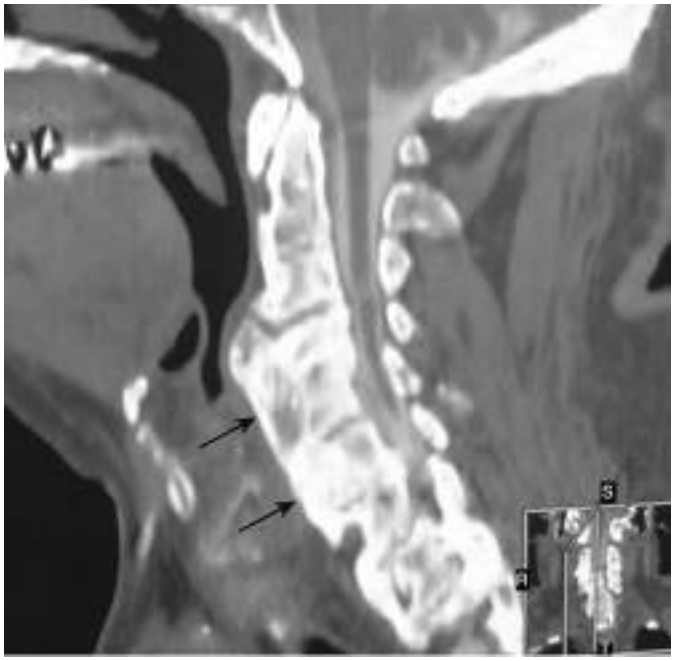

FIG. 77.3 Forestier's disease, or diffuse idiopathic skeletal hyperostosis, is characterized by extensive calcification of the anterior longitudinal ligaments *(arrows).*

2. Cervical osteomyelitis

Rarely infection of the vertebral bodies (osteomyelitis from adjacent infection or hematogenous seeding of the vertebral body; e.g., tuberculosis) may require surgery.

3. Neoplastic involvement of cervical spine

Malignancies metastatic to the vertebral bodies are usually treated with palliative radiation but may also require surgery for stabilization of the cervical spine.

4. Retropharyngeal abscess

Infection of deep neck spaces may result in a retropharyngeal abscess. This may result from a suppurative upper respiratory infection with involvement of the retropharyngeal lymph nodes, esophageal perforation, or a foreign body.

5. Zenker's diverticulum

Although most cricopharyngeal myotomies for Zenker's diverticulum are now performed endoscopically, an anterior cervical approach to the

cervical spine provides the necessary exposure of the cricopharyngeus and inferior pharyngeal constrictor muscle for performance of a myotomy or excision of diverticulum with a myotomy, especially in patients who are not candidates for an endoscopic approach.

6. Esophageal perforation

An esophageal perforation may result from intraluminal trauma (e.g., passage of a tube or esophagoscope), erosion by spinal hardware, or iatrogenic injury from neck surgery. A transcervical approach provides drainage of air/fluid to prevent infection and allows primary surgical repair.

7. Retropharyngeal lymphadenectomy

Neoplasms of the soft palate, pharynx, thyroid, and skull base may metastasize to retropharyngeal lymph nodes. Although the survival is poor in patients with squamous cell carcinoma metastatic to the retropharyngeal lymph nodes, retropharyngeal lymphadenectomy may be beneficial in selected patients with other types of neoplasms (esthesioneuroblastoma, thyroid cancer).

Contraindications

1. Active neck infection

Untreated neck infection is a contraindication to cervical spine surgery with instrumentation, unless the patient requires surgical treatment of osteomyelitis. Staging of surgery may be necessary with surgical drainage of infection and medical therapy prior to spine surgery.

2. Major medical comorbidities

If a patient is not a candidate for general anesthesia, limited surgery for biopsy or drainage of an abscess can be performed with minimal sedation and local anesthesia.

Preoperative Preparation

- Informed consent

Informed consent includes a discussion of potential risks and expected

sequelae of surgery. For anterior approaches, the greatest concern is postoperative hoarseness or aspiration due to injury to the superior or recurrent laryngeal nerves. Some degree of dysphagia is expected postoperatively and can persist for months in a minority of patients.[3] The risk of infection or significant bleeding is negligible. Perforation of the esophagus or hypopharynx is a remote possibility, but the risk is increased when displaced hardware or a large osteophyte is being removed.

- Neck incision

  The laterality of the incision is generally not important. Arguments can be made for either side, depending on the level of exposure, handedness of the surgeon, risk of retraction injury of the recurrent laryngeal nerve, deviation of the esophagus, and prior surgery. Most right-handed surgeons find a right-sided approach to be easier for instrumentation of upper cervical levels and a left-sided approach for instrumentation of lower cervical levels.

  Using the same side as a previous incision is preferred if the same cervical spine level is targeted, especially if spinal hardware needs to be removed. If there is paresis of a vocal cord or preoperative examination of the larynx was not performed, it is safer to operate on the same side to avoid possible paresis of the contralateral vocal cord.

  Assessment of the anatomic relationship of vertebral bodies to cartilaginous and bony landmarks is assessed with a lateral radiograph of the cervical spine or on CT or MRI (sagittal view; Figs. 77.1 and 77.2). The level of upper cervical vertebrae is judged based on their relationship to the hyoid bone. The level of midcervical vertebrae is best judged based on their relationship to the posterior cricoid cartilage and thyroid cartilage. Since cartilaginous landmarks are not well visualized on MRI, the epiglottis is a useful landmark. The anterior ring of the cricoid cartilage is a readily identifiable landmark for localizing the lower cervical vertebrae.

- Neurophysiology

  Neurophysiologic monitoring of spinal cord function is performed intraoperatively when there is preoperative compression of the spinal cord or when surgery on the spinal cord is performed. If there is severe preoperative compression, a baseline study is performed after

induction of anesthesia and prior to positioning. After positioning, the patient is reassessed to confirm that neurologic function has not worsened. Continuous monitoring is performed throughout surgery.

- Navigation

  Intraoperative image guidance with a navigational system is helpful for pathology of the upper cervical spine and cranial base but is impractical for lower levels. When a navigational system is used, a CT angiogram will provide good visualization of bony anatomy, as well as the course of the vertebral artery.

Operative Period

Anesthesia

- General

Positioning

- Supine

  Extension of the neck should be performed cautiously inpatients with cervical spine pathology. In patients with spinal compression, this should be done with neurophysiologic monitoring. The shoulder may be retracted with tape to avoid interference with a lateral neck radiograph (Fig. 77.4).

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin. A single dose of antibiotic given IV is sufficient for a clean case. If there is active infection, a therapeutic course of antibiotics may be necessary.
- Clindamycin if the patient is allergic to penicillin

Monitoring

- None. However, in reoperative cases, recurrent laryngeal nerve

monitoring could be considered.

Instruments and Equipment to Have Available

- Neck dissection set
- Monopolar and bipolar electrocautery

FIG. 77.4 Positioning of the patient for an anterior cervical approach. The neck is extended and the shoulder is retracted inferiorly with tape to avoid obstruction of a lateral cervical radiograph. The skin incision is marked.

- Right angle Mixter forceps
- Meyerding retractors
- Self-retaining spinal retractors

Key Anatomic Landmarks

- Sternocleidomastoid and omohyoid muscles
  - The surgical approach is between the sternocleidomastoid and strap muscles (sternohyoid, sternothyroid, thyrohyoid, and omohyoid

muscles). Inferiorly, the surgical window narrows between the sternocleidomastoid and omohyoid muscles.

  - The thyroid lobe is deep to the strap muscles.

- Carotid sheath
  - The carotid sheath contains the carotid artery, internal jugular vein, and vagus nerve. The vagus nerve is lateral to the vascular structures.
- Prevertebral fascia and longus colli muscles
  - The prevertebral fascia covers the longus colli muscles. In the midline, there is separation of the muscles.
- Recurrent laryngeal nerve
  - The recurrent laryngeal nerve runs vertically in the tracheal-esophageal groove and enters the larynx at the level of the cricothyroid joint.
- Superior laryngeal nerve
  - The superior laryngeal nerve is closely associated with the superior thyroid artery and crosses the surgical field obliquely (deep to the carotid artery) to enter the larynx at the thyrohyoid membrane.

Prerequisite Skills

- Neck dissection
- Repair of esophagus

Operative Risks

- Vascular injury

  The risk of vascular injury is greater in revision cases where there is scar tissue and medial displacement of the carotid artery.

- Injury to the esophagus

  The esophagus may be injured during the exposure or from excessive retraction.

- Injury to the recurrent laryngeal nerve

FIG. 77.5 Skin incisions for approaching, upper cervical spine (C3-5) and, lower cervical spine (C5-7).

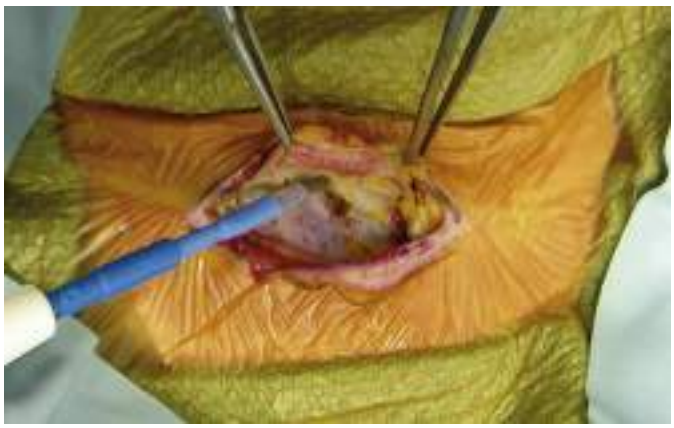

FIG. 77.6 Subplatysmal flaps are elevated.

The recurrent laryngeal nerve may be injured directly (transection, crush injury, thermal injury) or from retraction.[4,5]

- Superior laryngeal nerve injury

The superior laryngeal nerve is at greatest risk of injury with high cervical approaches.

Surgical Technique

- The level of the incision is dependent on the desired level of exposure

(vertebral level; Fig. 77.5). A transverse incision is planned in a natural skin crease in the mid- to upper neck for C2-C4 and the mid- to lower neck for C5-C7. The incision extends from the paramedian position (1 cm lateral to the midline) to the anterior border of the sternocleidomastoid muscle. The proposed skin incision is infiltrated with 10 cc of 0.5% xylocaine with epinephrine (1:200,000) and marked. After prepping, adhesive drapes are used to avoid the placement of metal instruments around the surgical field. These may interfere with intraoperative imaging (lateral radiograph or fluoroscopy) to confirm the cervical spine level.

- Subplatysmal flaps are elevated (Fig. 77.6), and dissection continues medial to the sternocleidomastoid muscle and lateral to the strap muscles (Fig. 77.7). The internal jugular vein is identified, and dissection continues medially (Fig. 77.8). Motor branches of the ansa cervicalis to the strap muscles are preserved when possible. In a patient with a muscular neck, transection of the omohyoid muscle is sometimes necessary to provide adequate exposure of lower cervical levels. The carotid sheath is identified, and blunt finger dissection medial to the carotid artery is usually sufficient to create a tunnel between the carotid sheath and the esophagus to expose the prevertebral fascia (Fig. 77.9).

FIG. 77.7 Dissection is performed between the sternocleidomastoid and omohyoid (forceps) muscles

(right neck).

FIG. 77.8 The internal jugular vein *(IJV)* and common carotid artery *(CCA)* are exposed and retracted laterally (right neck).

- The length of the exposure is extended superiorly and inferiorly with appreciation of the course of the laryngeal nerves. With a superior exposure, careful dissection is performed along the medial aspect of the carotid sheath. The superior laryngeal nerve crosses from lateral to medial deep to the carotid artery and is closely associated with the superior thyroid artery. Once the nerve is identified, dissection of the retropharyngeal space can be performed deep to the nerve with gentle superior retraction. It is rarely necessary to identify the recurrent laryngeal nerve. A plane of dissection is maintained deep to the nerve and esophagus to avoid injury.
- The larynx and esophagus are retracted medially, and the prevertebral fascia is incised in the midline with electrocautery (Fig. 77.10). The edges of the longus colli muscles are elevated from the underlying vertebral bodies at the desired levels. Venous bleeders from the surface of the bone are controlled with electrocautery. Excessive lateral dissection should be avoided due to potential risk to the vertebral arteries. The cervical spine level is confirmed radiographically by placing a spinal needle with a 1-cm "stair-step" bend at the tip in the intervertebral space and obtaining a lateral radiograph (Fig. 77.11).

Self-retaining or fixed retractors are then placed (Fig. 77.12). Further decompression and fusion are performed by the spine surgeon.

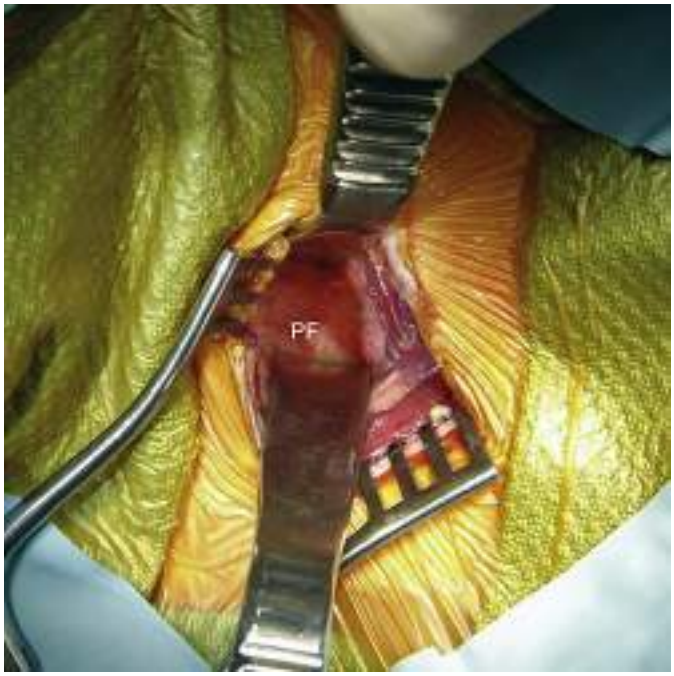

FIG. 77.9 The retropharyngeal space is bluntly dissected, and the larynx and esophagus are retracted medially to expose the prevertebral fascia *(PF)* (right neck).

FIG. 77.10 The prevertebral fascia is incised in the

midline and the longus colli muscles *(arrows)* are elevated from the vertebral bodies (right neck).

- Access to the retropharyngeal space for other disease processes is performed in the same way. Although the retropharyngeal lymph nodes may be approached anterior or posterior to the carotid sheath, an anterior approach is recommended, since there is less retraction of the carotid artery, less risk of injury to the sympathetic chain, and greater exposure. The sternocleidomastoid muscle and carotid sheath are retracted laterally, and the digastric muscle and hypoglossal nerve are retracted superiorly. Transection of the descendens hypoglossi nerve may be necessary to mobilize the hypoglossal nerve. The superior laryngeal nerve is identified, and a window is created between these nerves. The retropharyngeal lymph nodes are anterior to the superior sympathetic ganglion at the level of the transverse process of the atlas.[1]

FIG. 77.11 A spinal needle with the tip bent in stair-step

fashion is inserted into a disc space to mark the cervical spine level. A lateral cervical radiograph demonstrates the spinal needle *(arrow)* in the C5-C6 disc space.

FIG. 77.12 Self-retaining retractors are placed between the longus colli muscles.

- The wound is irrigated with saline, and a suction drain is placed between the muscles and medial to the carotid sheath. The platysma and skin layers are closed separately.

Common Errors in Technique

- Placement of skin incision

  Improper placement of skin incisions can create problems for the surgeon. An incision that is too far superior runs the risk of injury to the marginal mandibular branch of the facial nerve. An incision that is made too far inferior is obstructed by the sternal head of the sternocleidomastoid muscle. If the dissection is too medial, the strap muscles and the thyroid gland will interfere with the approach. Occasionally, an enlarged thyroid lobe is encountered and needs to be mobilized along its lateral margin. If the dissection is too far laterally, there is the potential of dissection lateral to the carotid artery with risk of injury to the vagus nerve and sympathetic chain (Horner's syndrome).

- Plane of dissection

  If the laryngeal retractor is not placed deep enough to protect the esophagus, an esophageal perforation may result. Failure to maintain a plane of dissection on the surface of the prevertebral fascia may injure the recurrent laryngeal nerve in the tracheoesophageal groove.

Postoperative Period

Postoperative Management

- The neck drain is removed in 1 to 2 days. If output remains high or the contents are cloudy, the patient should be evaluated with an esophagram to identify an esophageal leak.
- Postoperative care focuses on the function of the lower cranial nerves. Transient hoarseness may be due to edema of the vocal cord. Hoarseness that persists for more than a week should be evaluated further with examination of the larynx to evaluate vocal cord function. A significant percentage of recurrent laryngeal nerve injuries following cervical spine surgery go unrecognized. The patient should also be queried about aspiration. If a complete paralysis is observed, options include observation, vocal cord injection if symptoms are significant, and laryngeal EMG to evaluate the degree of injury.
- Transient dysphagia is to be expected, and most patients can accommodate a mechanical soft diet until it resolves. The incidence of postoperative dysphagia is 50% at 1 month, 32% at 2 months, 18% at 6 months, and 13% at 12 months.[3] Mechanisms of injury include laryngeal nerve injury, pharyngeal plexus injury, scarring of the pharynx, and obstruction by hardware. Persistent dysphagia should be evaluated with an esophagram. A follow-up radiograph will usually be obtained by the spine surgeon to assess adequate placement and retention of the spinal hardware.
- The following billing codes may be used for an anterior cervical approach to the cervical spine: 22554-62: *"spinal arthrodesis or fusion . . . incision is made through the neck, avoiding the esophagus, trachea, and thyroid . . . separate the intervertebral muscles,"* and 22585-62: *"each additional interspace treated in conjunction with the code for the primary*

procedure."

Complications

- It is possible to dissect lateral to the carotid sheath. If it is not detected, excessive medial displacement of the carotid artery by the retractors may result in carotid injury or ischemia. There is a greater risk of this mistake in revision cases when postoperative scarring results in medial displacement of the carotid artery. Direct injury to the vagus nerve can also occur.
- If the dissection is too superficial, there is a risk of injury to the esophagus and recurrent laryngeal nerve.
- Vocal cord paralysis secondary to injury of the recurrent laryngeal nerve may occur from direct nerve injury (transection, thermal injury from electrocautery), excessive and prolonged retraction, and overinflation of the endotracheal tube cuff.[4,5] Animal models and clinical studies have demonstrated that there is a sharp increase in endotracheal tube cuff pressures when retractors are placed. The recurrent laryngeal nerve is susceptible to ischemic injury where it enters the larynx at the cricothyroid articulation. The risk of neuropraxia can be reduced by readjusting the cuff pressure after retractors are placed. The anesthetist is asked to deflate the cuff and reinflate with the minimum amount of air necessary to achieve a seal. This is usually 1 to 2 cc less air.
- Vertebral artery

  The vertebral arteries are deep to the transverse processes of the cervical vertebrae. Excessive lateral dissection with electrocautery can injure the artery, where it is exposed in the transverse foramen.
- Dysphagia

  Postoperative dysphagia is common and results from tissue edema, compression from hardware, and rigidity of the spine.[3]
- Hoarseness

  Hoarseness may result from intubation trauma, surgical injury to the recurrent laryngeal nerve, or compressive neuropraxia from the

endotracheal tube cuff.

- Horner's syndrome

  Dissection lateral to the carotid sheath can cause Horner's syndrome.

Alternative Management Plan

- A cricopharyngeal myotomy for Zenker's diverticulum is preferentially performed using an endoscopic/microscopic transoral approach, unless the patient's anatomy is unfavorable.
- An esophageal perforation without neck abscess can be managed conservatively with a nasogastric feeding tube. Healing occurs by secondary intention.

Discussion

Evidence-Based Medicine Question

What are risk factors for dysphonia following anterior cervical spine surgery?

Dysphonia is a common postoperative complaint following cervical spine surgery. Most of the time, it is transient with full recovery. Injury to the superior or recurrent laryngeal nerves can result in chronic dysphonia.

In a review of 815 consecutive patients undergoing anterior cervical spine surgery, 3.9% developed postoperative dysphonia. All cases were performed using a team approach with a neurosurgeon and head and neck surgeon. Fiberoptic laryngoscopy demonstrated that only nine (1.1%) of these patients had ipsilateral vocal fold palsy. Of these nine patients, only one (0.1%) was found to have permanent vocal fold paralysis at 1-year follow-up. In contrast, a review of published studies reveals that the incidence of recurrent laryngeal nerve injury (both temporary and permanent paralysis) was 3.3% (100/3072).[5]

There is a low incidence of postoperative dysphonia when cervical spine exposure is provided by a head and neck surgeon. Factors associated with voice change and vocal cord motion impairment

included kyphosis, revision surgery, and level C6-C7 surgery. Kyphosis was the only independent factor correlating with voice change. Team surgery appears to reduce laryngeal complications and optimize the management of temporary or permanent postoperative dysphonia.

Editorial Comment

Transcervical approaches to the cervical spine provide an opportunity for multidisciplinary management of patients with cervical spine disease. The otolaryngologist can make valuable contributions to the surgical plan by providing access to the cervical spine, especially in patients who have multilevel disease or scar tissue from previous neck surgery, due to their knowledge and comfort level with the anatomy of the neck, specifically the course of the recurrent and superior laryngeal nerves. In addition, oversight by an otolaryngologist is helpful from the perspective of postoperative management of complications such as recurrent nerve injury, causing hoarseness or dysphagia that require swallow evaluation and therapy.

Rohan R. Walvekar

Review Questions

1. Indications for an anterior transcervical approach to the spine include all of the following, except

   a. **Laryngocele**

   b. Cervical spondylosis with nerve compression

   c. Retropharyngeal abscess

   d. Zenker's diverticulum with dysphagia

2. Injury to the recurrent laryngeal nerve can be avoided by

   a. Preserving the omohyoid muscle

   b. **Maintaining a plane of dissection deep to the esophagus**

   c. Preserving the superior thyroid artery

d. Maintaining constant endotracheal tube cuff pressure throughout the procedure

3. Risks of an anterior transcervical approach to the spine include all of the following, except

a. Vocal cord paralysis

b. Injury to the vertebral artery

c. **Chyle leak**

d. Horner's syndrome

Open Thyroidectomy

Yuan F. Liu, and Alfred Simental Jr.

Introduction

Although thyroid disease has been recognized for centuries, consistently accepted techniques of thyroid surgery date back approximately 100 years. With a combined mortality of 40% from hemorrhage and sepsis, thyroidectomy was banned by the French Academy of Medicine in 1850. However, with the advent of antiseptic technique, vascular ligation, and precise capsular dissection, Theodor Kocher reduced the perioperative mortality rate to less than 1% in 900 cases for benign goiter in 1895. He was awarded the Nobel Prize in Medicine in 1909 for his contributions to thyroid surgery. Crile, Lahey, and the Mayo brothers founded their internationally famous private clinics largely based on their ability to perform thyroid surgery safely.

Thyroid nodules are found by palpation in 4% to 7% of subjects and by imaging in 30% to 67% of the population. While nonmalignant thyroid abnormalities are quite common, 5% to 20% of nodules may contain malignancy on excision. Studies suggest that 33% of subjects have thyroid cancer on autopsy, and that approximately 50% of the population may have microscopic thyroid cancer.

Carcinoma of the thyroid accounts for approximately 3.8% of cancers in the United States, with an estimated 62,450 new cases in 2015 and 75% occurring in women. It is currently the fifth leading new cancer diagnosis in women and is projected to overtake colorectal cancer as the fourth leading cancer diagnosis overall in the United States by 2030. Although the incidence of thyroid cancer has risen in recent years, perhaps due to the increased use of ultrasound, its mortality rate has remained stable with a 5-year survival of approximately 98%, accounting for 0.3% of all cancer deaths in 2015.

Key Operative Learning Points

1. Identification and continued observation of the recurrent laryngeal nerve is the best way to avoid injury to the nerve.

2. Skeletonize the superior pedicle and ligate close to the thyroid gland to avoid injury to the superior laryngeal nerve and parathyroids.

3. Identify and lateralize the parathyroid glands with their blood supply.

4. Careful placement of the incision and protection of skin edges promote optimal cosmetic results.

Preoperative Period

History

1. History of present illness[1]

   a. Evaluate for onset, duration, change in size, growth rate, and pain.

      1) Asymptomatic nodules are often found on imaging.

      2) Rapid growth of a new or previously stable nodule is concerning for malignancy.

      3) Pain is not commonly associated with thyroid cancer and may represent thyroiditis or hemorrhage into a benign nodule.

   b. Compressive symptoms: Shortness of breath and dyspnea (especially with lying flat), persistent dysphagia

   c. Invasive symptoms: Hemoptysis, fixation of the overlying skin, or hoarseness from paralysis of the vocal cord

   d. Hyper or hypothyroid symptoms: Palpitations, weight change, fatigue, anxiety, sleep disturbance, or menstrual changes

2. Risk factors for thyroid cancer

   a. Age

      1) Less than 20: ~20% risk of malignancy in a solitary nodule

      2) 20 to 40: 5% to 10% risk of malignancy in a solitary nodule

3) Peak in women 45 to 50, men 65 to 70

b. Gender: There is a triple prevalence in women, but thyroid nodules in men are more likely to be malignant.

c. Two or more first-degree relatives with a history of thyroid cancer

d. Exposure to low dose radiation to the neck

3. Past medical history

a. Hashimoto's thyroiditis

1) Nodules are 30% more likely to contain papillary thyroid cancer.

2) Increased risk of lymphoma

b. Consider multiple endocrine neoplasia type 2 (MEN-2) and medullary thyroid carcinoma in patients with pheochromocytoma, hyperparathyroidism, marfanoid habitus, and/or mucosal neurofibromas.

c. Gardner syndrome (polyposis coli) and Cowden disease are associated with thyroid cancer.

Physical Examination

1. Complete examination of the head and neck.

a. Palpate thyroid for enlargement and nodules.

1) Note size, shape, firmness, movement with swallowing, fixation to skin, or underlying structures.

b. Palpate neck for lymphadenopathy.

c. Listen for hoarseness, stridor.

2. Direct or indirect laryngoscopy

a. This is essential in detecting vocal cord paralysis.

b. The voice may be normal despite a paralyzed vocal cord.

Laboratory Studies

1. Thyroid stimulating hormone (TSH)[1]

a. Initial study of choice to rule out hypo or hyperthyroidism

2. Thyroglobulin (Tg)[1]

a. Cannot reliably differentiate between benign and malignant thyroid disease

3. Calcitonin

a. Usually not recommended unless patient has a family history of medullary thyroid carcinoma or MEN-2, or biopsy shows medullary thyroid carcinoma

Imaging

1. Ultrasound (US)[1]

a. Thyroid US with attention to central compartment should be performed in all patients with a thyroid nodule, even when found on computed tomography (CT).

b. Provides details on size, consistency, other nodules, and associated cervical lymphadenopathy

c. Useful for serial monitoring of nodules and lymph nodes

d. Findings associated with malignancy include

1) Complex nodules

2) Irregular margins

3) Increased nodular vascularity

e. Microcalcifications are associated with markedly increased risk of malignancy, while cystic and spongiform appearance may be associated with benign lesions.

2. CT and magnetic resonance imaging (MRI)

a. Generally not needed

b. Can be helpful for

1) Substernal extension

2) Cervical and mediastinal lymphadenopathy

3) Invasion of surrounding structures such as trachea and

esophagus

4) Metastasis to distant body sites

c. Use of iodinated contrast may preclude the use of radioactive iodine (RAI) for 1 to 3 months.

3. Radionuclide scanning

a. Usually performed with ^{123}I or technetium 99m (^{99m}Tc) sestamibi

b. Incidence of malignancy is 4% in "hot" nodules and 10% to 15% in "cold" nodules.

c. Not routinely performed unless TSH level indicates hyperthyroidism

1) If hyperfunctioning nodule, no cytologic evaluation necessary and consideration for ablative radioiodine

2) If hypofunctioning, may indicate malignancy

3) Most cancers are isometabolic

Fine Needle Aspiration

1. Best initial diagnostic test

a. Minimally invasive, safe, and cost effective

b. Sensitivity 65% to 98%; specificity 72% to 100%

c. US guidance increases accuracy and success of fine needle aspiration (FNA)

2. Suspicious cervical lymph nodes should undergo FNA in addition to that of thyroid nodules.

3. When multiple nodules are present, the largest and/or most sonographically suspicious should preferentially be biopsied.

a. Multiple nodules may need to be biopsied to increase diagnostic yield.

4. Bethesda classification of thyroid cytopathology[2]

a. I: Nondiagnostic, 1% to 4% risk of malignancy

b. II: Benign, 0% to 3% risk.

c. III: Atypia of undetermined significance (AUS) or follicular lesion of undetermined significance (FLUS), 5% to 15% risk.

1) This is a gray zone where repeat FNA, observation with serial US, and surgery are all potential options.

d. IV: Follicular neoplasm, 15% to 30% risk

e. V: Suspicious for malignancy, 60% to 75% risk

f. VI: Malignant, 97% to 99% risk

Molecular Biomarkers

1. Newer studies introduced to increase accuracy of FNA and better characterize the risk of malignancy, especially in indeterminate cytology, AUS, and FLUS lesions.[3] These markers may

a. Reduce unnecessary surgery for benign lesions

b. Reduce completion thyroidectomy by guiding initial use of total thyroidectomy

c. Provide prognostic information

2. Examples: BRAF, RAS, TIMP1, RET/PTC, Pax8-PPARγ, galectin-3, cytokeratin, microRNA, gene sequencing

3. Uncertain evidence regarding efficacy and utility

Indications

Total Thyroidectomy

1. Differentiated thyroid carcinoma if one or more of the following:[1]

a. Tumor greater than 4 cm

1) Between 1 and 4 cm: Option of lobectomy or total thyroidectomy

b. Gross extrathyroidal extension

c. Contralateral thyroid nodule or cervical/distant metastasis

d. Multinodular goiter with radiation exposure to head and neck

e. First degree family members with thyroid cancer

2. Medullary thyroid carcinoma

3. Anaplastic thyroid carcinoma, depending on resectability

4. Bilateral indeterminate nodules

5. Multinodular goiter causing compressive symptoms

6. Medically refractory Grave's disease or hyperthyroidism

Thyroid Lobectomy

1. Papillary or follicular thyroid carcinoma if all of the following:[1]

   a. Less than 4 cm

   b. Low-risk pathology

   c. Unifocal/solitary thyroid nodule

   d. Intrathyroidal

   e. No prior head and neck radiation

   f. No cervical metastasis

2. Isolated, indeterminate nodule (AUS, follicular neoplasm, or suspicious for carcinoma)

   a. Patient may elect for total thyroidectomy to avoid completion thyroidectomy

3. Benign nodule greater than 3 to 4 cm

4. Nodule causing compressive symptoms

Contraindications

1. Uncontrolled, severe hyperthyroidism (relative contraindication)

   a. Risk of intraoperative thyroid storm

2. Pregnancy (relative)

   a. May elect to postpone until postpartum

b. If substantial growth, surgery may be performed in second trimester to reduce risk of miscarriage.

3. Prohibitive comorbid medical conditions

Preoperative Preparation

1. Screen for comorbidities.

2. Document vocal cord movement with indirect laryngoscopy prior to surgery.

3. Assure euthyroid state.

Operative Period

Anesthesia

1. Administer general endotracheal anesthesia.

2. Local anesthesia with sedation may be considered with significant comorbidities such as poor cardiac function, or in pregnant patients.

Positioning

1. Supine

a. Shoulder roll to slightly extend neck and elevate thyroid

b. Head placed in a donut to prevent rotation

2. The bed can be shifted away from anesthesia to provide more surgical space.

3. The back may be elevated 10 to 30° to reduce venous congestion.

4. Prepare neck and upper chest with povidone-iodine or chlorhexidine (entire chest if sternotomy anticipated for a substernal goiter).

5. Arms tucked at the side with padding of elbows and heels.

Perioperative Antibiotic Prophylaxis

1. Perioperative antibiotics are not necessary in clean thyroid surgery.

   a. A single preincision intravenous dose of broad-spectrum antibiotic such as second-generation cephalosporin or clindamycin antibiotic is acceptable.

Monitoring

1. Intraoperative laryngeal nerve monitoring (IONM) may be used.[4]

   a. Endotracheal tube with surface electrodes placed at level of vocal cords

   b. Becoming increasingly popular but efficacy is controversial

   c. No difference in rate of vocal cord palsy between visual identification and IONM

   d. Increased cost and setup time

   e. Not a substitute for gold standard of visual identification and careful dissection

   f. Useful adjunct for identification of the recurrent nerve, which may result in decreased operative time and increased surgeon comfort

Instruments and Equipment

1. Basic head and neck set

2. Ultrasonic scalpel (preferred by the senior author for its hemostatic ability and speed) and bipolar cautery

3. Mahorner, Lone Star, or Weitslander self-retaining retractors may be helpful if an assistant is not available.

4. Kittner/peanut sponges for blunt dissection, retracting and protecting nerves or parathyroid tissue from the heat of electrocautery or ultrasonic technology

5. Babcock forceps are helpful in grasping and retracting thyroid tissue.

6. McCabe dissector

   a. Has curved, precise, nonlocking tips

b. Excellent for identifying and dissection of nerves

7. Surgical clips

Key Anatomic Landmarks

1. Embryology

   a. Thyroid gland arises from the first and second pharyngeal pouches at the foramen cecum.

   b. It descends along the thyroglossal duct, anterior to the hyoid bone, to its final position overlying the second to fourth tracheal rings.

2. Thyroid gland[5]

   a. Lateral lobes: 4 to 5 cm tall, 1 to 2 cm wide, 2 to 4 cm thick

   b. Isthmus: 12 to 15 mm wide, absent in 5% to 10%

   c. Pyramidal lobe: Remnant of the thyroglossal duct, found as a superior extension of the isthmus in 40% to 50%

   d. Tubercle of Zukerkandl: Remnant of the lateral thyroid processes (ultimobranchial bodies), found as posterolateral projection (sometimes bifid) of each lobe in 63% to 78%

   e. Lies within the middle layer of the deep cervical fascia (pretracheal fascia)

   f. Attached by ligaments that are extensions of a thin but tightly adherent capsule, which extends as septa into the thyroid parenchyma, dividing it into lobules.

      1) Superomedial: Anterior suspensory ligament to thyroid and cricoid cartilages

      2) Posteromedial: Posterior suspensory ligament (Berry's ligament) to first and second tracheal rings and cricoid cartilage

3. Vasculature

   a. Arterial

      1) Superior thyroid artery: First branch of the external carotid artery (branch of the common carotid in 16%)

      2) Inferior thyroid artery: Branch of the thyrocervical trunk

3) Thyroidea ima artery (in thyrothymic adipose tissue)

a) Branch of the innominate, subclavian, or right common carotid, internal thoracic arteries, or aortic arch

b) Supplies thyroid isthmus inferiorly

c) Present in 2% to 12%

b. Venous

1) Superior thyroid veins: Run alongside the superior thyroid arteries and join with the internal jugular veins

2) Middle thyroid veins: Join the internal jugular veins

3) Inferior thyroid veins: Frequent anastomoses before joining the innominate veins

c. Lymphatics: Prelaryngeal, pretracheal, paratracheal, parapharyngeal, deep cervical, and supraclavicular nodes

4. Recurrent laryngeal nerve (RLN)

a. Emanates from the vagus nerve as it courses inferiorly, anterior to the aortic arch

1) Left: Wraps around the aortic arch below the ligamentum arteriosum, and returns to the neck in the trachea-esophageal groove

2) Right: Branches from the vagus higher than the left and wraps around the subclavian artery before ascending along the tracheoesophageal groove more laterally than the left

3) Courses beneath the inferior pharyngeal constrictor muscle and passes posterior to the cricothyroid joint

4) Enters larynx above the first tracheal ring, below cricoid cartilage

b. Function

1) External branch: All intrinsic muscles of the larynx (except the cricothyroid muscle)

2) Internal branch: Sensation to the laryngeal mucosa of the glottis and subglottis

c. Landmarks

1) Simon's triangle: Bound by common carotid artery laterally, esophagus medially, and inferior thyroid artery superiorly

2) Variably associated with the inferior thyroid artery

a) Found behind or between branches of the artery in 80%

b) Relationship between the RLN and the inferior thyroid artery different on the left and right in about 50% of cases

3) Usually in the vicinity of the inferior parathyroid gland

4) Majority found within 3 mm of Berry's ligament, often laterally, and sometimes passing through the ligament

5) May pass through the capsule of the thyroid gland

6) Deep to the tubercle of Zukerkandl in 98% of patients

7) Nonrecurrent laryngeal nerves can be found in up to 0.7% of patients.

a) Primarily on the right (associated with aberrant subclavian), except in cases of situs inversus (dextrocardia)

b) May arise at the level of the thyroid cartilage or superior pole of thyroid and course directly into the larynx

8) May divide at various levels, and 40% to 65% bifurcate or trifurcate more than 5 mm below the cricoid cartilage

5. Superior laryngeal nerve (SLN)

a. Arises from the nodose (inferior) ganglion of the vagus nerve about 4 cm above the carotid bifurcation, near the jugular foramen

1) Descends lateral to the pharynx and posteromedial to the carotid sheath

2) Divides into internal and external branches about 2 cm above the superior pole of the thyroid, with the former penetrating through the posteroinferior thyrohyoid membrane

b. Function

1) Internal branch: Sensation and secretomotor function to the supraglottis, epiglottis, base of tongue, piriform sinus, and

upper esophageal sphincter

2) External branch: Cricothyroid and inferior constrictor muscles. Tensor of vocal cords

c. SLN external branch landmarks

1) Sternothyrolaryngeal triangle (Joll's triangle): Bound by the midline medially, superior thyroid pole laterally, and attachments of the strap muscles superiorly

2) The nerve is deep to the superior thyroid artery 82% to 86% of the time and penetrates the inferior constrictor muscle at variable levels.

3) Can be found below and up to 1 cm above the level of the upper pole of the thyroid in 37% of patients

Prerequisite Skills

1. Intricate knowledge of surgical instrument use and meticulous soft tissue/neural dissection

Operative Risks

1. Injury to the recurrent laryngeal nerve

a. Preferential visual identification of the RLN before the thyroid is dissected off of the trachea

2. Injury to the superior laryngeal nerve

a. Carefully dissect out the superior pole to ensure that the SLN is not hidden within the vascular pedicle before ligation.

3. Injury to or devascularization of the parathyroid gland

a. Lateralize parathyroids with their blood supply when medializing the thyroid gland

b. Re-implant normal, frozen biopsy confirmed parathyroids.

4. Intraoperative hemorrhage

a. Anterior jugular veins: Carefully undermine subplatysmal skin flaps

and ligate large vessels.

b. Carotid artery: Use a blunt instrument when dissecting in this region, especially superior pole, and be aware of depth of dissection at all times.

c. Thyroid gland and surface vessels: Use blunt dissection close to the thyroid capsule and meticulously seal or ligate vasculature.

Surgical Technique

Thyroid Lobectomy

1. Marking

   a. Mark a 3 to 5 cm horizontal incision line between the cricoid cartilage and suprasternal notch.

      1) Usually 2 to 3 cm above the sternal notch

   b. Use an existing neck crease or line of relaxed skin tension.

   c. Mark the incision higher in younger patients, because the scar will migrate lower over time and a scar below the clavicle is often unsightly.

2. Local anesthesia

   a. Inject 0.25% bupivicaine with 1:200,000 epinephrine 1 to 2 cm above and below the incision line to reduce distortion, since the arterial supply is coming from below.

3. Incision

   a. Use a #15 blade to incise the dermis to the platysma.

   b. Incise through the platysma to the subcutaneous tissue with electrocautery to the investing fascia.

   c. Avoid injuring the communicating anterior jugular veins.

4. Elevate the skin flaps.

   a. Using skin rakes for tension, subplatysmal flaps are elevated with blunt dissection and electrocautery in the plane just above the investing fascia and anterior jugular veins up to the thyroid notch

and down to the sternal notch.

b. Ligate large vessels with 2 to 0 silk ties.

c. Protect the skin with occlusive material such as Steri-Strips (preferred by the senior author; Fig. 78.1).

1) Suture in place with locking 2 to 0 silk running stitches

2) Protects the skin from heat or instrument injury

d. Place a self-retaining retractor if an assistant is not available.

5. Divide and elevate the strap muscles.

a. Identify the median raphe of the strap muscles.

b. Divide the strap muscles in the midline up to the thyroid notch and down to the sternal notch with electrocautery.

c. Elevate the strap muscles off of the thyroid.

1) Elevate bluntly with a Freer elevator, peanut sponge, or with electrocautery.

FIG. 78.1 The skin edges are protected with running, locking silk sutures after raising subplastysmal flaps.

FIG. 78.2 The strap muscles are divided at the median raphe with electrocautery.

2) The strap muscles should be sacrificed with a healthy margin if there is any tumor infiltration of the muscles.

6. Ligate the superior vascular bundle.

a. Using an Army-Navy retractor, retract the strap muscles superolaterally to expose the superior pole.

b. The sternothyroid and or thyrohyoid muscles may have to be divided to provide better exposure of the superior pole in large goiters.

c. Once the superior vascular bundle has been identified, skeletonize the vessels circumferentially using a right-angle clamp.

d. Make sure the external branch of the SLN is not within the pedicle.

e. Use the ultrasonic device to ligate the superior vascular pedicle (Fig. 78.2).

1) Ligating the superior pole close to the thyroid helps decrease the risk of SLN injury

2) Cauterize the pedicle at two to three areas before transecting the pedicle to ensure hemostasis.

FIG. 78.3 The superior vascular pedicle is ligated with an ultrasonic scalpel close to the superior pole of the thyroid.

3) The proximal stump will retract back into the neck, and bleeding from the stump can be difficult to control.

4) Electrocautery, surgical clips or ties may also be used to augment superior pedicle ligation.

7. Mobilize the thyroid medially.

a. Dissect the thyroid carefully inferiorly and medially using a peanut sponge.

b. The thyroid can be retracted with Babcock clamps for relatively atraumatic grasping.

c. The middle thyroid veins are encountered and ligated with the ultrasound scalpel.

8. Identify the RLN.

a. Rotate the thyroid gland medially.

b. Using the McCabe dissector, dissect near the cricothyroid joint and the tracheoesophageal groove to identify the RLN.

1) Do not close the clamp when the tips are buried in tissue.

2) Once the RLN is identified, dissecting parallel and directly on the nerve sheath prevents damaging the nerve and its branches (Fig. 78.3).

3) Trace the RLN from the paratracheal region up to the

cricothyroid muscle, being careful not to damage either the anterior or posterior branch.

c. Once the RLN has been identified, transect Berry's ligament with the ultrasonic device.

1) Take care to protect the RLN by retracting it gently with a peanut sponge to avoid heat from the ultrasonic blades and heated fluids generated from cautery.

2) Sometimes a small cuff of thyroid tissue may have to be left behind to prevent injury to the RLN.

d. Carefully dissect and lateralize the parathyroid glands with their blood supply when dissecting the thyroid capsule.

1) The parathyroids usually receive their blood supply from the inferior thyroid arteries, but the superior parathyroids may derive their arterial supply from the superior thyroid artery.

2) Auto-transplant any parathyroid glands that have been devascularized immediately.

a) Send a biopsy for frozen pathology to confirm normal parathyroid tissue.

3) Finely mince the parathyroid gland before re-implantation.

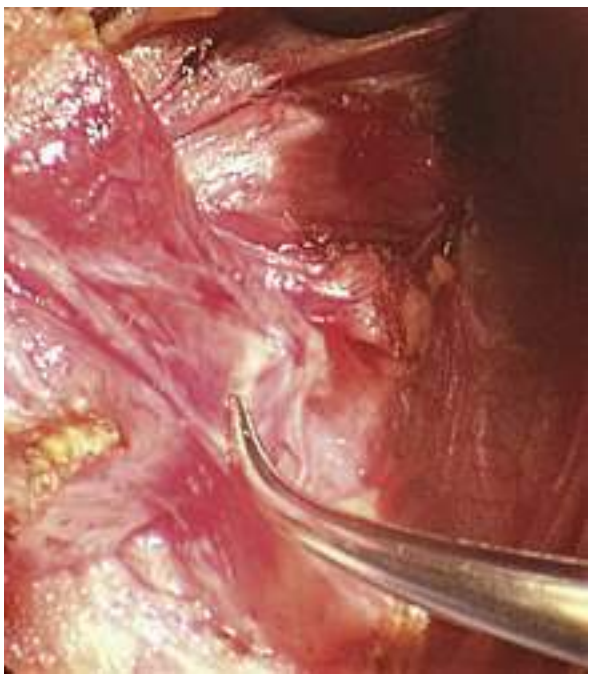

FIG. 78.4 The recurrent laryngeal nerve is found and dissected along its pathway immediately on top of the nerve with a McCabe dissector.

4) Implant in muscle pockets of the ipsilateral strap or sternocleidomastoid muscle.

e. Do not suction near the RLN or on the parathyroid glands.

9. Deliver the thyroid lobe and ligate the inferior pole.

a. Once the RLN and the inferior parathyroid gland have been safely identified, ligate the inferior vascular pedicle while the thyroid is mobilized medially.

1) Make sure to identify early branching of the RLN near the inferior pedicle before ligating the pedicle.

2) Ligate the inferior pedicle close to the thyroid to avoid devascularizing the inferior parathyroid.

b. Using the ultrasonic device, dissect the thyroid off of the trachea along the pretracheal fascia.

1) Keep the active blade of the ultrasonic device away from the trachea.

2) Protect the recurrent nerve with a moistened peanut (Fig. 78.4).

c. Transect the thyroid at the junction of the isthmus and the contralateral lobe.

d. Remove the pyramidal lobe if present, up to the thyroid notch.

10. Achieve hemostasis

a. Irrigate the wound thoroughly, and evaluate bleeding during Valsalva by anesthesia with bipolar cautery hemostasis.

b. Hemostatic agents such as Surgicel may contribute.

c. A drain is not typically used.

11. Wound closure

a. The strap muscles are approximated with absorbable sutures (3-0 vicryl).

1) Leave a space inferiorly to allow drainage of potential

hematomas.

b. Approximate the platysma layer carefully.

c. Close the skin with absorbable subcuticular stitches (4-0 monocryl).

d. Dress the skin with an adhesive such as Mastisol and apply Steri-Strips.

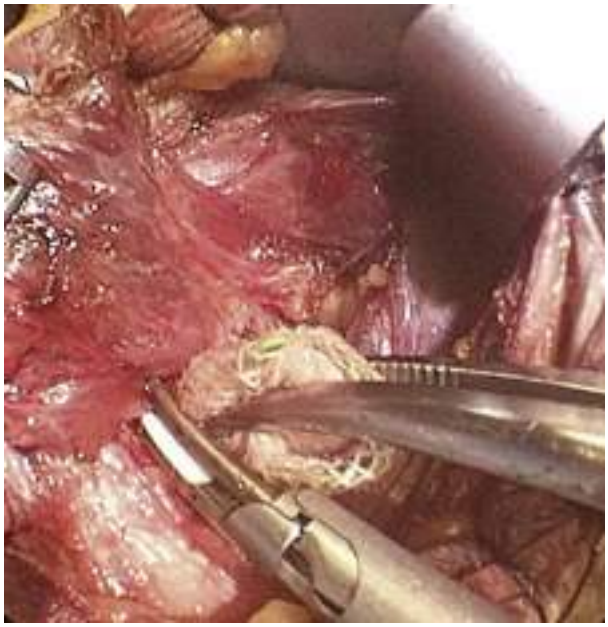

FIG. 78.5 The thyroid lobe is dissected off the trachea with an ultrasonic scalpel, while the recurrent laryngeal nerve is protected with a peanut sponge.

Total Thyroidectomy

1. The contralateral side is removed in the same manner as the previously described lobectomy.

2. It is especially important to prevent excessive manipulation of the parathyroid glands to prevent temporary calcium imbalance after total thyroidectomy.

3. Carefully inspect and palpate the thyroid bed and surrounding areas for irregular lymph nodes, possible residual thyroid tissue, or other suspicious lesions, and send to the pathology department.

4. If cartilage invasion is present, shave resection may suffice but is not

preferred.

a. Shave resection is defined as removal of all macroscopic disease without formal resection of the full thickness of the adherent trachea or larynx.

b. There is no survival benefit with extensive resection versus shave resection; however, the recurrence rate is decreased with en bloc resection.

5. Management of the neck in differentiated thyroid cancer

a. Remove central compartment (level VI) nodes if there were suspicious nodes on preoperative imaging or intraoperative exploration.

b. Perform a selective or modified radical neck dissection for metastatic lateral neck lymph nodes after biopsy proven metastasis is identified.

c. Elective neck dissection is not indicated.

d. Do not "berry pick" individual nodes.

Common Errors in Technique

1. Failure to skeletonize the superior pole before ligation, risking injury to the superior laryngeal nerve

2. Failure to identify the RLN, its pathway, and both branches (Fig. 78.5)

3. Not dissecting directly on top of the RLN when following its course

4. Transecting vasculature to the parathyroid glands

5. Inadequate hemostasis throughout surgery puts nerves and parathyroids at risk.

6. Overstretching and burning the skin edges with hot instruments

Postoperative Period

Postoperative Management

1. Check serum parathyroid hormone (PTH) after 1 hour in the recovery unit for total or completion thyroidectomy.

   a. Implement overnight observation if PTH is less than 15 pg/mL.

   b. Serum calcium may take more than 12 hours to stabilize with a change in PTH.

2. Pain medications: Ibuprofen or acetaminophen with narcotics for breakthrough

3. Wound care

   a. Neck incision may be wet after 48 hours.

   b. Examine the patient in 1 week and replace Steri-Strips to prevent scar formation.

4. Thyroid replacement medication is necessary if total thyroidectomy is performed.

   a. Thyroid hormone withdrawal for RAI treatment

   b. May start liothyronine and stop 2 weeks prior to RAI

5. RAI therapy will be dependent on the pathology of the tumor and presence of metastasis.

Complications

1. Hematoma

   a. Usually detected within 2 hours of surgery

      1) Dyspnea

      2) Dysphagia

      3) Expanding mass

   b. Immediately open incision and suction out blood and clots to prevent airway obstruction and prevent the patient's death.

   c. Take the patient back to the operating room to explore the wound and achieve hemostasis.

2. RLN injury

   a. Hoarseness and a weak voice with the vocal cord in the paramedian

position

b. The patient may aspirate.

c. Intraoperative transection may require immediate re-anastomosis, which may provide tone and decrease vocal cord atrophy.

d. Consider early vocal cord medialization for known transection.

e. Bilateral RLN injury will result in airway distress and stridor after extubation, and may necessitate re-intubation and tracheostomy (Fig. 78.6).

3. SLN injury

a. Results in difficulty projecting voice or poor pitch control in high frequencies

b. Voice therapy may be helpful.

4. Hypoparathyroidism

a. Risk with total or completion thyroidectomy or patients previously operated for hyperparathyroidism

b. The patient may need oral calcium carbonate and vitamin D supplementation temporarily or for life.

c. Treat severe symptoms with IV calcium gluconate.

d. Implement cardiac monitoring in cases of severe hypocalcemia.

FIG. 78.6 Following the recurrent laryngeal nerve pathway led to identification of two branches, both of which must be traced and protected before dissecting the thyroid off the trachea.

Alternative Management Plan

1. Endoscopic or robotic thyroid surgery

2. Low risk nodules may be observed with serial US exams every 6 to 12 months

3. Chemotherapy and/or radiation for anaplastic thyroid cancer

Discussion

Evidence-Based Medicine Question: What is the role of prophylactic central neck dissection (CND) in thyroidectomy?

A meta-analysis in 2010 of 1264 patients comparing thyroidectomy versus thyroidectomy with CND showed no difference in central or lateral neck recurrence, and a retrospective study of 266 patients in 2009 showed no advantage in disease-free survival in patients undergoing prophylactic N0 CND. A meta-analysis in 2009 of 1132 patients showed

an increased risk of temporary hypocalcemia in those undergoing CND, but not of temporary or permanent vocal cord paralysis. Another large retrospective study found increased temporary and permanent hypoparathyroidism in those undergoing CND. At this time, prophylactic CND is likely not indicated and may cause significantly increased morbidity, except possibly in T3 or T4 disease or if there are involved lateral neck nodes.

Editorial Comment

Thyroidectomy has evolved over the last 150 years to become a safe and reproducible treatment for many thyroid problems. While complications are still a risk, these can be minimized by adherence to standardized principles of hemostasis, preservation of the parathyroids, and identification of the recurrent laryngeal nerves. Most patients can expect to safely undergo outpatient surgery with minimal cosmetic sequelae.

Review Questions

1. Landmarks for the RLN include all of the following except

   a. The inferior thyroid artery

   b. Berry's ligament

   c. The tubercle of Zukerkandl

   d. **The superior parathyroid gland**

2. Which of the following is not a direct complication of thyroid surgery?

   a. Tracheocutaneous fistula

   b. **Hypercalcemia**

   c. Carotid artery injury

   d. SLN damage

3. Which of the following is not an indication for total thyroidectomy?

a. **A 2 cm benign thyroid nodule found during pregnancy**

b. A 3 cm isolated papillary thyroid carcinoma

c. A 1.7 cm thyroid nodule containing malignancy in a 60-year-old female

d. A 0.5 cm thyroid nodule containing medullary thyroid carcinoma

Minimally Invasive Video-Assisted Thyroidectomy

Robert L. Ferris, and Meghan T. Turner

Introduction

Thyroid nodules are a common clinical problem, diagnosed by palpation on clinical examination in approximately 5% of women and 1% of men in Western society. Their presence requires evaluation to exclude thyroid cancer, the incidence of which is 15% in at-risk groups. In recent decades, the incidence of thyroid cancer has nearly tripled from 4.9 per 100,000 in 1975 to 14.3 per 100,000 in 2009. Today, it is currently the 10th most common cancer among men and women in the United States, according to the Centers for Disease Control. The National Cancer Institute's surveillance, epidemiology, and end results (SEER) Program estimates that there will be 62,450 new cases of thyroid cancer in 2015, accounting for 3.8% of all new cancer diagnoses but only 0.3% of all cancer deaths.[1] The increased incidence is partially attributed to the increasing use of high-resolution ultrasound in the evaluation of benign thyroid disease and solitary thyroid nodules as well as the discovery of "incidentalomas" on high-resolution computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scans performed for other indications.[1] In recent years, increasingly strict guidelines have been created to prevent overtreatment. There has also been a trend toward development of less invasive techniques in order to prevent morbidity in young patients with benign and low-risk papillary thyroid cancer (PTC).

In the 1990s, surgeons in Japan and Italy pioneered the development of endoscopic surgery for both benign and malignant thyroid pathology. This was driven by patient demand for either a smaller cervical scar or no scar, instead of the 8-cm incision originally described by Kocher.[2]

Since the first minimally invasive approach, various techniques have been described in the literature (Table 79.1).

The technique now known as minimally invasive video-assisted thyroidectomy (MIVAT), which has demonstrated widely reproducible results, will be the focus of this chapter. First and best described by Miccoli[2] in 1999 for the treatment of benign thyroid disease, this technique has been expanded to include solitary nodules, low-to-intermediate risk malignancy, and central compartment neck metastases. Groups in the United States have tested its efficacy and safety, while expanding indications to include previous, relative contraindications such as patients with high body-mass index, thyroiditis, prior neck surgery, larger nodules, goiters, and completion lobectomies.[3-5]

Key Operative Learning Points

- Careful patient selection is necessary for safe and expedient MIVAT surgery. Ideal candidates for MIVAT have nodules less than 3.5 cm and a thyroid gland volume less than 25 mL.
- Subplatysmal flaps are unnecessary and create dead space for seroma formation.
- Two assistants are needed: one to hold the retractors and expose the superior pole and tracheoesophageal groove and another to hold the endoscope during dissection of the superior pole, parathyroid glands, and the recurrent laryngeal nerve.
- Use of the harmonic scalpel for superior and inferior pole vessels can significantly reduce operative times.
- Conversion to open thyroidectomy (OT) should be performed for posterior nodules that prevent visualization of the recurrent laryngeal nerve (RLN), large glands that cannot be delivered through the incision, or excessive bleeding that prevents safe identification of the RLN.

Preoperative Period

Ideal candidates for MIVAT include patients with asymptomatic solitary

nodules or patients with low-to-intermediate risk well-differentiated thyroid cancer and account for about 10% of all patients referred for thyroidectomy.[6] Careful patient selection is necessary in the preoperative evaluation for MIVAT, especially for the novice surgeon. Clinical evaluation of any patient with a mass in the thyroid gland begins with a careful history and physical examination. The history, physical examination, and workup should help the surgeon exclude patients with the absolute and relative contraindications to this surgical technique, according to the surgeon skill set.

History

- History of present illness
  - Presentation: How and when was the thyroid nodule discovered?
  - Has it been biopsied under ultrasound?
  - Does the patient have any symptoms of hyper- or hypothyroidism?
  - Does the patient have hoarseness, dyspnea, dysphagia, or aspiration?
  - Has the patient noticed any masses in his or her neck?
  - Has the patient noticed progressively enlarging nodules?
- Past medical history
  - Has the patient been diagnosed with hyper- or hypothyroidism?
  - Does he or she have other autoimmune disease, such as Grave's disease or acute Hashimoto's thyroiditis?
  - Has the patient had prior radiation of the head and neck?
  - Has the patient been exposed to ionizing radiation?
  - Does the patient have a history of previous cardiac stent, deep vein thrombosis, or pulmonary embolization requiring anticoagulation or antiplatelet therapy?
  - Is the patient pregnant?

TABLE 79.1

Minimally Invasive and Endoscopic Thyroidectomy Techniques
Minimally invasive—mini-incision
Video-assisted transcervical endoscopic
Completely closed endoscopic
Transcervical approach
Axillary approach
Anterior chest approach
Breast approach

- Past surgical history
  - Has the patient had any previous thyroid surgery or parathyroid surgery?
  - Has the patient had other prior neck surgery?
- Family history
  - Is there a family history of thyroid cancer or cancer-related syndrome?
  - Is there a family history of thyroid disease?
  - Is there a presence of familial bleeding disorders?
  - Is there a family history of hyperthermia or acetylcholinesterase deficiency with any previous anesthesia?
- Medications
  - Is the patient taking thyroid hormone replacements?
  - Is the patient on antiplatelet therapy or anticoagulation?

Physical Examination

- Voice
  - Assess the quality of voice; is it coarse or breathy?
- Breathing

- Does the patient have stridor?

- Thyroid gland
  - Assess the size of the nodule and its mobility on swallowing.
  - Assess the mobility of the overlying tissues.

- Neck
  - Palpate deeply to detect any cervical lymphadenopathy that would suggest metastatic disease, as this would be a contraindication to MIVAT and would require OT with neck dissection.
  - Examine the neck in extension in order to detect any substernal extension that might require OT.

- Flexible laryngoscopy
  - Preoperative paresis or paralysis suggests invasive cancer that should be treated with open techniques.
  - Identification of contralateral paralysis is also crucial in patients who are to undergo completion lobectomy.

Imaging

- Ultrasound and ultrasound-guided fine-needle aspiration biopsy (US-FNAB)
  - Ultrasound can detect additional suspicious nodules (solid or hypoechoic nodules with irregular margins, microcalcifications, and/or taller than wide shape, as well as evidence of soft tissue invasion or extrathyroidal extension), hypervascularity associated with thyroiditis, large thyroid volume, or substernal extension that may contraindicate MIVAT.[7]
  - Ultrasonography of the neck to evaluate lateral lymph nodes for cervical metastases is indicated for all patients being considered for MIVAT. Those patients with lateral metastases should have OT and selective neck dissection.[2,8]

- CT/MRI neck
  - Patients are often referred for evaluation of a thyroid nodule after incidental discovery on other imaging. For those cases where CT or

MRI leads to detection of the nodule, no further imaging of the neck is necessary to look for metastatic cancer.

- PET/CT
  - The incidence of focally, fluorodeoxyglucose-avid (FDG-avid) thyroid nodules on PET-CT performed for other means is 1% to 2%. Because there is a 35% risk of cancer in such cases, hemi-thyroidectomy is indicated for pathologic tissue analysis.[7]

Indications

The main indications for MIVAT in the literature include benign lesions, indeterminate nodules, and low-risk papillary thyroid carcinoma.[3-5,8]

- Small thyroid nodules (25 to 30 mm in diameter)
- Thyroid gland volume (about 20 cm^3)
- No evidence of acute thyroiditis
- Specific groups
  - Children
    - Thyroid masses in children are most commonly well-differentiated papillary thyroid carcinoma (WDPTC) and medullary thyroid carcinoma (MTC).
    - Fine-needle aspiration biopsy (FNAB)–proven, WDPTC is an indication for MIVAT.
    - FNAB-proven MTC is a relative contraindication, as the patient requires total thyroidectomy with central compartment and possible lateral neck dissections. Prophylactic treatment of pediatric patients with familial disease and positive RET (rearranged during transfection) proto-oncogene testing, who display no evidence of thyroid nodules or neck metastases on exam or imaging, can be treated by MIVAT alone in experienced hands.[8] An advantage of MIVAT in these two patient populations is the significant reduction in postoperative pain, as compared with standard thyroidectomy.
  - Patients with a history of exposure to ionizing radiation

- Patient's with occupational or environmental radiation exposures are considered to be in the high-risk category and are more likely to have multifocal cancer requiring total thyroidectomy. A third of abnormalities in the thyroid gland in patients with a history of radiotherapy will be malignant.[7] These patients are perfect candidates for MIVAT.
- Patients with a history of therapeutic head and neck radiation should undergo OT, as the radiation creates scarring, radiation changes and an adverse surgical field with increased risk for bleeding.

- Geriatric patients
  - This group can undergo MIVAT safely with low morbidity, as with younger patients. However, MIVAT has been shown to require longer anesthesia times as compared with conventional techniques in inexperienced hands.[6,9] Therefore only experienced surgeons, with comparable operative times to conventional open approaches, should offer MIVAT for patients in the geriatric age group.[6]

Contraindications

As centers have become more facile with MIVAT, the indications have expanded and the contraindications have been revised. For example, many groups have proven that larger nodules, nodules in patients with Hashimoto's thyroiditis, Grave's disease, prior neck surgery (as in completion thyroidectomy), and central compartment lymph node metastases requiring central neck dissection are no longer contraindications, but should still remain relative contraindications in less than experienced hands.[3,4,8]

- Absolute contraindications include thyroid disease requiring OT.
  - Large multinodular goiters
  - Substernal thyroid nodules or goiters
  - Revision thyroidectomy
  - Prior ipsilateral neck surgery or external beam radiation to the neck

- Biopsy proven MTC
- Presence of lateral lymph node metastases

- Relative contraindications include conditions that would make minimally invasive approaches more difficult and therefore increase morbidity.
  - Active thyroiditis
  - Grave's disease
  - Adverse anatomic aspects (short neck in the obese patient)
  - Nodules greater than 4 cm
  - Completion thyroidectomy
  - Central compartment metastases

Preoperative Preparation

- Thyroid function tests
  - Preoperative thyroid-stimulating hormone (TSH) levels with reflexive triiodothyronine (T_3) and thyroxine (T_4) testing to ensure the euthyroid state and avoid thyroid storm.
  - Subnormal TSH levels require a radioactive iodine scan to diagnose a possible benign hyperfunctioning adenoma that can be medically treated.
- Serum thyroglobulin
  - Thyroglobulin levels are not routinely indicated in the preoperative workup of nodules and low-risk cancer, as they can be elevated in many types of thyroid disease.
- Antibodies
  - Antithyroglobulin antibody, antithyroid peroxidase antibody, and thyroid stimulating immunoglobulin can rule in or rule out thyroiditis, which is a relative contraindication to MIVAT. This may be particularly helpful to the novice surgeon and discourage his or her use of MIVAT, due to the higher likelihood of intraoperative bleeding and less favorable conditions for identification and

preservation of the RLNs and parathyroid glands.

- FNAB
  - FNAB should be performed on thyroid nodules greater than 1 cm and suspicious cervical lymph nodes and sent for cytologic analysis according to the Bethesda Guidelines for Cytologic Evaluation and Reporting.[7]
  - FNAB may diagnose atypia, a follicular lesion, or a Hürthle cell lesion, in which case one might perform a minimally invasive thyroid lobectomy for diagnosis and risk stratification.
- Molecular testing
  - Testing for various mutations known to be associated with a high-risk of malignancy has been performed on FNAB specimens, allowing surgeons to be more selective about performing diagnostic lobectomy for Bethesda III and IV lesions using minimally invasive techniques.

Operative Period

Anesthesia

- MIVAT is usually performed with the patient under general anesthesia. MIVAT has been described under local anesthesia, employing bilateral cervical plexus blocks.[2]
- Careful preoperative planning with the anesthesia team is required. Only short-acting paralytic agents should be administered if the surgeon intends to use intraoperative nerve monitoring (IONM).
- For those cases where IONM is being employed, intubation should be carried out with the GlideScope or followed by direct laryngoscopy so that the surgeon can observe proper placement of the endotracheal electrodes in the larynx.

Positioning

- The patient is placed in supine position and centered on the table.

- Arms should be tucked at the patient sides, with care to protect the ulnar nerves.
- The head is positioned at the very top of the table and stabilized with a donut cushion.
- A shoulder roll facilitates exposure of the gland in patients with a short neck, but it is sometimes not necessary.
- Excessive neck extension should be avoided.
- Ventilation tubing extensions are required so that the table may be moved away from the anesthesia team and allow for the positioning of the endoscopic video tower and slave monitor at the patient's head, where the surgeon and endoscopist can easily see them (Fig. 79.1).

Perioperative Antibiotic Prophylaxis

- Thyroidectomy is considered "clean head and neck surgery." Thus perioperative antibiotics are not required.
- Administration of one dose prior to surgery for coverage of skin flora is acceptable. The most common choice is a first-generation cephalosporin or clindamycin, for those with penicillin allergy that may have cross-sensitivity to cephalosporins.

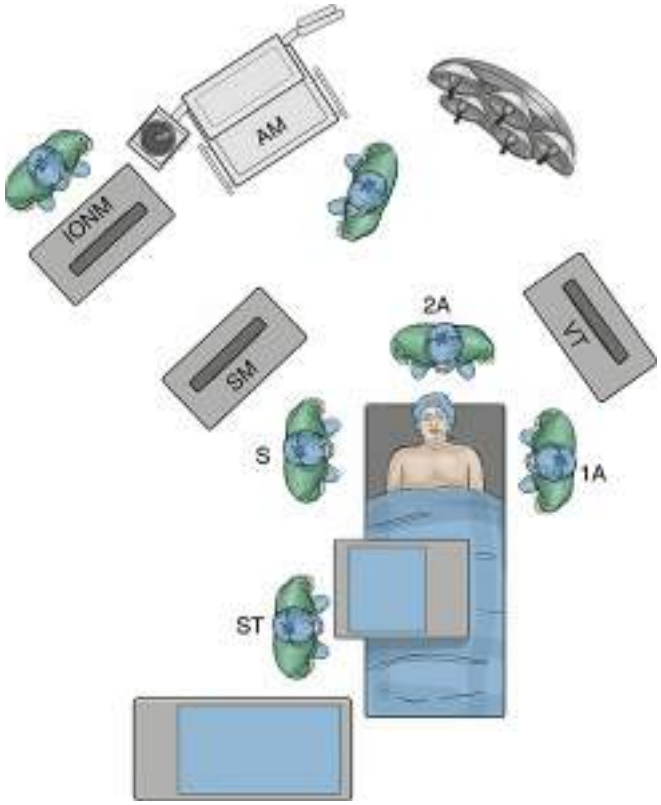

FIG. 79.1 Operating room setup plays an important role in minimally invasive video-assisted thyroidectomy.

The surgical team needs adequate room for the surgeon, two assistants, a video tower, and a slave monitor. This requires adequate distance from the anesthesia monitor and team, with the use of ventilation tube extensions. It also involves positioning of nerve monitoring equipment. *AM,* Anesthesia machine; *IONM,* intraoperative nerve monitoring system; *SM,* slave monitor; *ST,* surgical tech; *S,* surgeon; *VT,* videotower; *1A,* first assistant/endoscopist; *2A,* second assistant.

Monitoring

- Intraoperative nerve monitoring (IONM) of the RLN is routinely used by many groups.[3-5,8]
- Endotracheal tube electrodes are placed in contact with the mid vocal folds bilaterally under direct vision by the surgeon.
- The nerve is stimulated when identified to confirm identification and

integrity.

- It is then stimulated after lobectomy.

Detectable responses after direct stimulation of the RLN confirm that the nerve is intact and functional after lobectomy. Loss of response after lobectomy may indicate injury or neuropraxia in an intact nerve and may direct immediate management, allowing the surgeon to abort a total thyroidectomy in favor of completion thyroidectomy when nerve function returns.

Instruments and Equipment to Have Available

- Standard neck dissection/thyroid set
- Endoscopic video tower and slave monitor
- 5-mm 30-degree endoscope
- Endosurgery harmonic scalpel
- Bipolar forceps and cautery
- Intraoperative nerve monitoring system and nerve stimulator

Key Anatomic Landmarks

- Same as for conventional OT. See Chapter 102.

Prerequisite Skills

- Same as for conventional OT. See Chapter 102.
  - Some groups have described the need for conversion to OT in those cases where unexpected bleeding is encountered, in cases of substernal goiter, or when the RLN cannot be identified prior to removal of the lobe.
  - A recent systematic review of randomized controlled trials looking at MIVAT versus OT found the conversion rate to be 3.4%.[9] This number varies with the experience of the surgeon, the selection

criteria, and the difficulty of the case being attempted.

- Central compartment neck dissection (CND)
  - Suspicious central compartment nodes appreciated by the surgeon at the time of surgery or thyroid cancers with high risk of central neck metastases (such as follicular variant) may require elective central neck dissection. Several groups have shown that this can be safely performed with MIVAT.[3,4,8]

Surgical Technique

Minimally Invasive Video-Assisted Thyroidectomy

- The incision is designed in a line of relaxed skin tension (Fig. 79.2). The best time to plan the incision is in the preoperative area while the patient is in the upright, sitting position with the neck in neutral position.[5] In a patient who has a long, slender neck, the incision must be placed somewhat more superior to be able to achieve adequate exposure. The incision should ideally be 2 to 3 cm.[3]
- Surgeons performing total thyroidectomy should begin the operation on the side of the biopsy-proven cancer or suspicious nodule to ensure removal of the suspected malignancy should the case need to be aborted after lobectomy. The surgeon should then switch sides for removal of the contralateral lobe.

FIG. 79.2 Postoperative incision site following minimally invasive video-assisted thyroidectomy procedure.

The incision has reverted to the 2.0-cm initial length approximately 1 month after minimally invasive video-assisted thyroidectomy. From Lai ST, Walvekar RR, Ferris RL: Minimally invasive video-assisted thyroidectomy: Expanded indication and oncologic completeness. *Head Neck* 30(11):1403-1407, 2008.

- The incision may be made with a cutting instrument, whether a cold knife, electrocautery, or a Shaw scalpel. The incision is carried down through the platysma muscle, avoiding injury to the anterior jugular veins.
- Subplatysmal flaps are intentionally avoided during MIVAT, as this does not increase exposure and increases the risk of seroma.
- The median raphe of the strap muscles is then opened widely, from approximately 2 to 3 cm above the cricoid and inferiorly below the gland.
- The thyroid gland is then mobilized from the strap muscles and carotid sheath with meticulous blunt dissection and careful hemostasis, using retractors (Army-Navy, Terris retractors, or Micolli retractors) and Kitner sponges on a Kelley clamp.
- The superior pole is then isolated with retraction inferiorly and blunt dissection. A Babcock clamp helps with this maneuver.
- The 30-degree endoscope is introduced into the wound, visualizing the superior pole. The external branch of the superior laryngeal nerve (SLN) can be identified with endoscopy and preserved with gentle upward retraction and by ligating the superior pole vessels as they enter the superior pole (Fig. 79.3).
- The harmonic scalpel is used to ligate vessels at 12 o'clock, 10 o'clock, and 2 o'clock positions, ensuring safe and expeditious control of the blood supply of the thyroid gland.[10]
- The thyroid gland is then delivered through the wound and retracted medially using blunt Sen retractors.
- The endoscope is kept in the operative field and aids in identification

and preservation of the parathyroid glands in their adipose tissue pads near the tubercle of Zuckerkandl and the inferior thyroid artery (see Fig. 79.3). Once the adipose tissue pads are dropped laterally, the RLN is identified and preserved.

- Once the nerve is exposed, wet sponges and Kitners should be used for hemostasis to prevent retraction injury and trauma to the nerve.
- The branches of the inferior thyroid artery should be identified and ligated as they enter the gland just medial to the parathyroid glands, either with bipolar cautery or clips. Great care is taken to identify and visualize the course of the RLN prior to ligation. Small bleeding vessels around the nerve should be controlled using patience, pressure, and precise bipolar cautery, so as not to injure the nerve.

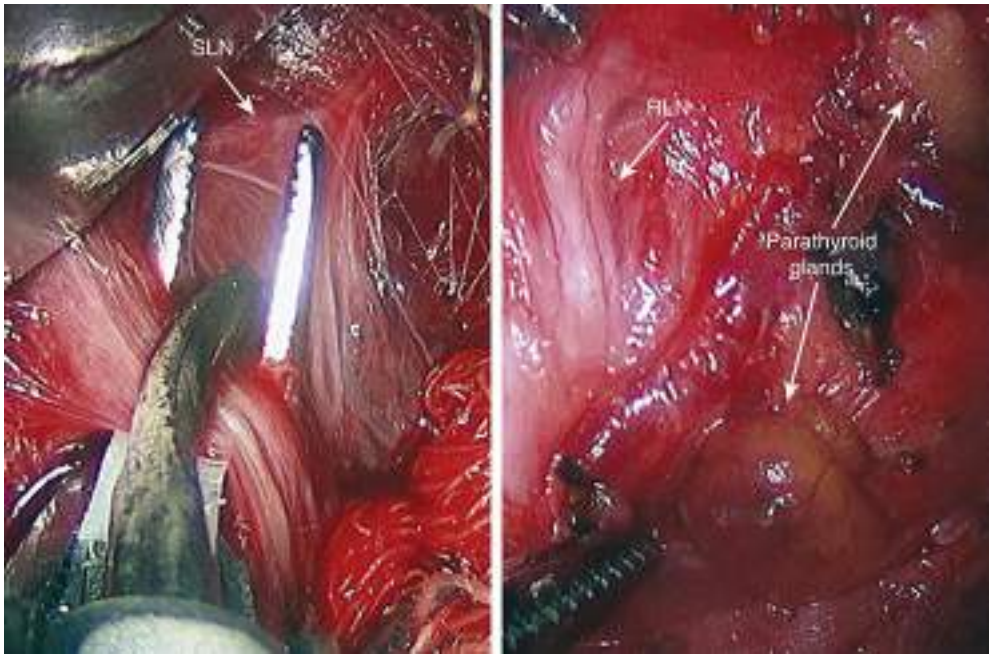

FIG. 79.3 Improved visualization of critical anatomic structures.

Minimally invasive video-assisted thyroidectomy permits excellent intraoperative visualization of the superior laryngeal nerve *(SLN; left panel)*, as well as the recurrent laryngeal nerve (RLN) and parathyroid glands *(right panel)*. From Lai ST, Walvekar RR, Ferris RL: Minimally invasive video-assisted thyroidectomy: Expanded indication and oncologic completeness. *Head Neck* 30(11):1403-1407, 2008.

- The RLN should be dissected until it enters the larynx and is freed from the thyroid lobe. Berry's ligament can then be exposed and transected. This is first done sharply with tenotomy scissors in order to prevent thermal injury to the RLN. Then monopolar cautery can be used to dissect the lobe and isthmus from the trachea.
- The isthmus can either be divided with the harmonic scalpel or left intact while the surgeon proceeds with mobilization of the contralateral lobe in cases of total thyroidectomy via MIVAT.
- The specimen is appropriately marked and sent to pathology. All bleeding points are controlled, and the wound is irrigated. Surgicel is placed within the wound.
- Gelfoam is placed in the tracheoesophageal groove to protect the parathyroid glands and RLN during closure.
- The strap muscles are then loosely approximated in the midline with 3-0 Vicryl suture. The platysma is also reapproximated with 3-0 Vicryl suture. The dermis is then reapproximated using undyed 4-0 Vicryl, and the skin is closed with a 4-0 monofilament suture in running subcuticular fashion. Finally, adhesive and Steri-Strips are applied to the skin.

Common Errors in Technique

- An unsightly scar may result from a poorly designed incision that is not in a relaxed skin tension line or those that lie too low over the clavicles.
- Raising subplatysmal flaps creates more dead space, puts patients at risk for postoperative seroma, and may require postoperative drain placement.
- Failure to identify the RLNs may lead to inadvertent transection.
- Failure to identify and preserve the parathyroid glands on at least one side may result in hypoparathyroidism and hypocalcemia.
- Failure to maintain a bloodless field can result in difficult visualization and possible injury to the RLNs and parathyroid glands.

Postoperative Period

Postoperative Management

- Postoperative care is best undertaken by nurses experienced with thyroidectomy patients, because of the potential for airway complications and postoperative hypocalcemia.
- Patients who have undergone a lobectomy are regularly discharged the same day after a short period of observation.
- Patients who are undergoing completion lobectomy or total thyroidectomy may need to stay for calcium monitoring. Serial serum calcium levels are used to help guide postoperative calcium supplementation. Most patients are discharged by postoperative day 1 when calcium levels stabilize and require some level of calcium and vitamin D supplementation. Patients with symptomatic hypocalcemia are supplemented with additional doses. Those that resolve with immediate oral calcium are managed expectantly. Those that do not are asked to come to the ER for measurement of serum calcium levels and are treated accordingly.
- Hypothyroidism after total thyroidectomy is managed with hormone replacement. Levothyroxine sodium or liothyronine may be initiated in the immediate postoperative period, depending on the pathology report.
- ^{131}I scanning can be used postoperatively to determine the completeness of the surgical procedure and to detect residual or metastatic cancer. Small foci of residual cancer or occult distant metastasis can be adequately treated with therapeutic doses of radioactive iodine. Patients with thyroid carcinoma treated by MIVAT can be expected to have similar radioactive iodine scanning results as those treated by OT.[3] Postoperative thyroglobulin levels are also similar among patients with well-differentiated thyroid cancer (WDTC) treated by MIVAT and conventional OT and can thus still be used for surveillance in patients with WDTC who have elevated serum thyroglobulin preoperatively.[3]

Complications

- Prominent or hypertrophic scarring
  - A low incision, planned when the patient is in the extended position, may come to rest over the clavicles. This may produce a stretched or prominent scar that can be disguised only by clothing or jewelry.
- Hematoma
  - This complication is rare after both OT and MIVAT. A recent meta-analysis of randomized controlled trials comparing outcomes following OT and MIVAT found no difference in the rate of postoperative hematoma between groups. Similarly, the rate of postoperative hematoma was not increased in any of, and was not seen in any of the large tertiary care cancer centers looking at expanded indications for MIVAT.[3-5,9]
  - I Hematoma is generally detected in the first few hours after surgery and presents as a mass in the anterior neck, sometimes with overlying ecchymosis, bleeding from the incision, and loss of palpable landmarks (including cricoid and sternal notch). As it expands, the patient may develop hoarseness or stridor and finally experience respiratory distress.
  - Circumferential neck dressings are forbidden, as they prevent nurses and physicians from recognizing potential cervical hematoma. A constricting dressing in the presence of an expanding hematoma places the patient on a "death trajectory" from compression of the airway.
  - Hematoma s occur because of insufficient hemostasis at the time of surgery. All patients should be observed in the post-anesthesia care unit (PACU) for several hours prior to discharge in order to allow for prompt return to the operating room if a hematoma develops.
- Nerve injury
  - The external branch of the SLNs and the RLNs is vulnerable to injury during MIVAT.
  - In a systematic review of randomized controlled trials comparing MIVAT and OT, there were no reported injuries to the external

branch of the SLN in those undergoing MIVAT, while 2% of patients incurred this injury following OT.[9]

- Current rates of temporary and permanent injury to the RLN reported in the literature are comparable to that reported after OT. Transient injury rates range from 4.8% to 17%, being higher in studies in which routine postoperative laryngoscopy was performed in the PACU.[3,4] Permanent injury rates, defined as recurrent nerve dysfunction lasting longer than 6 months, are reportedly low, ranging from 0% to 1.9% in single institution studies[3-5] and 0.3% in a systematic review.[9] Unilateral recurrent nerve paralysis is often asymptomatic in the immediate postoperative period and not often symptomatic until postoperative day 2 or 3. Patients suspected of injury to the nerve should have indirect laryngoscopy performed either in the PACU or at the first postoperative visit to confirm the presence of vocal cord paresis/paralysis.[5] To date, no case of bilateral cord paralysis following MIVAT has been reported.

- Hypoparathyroidism
  - The rate of this complication is not reported to be significantly different between groups following MIVAT or OT, reported as 4.1% and 3.7%, respectively.[9] If thyroid lobectomy has been carried out, no further testing is done in the postoperative period unless the patient has previously undergone thyroid surgery. We implement oral calcium and vitamin D supplementation on all patients undergoing a total or completion thyroidectomy. Serum magnesium is drawn and repleted as necessary, since it is a cofactor for the functional parathyroid hormone (PTH). Serum calcium levels are measured repeatedly on the first and second postoperative days in order to prescribe tailored supplementation based on serum calcium levels.

Alternative Management Plan

- Operative
  - Conversion to OT for hemorrhage or inability to identify the RLN
- Postoperative care

- Patients undergoing total thyroidectomy may be observed as described with serial calcium levels.
- Alternatively, patients may be discharged with a planned, postoperative calcium taper without measurement of calcium levels, unless the patient develops symptoms of hypocalcemia that are not treated with additional oral calcium.
- Postoperative PTH levels can also be drawn after surgery to guide postoperative calcium management. PTH levels less than 10 pg/dL may predict transient hypocalcemia, require overnight observation, and the addition of calcitriol to the postoperative calcium regimen.

- Observation with serial imaging for medically fragile patients
- Radioactive Iodine therapy, external beam radiation or tyrosine kinase inhibitors for unresectable thyroid cancer

Discussion

Evidence-Based Medicine Question

What is the role of elective central CND in MIVAT?

For patients undergoing MIVAT, management of the neck is limited to central CND. Originally central neck metastases were a contraindication to MIVAT but now are merely a relative contraindication. Several groups have proven the safety and efficacy of CND through the MIVAT technique.[3,4,8] Despite the fact that in multivariate analyses cervical lymph node metastasis has no prognostic importance in dealing with papillary carcinoma of the thyroid, we are recognizing neck recurrence more frequently with modern imaging. The question then becomes, "How necessary is central neck dissection?" More recent philosophy suggests that paratracheal (level VI) lymph node dissection should be carried out at the time of thyroidectomy. However, in some reports, CND resulted in higher rates of transient and permanent postoperative hypocalcemia. More data should be collected about the safety and efficacy of CND via MIVAT.

Editorial Comment

Advances in imaging and laboratory testing result in increasing numbers of patients requiring thyroid surgery for low-risk cancer. Fortunately, advances in hemostasis, anesthesia, and medical optics have provided the opportunity for less invasive surgical techniques in thyroid surgery. MIVAT appears to offer equal efficacy in treating low-risk cancer, while simultaneously decreasing postoperative pain, bleeding, and surgical scarring, and continuing to maintain minimal complications. Minimally invasive surgery has been widely sought by patients in general, and MIVAT has provided thyroid surgeons and patients an alternative to standard thyroidectomy. MIVAT appears to be easily learned and adopted by surgeons with prior experience in thyroid surgery.

Review Questions

1. Which is not an absolute contraindication to MIVAT?

   a. Substernal goiter

   b. Thyroidectomy needed for focally avid thyroid nodule on PET-CT, performed for a laryngeal cancer treated with chemoradiotherapy

   c. **Hashimoto's thyroiditis**

   d. Revision lobectomy needed for substernal goiter

2. Which is an absolute contraindication for MIVAT?

   a. **Medullary thyroid cancer with lateral cervical metastases**

   b. RET-positive patient without thyroid nodules or abnormal lymph nodes needing only prophylactic thyroidectomy

   c. Thyroiditis

   d. Completion thyroidectomy

3. Which is the best candidate for MIVAT?

   a. A 30-year-old woman with Grave's disease, large goiter, and a suspicious thyroid nodule

   b. **A 5-year-old patient with a family history of MTC, positive RET**

testing, and negative serologic studies, who needs only prophylactic thyroidectomy

c. A patient with a 5-cm PTC

d. A patient with prior high-dose neck radiation and a 2-cm nodule with suspicious features on ultrasound

4. What is the rate of conversion to OT for properly selected patients?

a. 20%

b. 10%

c. **3% to 4%**

d. <1%

5. True or False: MIVAT and conventional OT provide similar results in terms of removal of thyroid tissue based on radioactive iodine scanning.

a. **True**

b. False

Robotic-Assisted Thyroidectomy

Chwee M. Lim, and Umamahaeswar Duvvuri

Introduction

Open thyroidectomy incorporated a midline skin crease was first popularized by Kocher in 1906; since that time it has remained the standard surgical technique for thyroidectomy.[1] This approach provides the most direct route to the thyroid bed and offers complete visualization of the surgical field. Therefore it results in excellent, predictable, and reproducible clinical outcomes with consistent preservation of the parathyroid glands and recurrent laryngeal nerves (RLN).

Gaining access to the thyroid bed from a remote site was made possible with the recent development of the da Vinci robotic system (Intuitive Surgical Inc., Sunnyvale, California). There are two approaches to the thyroid bed during robotic thyroidectomy. The first approach accesses the thyroid bed from the lateral direction by entering the bed between the anterior border of the sternocleidomastoid muscle and the sternothyroid muscle. This is accomplished either by way of the transaxillary (TA) or retroauricular (RA) approach. The former method was described first by Chung et al. and has been widely adopted as a single-incision gasless approach to the thyroid bed from the axilla.[2] The RA, or modified facelift technique, was first described by Terris et al. and has become a popular remote access to the neck for robotic-assisted approaches.[3] Byeon et al. recently demonstrated an acceptable cosmetic outcome with a good safety profile in their series of 87 patients undergoing RA thyroidectomy.[4]

The second surgical access to the thyroid bed begins in the midline using the bilateral axillobreast (BABA) technique.[5] This approach offers the surgeon the same midline approach as open thyroidectomy. The main benefit of remote access thyroidectomy is that it leaves no scar on

the neck, which is obviously important to some patients. The robotic system also provides the surgeon with a magnified, three-dimensional view of the surgical field which enhances the ability to preserve the RLN, external branch of the superior laryngeal nerve (EBSLN), and the parathyroid glands. In this chapter, we describe the robotic thyroidectomy performed via the lateral approach from either the TA or RA incision.

Key Operating Learning Points

1. It is essential to gain exposure and create a wide working space before proceeding to the console to perform robotic thyroidectomy.

2. Make sure that the robotic working arms are docked between 30 and 45 degrees to the camera arm so as to increase the maneuverability of both working instruments.

3. Identify the omohyoid muscle first before proceeding to mobilize the thyroid gland; this is important in preventing inadvertent injury to the internal jugular vein (IJV).

4. Owing to the lack of haptic feedback to the console surgeon, proper identification of the trachea and cervical esophagus is crucial in avoiding accidental injury to these structures.

5. It is important to ensure a near bloodless field when the RLN is dissected at Berry's ligament to prevent inadvertent injury to the nerve and postoperative hematoma.

6. Monitoring of the RLN is helpful to confirm both anatomic and functional preservation of the nerve during surgery and upon completion of the thyroidectomy.

Preoperative Period

History

1. Previous thyroidectomy or other neck surgery

2. Thyroid status (e.g., hypothyroid or thyrotoxic)

3. History of neck or shoulder problems

4. History of keloid or hypertrophied scar

Physical Examination

1. Body mass index (BMI)

2. Size of thyroid nodule, unilateral or bilateral nodules

3. Range of motion of cervical spine and shoulder

4. Direct laryngoscopy before surgery to evaluate vocal cord function

Imaging

Thyroid Ultrasound

Because of the operator-dependent nature of this modality, thyroid ultrasound is best performed by a physician specializing in thyroid imaging. The overall size of the gland, number of thyroid nodules, and any features raising suspicion of malignancy (e.g., taller than wide, hypoechoic nodule, peripheral vascularization, microcalcifications, irregular margins) should be documented. The presence of enlarged and suspicious lymph nodes in the central compartment should also be noted.

Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy (FNAB) is helpful for categorizing nodules according to risk of malignancy. At both our institutions, the Bestheda classification system is adopted. Additionally, we perform molecular markers (using a panel of common mutation markers) to help further risk-stratify nodules categorized as indeterminate (e.g., follicular lesion of undetermined significance (FLUS), follicular neoplasm, suspicious for malignancy). Using this panel of markers, preoperative counseling for upfront total thyroidectomy, rather than a diagnostic thyroid lobectomy, can be achieved in order to avoid completion thyroidectomy as a second-stage procedure.[6]

Thyroid Scan

This is seldom performed unless there is clinical suspicion of a hyperfunctioning solitary thyroid nodule that could account for a thyrotoxic state. In this instance, the scan will demonstrate a solitary "hot" thyroid nodule, and surgery to remove this nodule would be indicated to restore a euthyroid state.

Indications for Robotic Thyroidectomy

1. Thyroid nodule smaller than 5 cm

2. BMI less than 35

3. No prior neck surgery

4. Small T1–T2 thyroid cancer (well-differentiated variant papillary thyroid cancer or follicular cancer)

TABLE 80.1

Differences Between the Transaxillary and Retroauricular Approaches

	Retroauricular Approach	Transaxillary Approach
Elevation of the cervical flap	Shorter distance to thyroid bed	Longer distance to thyroid bed
Identification of the superior thyroid pedicle/EBSNL	Excellent	Good
Identification of the recurrent laryngeal nerve	Excellent	Excellent
Concurrent central compartment neck dissection	Excellent	Good
Brachial nerve neuropathy	No	Rare (2%)
Maximum number of deployable operating robotic arms in the da Vinci Si system	Two	Three

EBSNL, External branch of the superior laryngeal nerve.

Contraindications

1. Graves disease

2. Substernal extension of the gland

3. Locally advanced thyroid cancer with invasion of the RLN/tracheoesophageal complex/strap muscles

4. Known central compartment or lateral cervical lymph node metastasis

5. Medullary thyroid cancer

Relative Contraindications

1. Thyroid pathologies that require primary total thyroidectomy (e.g., multinodular goiter with sizable nodules on both thyroid lobes, thyroid cancer)

2. Suspicion for central compartment lymph node metastasis in patients with thyroid cancer

Preoperative Preparation

The choice of the surgical approach should be discussed preoperatively with the patient. We have no specific preference in the choice of surgical access, although an RA approach is associated with a shorter dissection distance to the thyroid bed, and this access is also more intuitive for head and neck surgeons. Nevertheless, in the TA approach, up to three operating robotic arms may be deployed, which can facilitate the retraction of tissue by the third operating arm. This third arm may be inserted directly from the TA incision or via another 5- to 8-mm periareolar incision. However, in our experience with the RA approach, the deployment of the third operating arm through this incision often makes it collide with the working arms, since operating arms of the da Vinci Si system are bulky. A comparison of these two approaches is summarized in Table 80.1.

Operative Period

Anesthesia

The patient is placed in the supine position, and an orotracheal tube (a laryngeal monitoring tube) is inserted for intraoperative monitoring of the RLN. The orotracheal tube is placed to the side opposite the site of thyroidectomy, and the airway circuit is brought down toward the patient's feet.

Position

In the TA approach, the upper arm is extended with the elbow flexed and internally rotated so as to expose the entire axilla without undue tension on the brachial plexus (Fig. 80.1). It is critical to make sure that the bony pressure points of the upper limb are adequately protected with soft cotton padding so as to prevent skin necrosis. Because of the remote risk of traction brachial plexopathy with prolonged shoulder extension, some surgeons have adopted additional intraoperative monitoring for both the radial and ulnar nerves. However, we have not found this to be necessary as the key to prevention lies in avoiding undue tension on the brachial plexus with the modified position of the upper limb. In the RA approach, both arms are tucked alongside the body in neutral position, and the head is turned away from the site of operation. We do not use a shoulder roll for neck extension in either of these approaches.

FIG. 80.1 Modified arm position for transaxillary thyroidectomy (arm is flexed at the elbow to avoid undue tension on the axilla).

Perioperative Antibiotic Prophylaxis

A thorough cleaning of the surgical field with Betadine iodine is adequate, and no perioperative antibiotic is necessary.

Instruments and Equipment to Have Available

At both our institutions, robotic thyroidectomy is performed using the da Vinci Si robotic system. We use the 10-mm 30-degree camera, which is positioned downward in order to visualize the entire surgical field. The two robotic working arms are the harmonic shears (8 mm) and the Maryland grasper (5 mm). An atraumatic Prograsp (8 mm) may be used instead of the Maryland grasper.

The assistant surgeon is stationed at the patient's side and assists the console surgeon in the following ways:

1. Providing countertraction during dissection

2. Retraction of the sternocleidomastoid muscle (in the RA approach)

3. Hemostasis using a fine long-tip bipolar cautery

4. Suctioning of the smoke fumes during surgery

5. Ensuring that the working arms are functioning at an optimal position without collision

The equipment that is essential to perform these functions is as follows:

1. Long-tip monopolar and bipolar cauteries

2. Lighted retractor system during flap elevation

3. Headlight

4. "Chung" retractor system

5. Rolled cotton pledgets

6. Yankauer suction

Key Anatomic Landmarks

1. Omohyoid muscle

2. Trachea

3. Cricothyroid muscle

4. Inferior thyroid artery (ITA)

Prerequisite Skills

Before embarking on robotic thyroidectomy, the surgeon must have sufficient experience in performing open thyroidectomy. A prior experience in endoscopic surgery was not identified as a significant requirement among fellowship-trained surgeons embarking on robotic thyroidectomy.[7] The console surgeon should be familiar with the setup and functions of the da Vinci robot. This can be accomplished through either structured credentialing courses (offered by Intuitive Surgical Inc.) or through a comprehensive head and neck fellowship program including a large volume of robotic surgery. Additionally, both dry and wet laboratory training are helpful in shortening the learning curves involved. In the dry laboratory, computer-simulated programs mimicking several surgical situations can increase the surgeon's skills in accomplishing the tasks required by robotic surgery. Similarly, wet laboratory cadaveric training with hands-on operative experience is invaluable in enhancing the learning experience. We recommend that the beginning surgeon perform the first five cases under supervised proctorship by an experienced surgeon in order to gain confidence with this new technique.

Operative Risks

In addition to the specific risks to the RLN and EBSLN, robotic thyroidectomy carries with it several potentially serious complications that are not usually encountered in standard open thyroidectomy. Perforation of the trachea and vascular injuries have been reported, which may be related to the lack of haptic feedback afforded to the console surgeon.[8] However, a good understanding of the surgical anatomy and keeping the surgical field bloodless will help to minimize these complications. In the TA approach, excessive and prolonged traction on the shoulder may result in brachial plexopathy. With our modified positioning of the upper limb, we have not encountered this complication. Injuries to vascular structures such as the carotid artery or

IJV may occur during dissection, especially if the dissection is performed in a rough manner. In the event of an injury to the carotid artery, direct external pressure to the carotid artery should be applied while the surgeon opens the neck in the conventional manner to expose the carotid sheath. As for injury to the IJV, bleeding from minor lacerations may be stopped with bipolar cautery or hemostatic surgical clips. In the instance of a major injury to the IJV, this vein may have to be sacrificed in order to gain complete hemostasis.

In patients who develop delayed postoperative hemorrhage or hematoma, securing hemostasis under general anesthesia is performed through the same remote access incision and without using the da Vinci robot. In this situation, a 10-mm endoscope (both 0 and 30 degrees) will help the surgeon to stop the bleeding points with either bipolar cautery or harmonic shears.

Surgical Technique

The surgical techniques of robotic thyroidectomy can be divided into the following categories.

Creating the Working Space

The creation of an adequate working space over the thyroid bed is critical to gain unrestricted maneuverability of the robotic instruments. This part of the operation is performed under direct vision using a long-tip monopolar cautery and a headlight for adequate illumination of the surgical field. A lighted retractor system is progressively deployed once the skin flap has been raised approximately 5 cm from the incision. A Yaukeur suction is used to aspirate the smoke and provide countertraction during the dissection. The typical length of the skin flap raised for the TA and RA approaches is between 12 to 14 cm and 10 to 12 cm from the incision, respectively.

FIG. 80.2 Planned incision of retroauricular approach to the thyroid (arrow).

In the TA approach, a 4- to 5-cm incision is placed 5 to 8 mm posterior to the anterior axillary fold in order to conceal the scar posterior to the skin fold. A skin flap is elevated over the pectoralis major muscle until the clavicle is encountered. Beyond this point, the skin flap is elevated in a subplatsymal fashion. The skin flap is elevated over the clavicular and sternal attachments of the sternocleidomastoid muscle until the level of the thyroid cartilage and just beyond the midline of the neck. Care must be taken to identify the omohyoid muscle and avoid getting deep to this muscle, since the carotid sheath and the IJV lie deep and medial to this plane.

In the RA approach, a 4- to 5-cm incision is placed approximately 5 to 8 mm posterior to the hairline in order to conceal the incision (Fig. 80.2). The flap is raised in the direction of the suprasternal notch, and this plane is also approximately the axis where the retractor blade will be positioned to retract the flap. First, the line of incision is infiltrated with xylocaine with adrenaline (1:80,000). A subplatysmal skin flap is elevated over the sternocleidomastoid muscle, taking care to preserve the greater auricular nerve and external jugular vein. The skin flap is elevated medially over the strap muscles beyond the midline raphe and as far superior as the clavicle at the inferior limit. The flap is elevated over the tail of the parotid and up to the ramus of the mandible. Care must be exercised to avoid injuring the marginal mandibular nerve.

Docking the da Vinci Si Robot

Once the working space has been created, the sternohyoid muscle is elevated off the thyroid bed, and the Chung retractor is inserted under the muscle to maintain exposure of the thyroid bed throughout the dissection. The Chung retractor is then secured and fixed onto the operating table. Upon retraction of the skin flap, it is important to note that the vertical height from the base of the incision to the skin flap upon suspension should be more than 5 cm (Fig. 80.3). This aspect is crucial so that an adequate working space is established before the robotic arms are brought into the field.

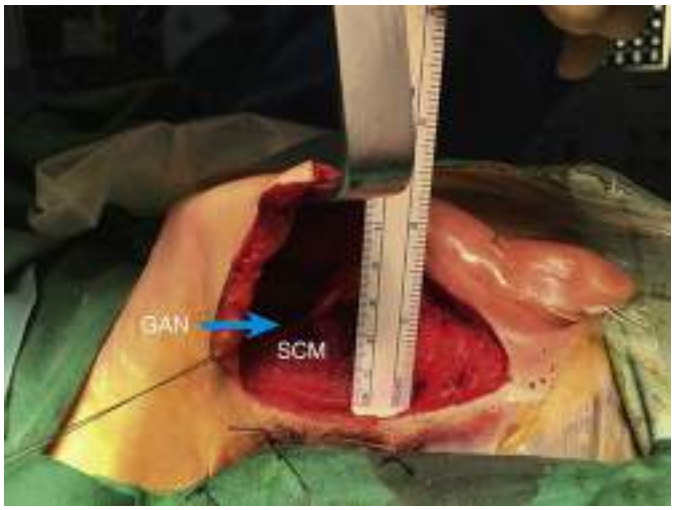

FIG. 80.3 Adequate working space must be ensured in the retroauricular approach to thyroid (height of elevation should be more than 5 cm) (arrow). *GAN,* great auricular nerve; *SCM,* sternocleidomastoid muscle.

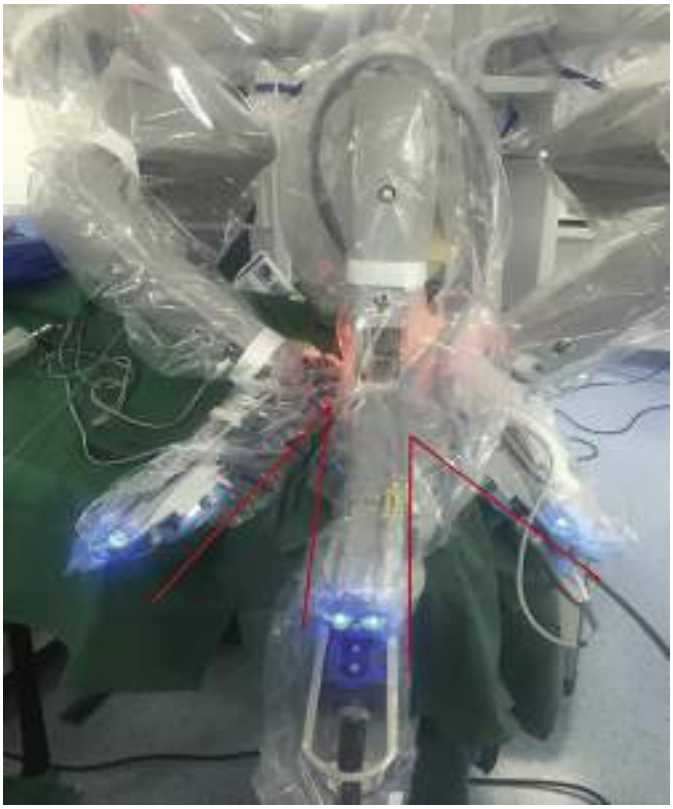

FIG. 80.4 Docking of da Vinci robotic arms in retroauricular approach.

The da Vinci robot is then brought into the surgical field opposite the site of operation. The robot is brought in at a 30- to 45-degree angle to the surgical table, approximately at the level of the patient's shoulder. The robot is subsequently docked, and the three working arms are brought into the working space. The camera port (10 mm) is docked in the midline, with the two working arms positioned at an angle of 30 to 45 degrees to the axis of the camera arm (isosceles triangle configuration) (Fig. 80.4). The rationale for placing these two working arms in this configuration is to minimize collision of these arms during dissection.

Our preference is to use the 8-mm harmonic shears and 8-mm atraumatic Prograsp forceps as our working instruments for robotic thyroidectomy. Some surgeons may opt for the 5-mm Maryland grasper, since it is narrower and hence may minimize the working space necessary to maneuver the instrument. However, we believe that the tip of the 5-mm Maryland grasper is too sharp and can cause inadvertent trauma to the thyroid tissue during tissue handling. This may result in unnecessary bleeding during the dissection, which can obscure the

surgical field. Once the robot is docked, the entire thyroid bed should be visualized before the surgery is performed (Fig. 80.5).

FIG. 80.5 Exposure of the left thyroid bed from the retroauricular approach.

Ligation of the Superior Thyroid Artery

In both the RA and TA approach, the thyroidectomy begins by mobilizing the superior pole of the thyroid gland. The sternothyroid muscle may be transected for better exposure and visualization of the superior pole of the gland. A lateral and medial plane are delineated around the superior pole, and the superior thyroid artery (STA) is isolated and ligated using the harmonic shears. We do not routinely identify the EBSLN, but we avoid injury to this nerve by ligating the STA close to the thyroid gland. With the magnified view of the superior pole, our experience is that the EBSLN can often be visualized and preserved during ligation of the STA. Next, the cricothyroid muscle is identified, since this landmark is helpful in demarcating the level where the RLN enters the larynx.

Preservation of Parathyroid Glands

With both the RA and TA approaches, we reach the thyroid gland from lateral to medial. The thyroid gland is mobilized and reflected medially toward the trachea. The middle thyroid vein is often encountered and is ligated using the harmonic shears. The superior parathyroid gland is identified superiorly and freed from the thyroid gland again using the harmonic shears. Next, attention is focused on the inferior pole of the thyroid gland. The ITA is often encountered and ligated as distal as possible to preserve the vascular supply to the parathyroid glands. The ITA is not a useful landmark for identifying the RLN, since their relationship is inconsistent. In a similar fashion, the inferior parathyroid gland is identified and freed from the thyroid with its vascular pedicle intact. Use of the robotic system allows the surgeon to have a magnified view of the operative field and aids in identifying and preserving these structures.

FIG. 80.6 Right thyroid bed after robotic thyroidectomy demonstrating the recurrent laryngeal nerve *(RLN)* and common carotid artery *(CCA)*.

Identification of the Recurrent Laryngeal Nerve and Freeing the Thyroid Gland From Berry's Ligament

The trachea is next identified and exposed. This orients the console surgeon with regard to the medial limit of the dissection. With the thyroid gland reflected medially by the Maryland grasper, the RLN is identified in the tracheoesophageal groove. Care must be taken to avoid

inadvertent injury to the esophagus in this area. We generally prefer to identify the RLN close to the cricothyroid joint, since this is the most consistent location of the nerve that is not influenced by anatomic variantion or by pathologies of the thyroid gland. Once the RLN has been identified, the nerve is traced toward Berry's ligament. At this point meticulous dissection of the nerve is required, since there are usually small vessels overlying the nerve near Berry's ligament. These vessels must be individually identified and ligated using the harmonic shears. We like to place a wet rolled cotton pledget over the RLN at this point to protect it from thermal injury from the harmonic shears. The cotton pledget can also be used to bluntly dissect the nerve at the cricothyroid area. If the nerve is closely adherent to the cricothyroid area, a fine-tip bipolar cautery may be applied to divide Berry's ligament. Once Berry's ligament has been divided, the thyroid lobe is mobilized off of the trachea. The thyroid isthmus is divided and the thyroid lobe removed. The thyroid bed is irrigated with warm saline, and the RLN is stimulated at 0.5 to 1 mA to confirm preservation of its function. The view of the thyroid bed following robotic thyroidectomy is illustrated in Fig. 80.6. The wound is closed over a drain, and the drain is brought out at the edge of the incision.

Common Errors in Technique

1. Inadequate countertraction when elevating the skin flap may result in perforation of the flap.

2. Getting deep to the plane of the omohyoid muscle prematurely risks possible injury to the IJV or one of its branches.

3. Dividing a large piece of tissue at the superior pole of the thyroid gland. The individual superior thyroid vessel should be skeletonized before ligating it with the harmonic shears. This is important, since the vessel may not be completely exposed during ligation if additional soft tissue is still attached to the vessel. Additionally, a low-lying EBSLN (Cernea type 2b) may be at risk if an indiscriminate ligation of the STA is performed.

4. Dividing Berry's ligament without completely mobilizing the entire thyroid lobe

Postoperative Period

Postoperative Management

1. Surgical drainage is charted, and the drain is removed when the drainage is less than 20 mL over a 24-hour period.

2. Compression dressing is not necessary to compress the skin flap in the immediate postoperative period. Some degree of edema of the flap is expected and will subside within 1 to 2 weeks in most instances.

Complications

1. Wound infection

2. Hematoma formation

3. RLN injury

4. Temporary numbness over the anterior chest wall (TA approach) and around the ear (RA approach)

Alternative Management Plan

Open thyroidectomy should always be discussed with patients undergoing robotic thyroidectomy. The chance of conversion to an open approach is exceedingly low with proper patient selection. In rare instances when vascular injuries are encountered (e.g., of the IJV or carotid artery), an open approach may be required to secure hemostasis in an expedient manner.

Discussion

Evidence-Based Medicine Question

Numerous studies have reported robotic thyroidectomy to be a safe and feasible alternative to open thyroidectomy.[4,5,8,9] As with all new surgical techniques, a learning curve is involved in achieving good clinical

outcomes. A thorough understanding of the surgical anatomy and prior experience in open thyroidectomy will invariably shorten the learning curve in robotic thyroidectomy.

Because there are no randomized clinical trials comparing open thyroidectomy to robotic thyroidectomy, most evidence for robotic thyroidectomy is limited to large case series in high-volume centers. A meta-analysis conducted by Lang et al. concluded that robotic thyroidectomy was associated with an increased risk of temporary RLN palsy,[10] although there was no significant difference in permanent morbidity or complications. However, in a subsequent meta-analysis by Son et al., there were no significant differences in terms of either temporary or permanent RLN injuries or hypocalcemia. One of the reasons for this difference is that Son et al. excluded cohort studies of less than 40 patients in their analysis, and this observation suggests that surgical experience is relevant in the initial learning curve toward achieving good clinical outcomes in robotic thyroidectomy. Additionally, when robotic thyroidectomy was performed on patients with thyroid cancer, the mean postoperative thyroglobulin assays did not differ significantly among patients receiving either open thyroidectomy or robotic thyroidectomy.

It is therefore premature at this juncture to draw conclusions about the long-term oncologic outcomes among patients receiving robotic thyroidectomy for thyroid cancer. Certainly, with proper patient selection and familiarity with the da Vinci robotic system, robotic thyroidectomy may be adopted as a means of treating patients with thyroid disease.

Editorial Comment

Over the past 150 years, thyroid surgery has developed into a relatively safe and reliable procedure for the treatment of various thyroid diseases. The current techniques are readily taught in a reproducible manner with a low incidence of complications, even for the occasional practitioner. The evolution of thyroid surgery to progressively less invasive strategies has been aided by advances in visual, hemostatic, and anesthetic techniques. Robotic thyroidectomy certainly represents the current pinnacle of technological advances in thyroid surgery. However,

contrary to other techniques, robotic surgery requires special surgical expertise and experience with robot technology. This unfortunately is not easily taught or readily available to all surgeons and must be approached with relative caution when recommending this potentially beneficial technique to appropriately selected patients.

Review Questions

1. Which of the following is the most likely benefit to patients receiving robotic thyroidectomy?

   a. Better visualization of the recurrent laryngeal nerve

   b. Better visualization of the parathyroid glands

   c. **Improved cosmetic outcome by avoidance of a scar on the neck**

   d. Enhanced wrist maneuverability of the robotic arms

   e. Reduced risk of postoperative bleeding

2. Which is the most important step in robotic thyroidectomy?

   a. Docking of the robotic arms at an "isosceles" angle to the camera arm so as to minimize collision of the working arms

   b. **Complete exposure of the thyroid bed before docking the robot**

   c. Monitoring of the recurrent laryngeal nerve to minimize injury

   d. Using a 30-degree camera scope rather than a zero-degree camera scope for better visualization

   e. Using the 8-mm fenestrated bipolar Cadiere forceps rather than the 8-mm fenestrated Maryland bipolar for hemostasis

3. Which of the following is the best candidate for robotic thyroidectomy?

   a. A 70-year-old male with a 6-cm benign solitary right thyroid cyst

   b. A 34-year-old female with Graves disease and, on ultrasound, a diffusely enlarged thyroid gland with no discrete nodules

c. A 55-year-old man with a 4.5-cm right thyroid nodule and FNA cytology showing papillary thyroid cancer

d. A 60-year-old female with a history of keloid scar and ultrasound showing multiple thyroid nodules in both lobes (largest measuring 4 cm)

e. **A 27-year-old female with a 3-cm solitary thyroid nodule and FNA cytology showing a follicular lesion of undetermined significance**

Massive and Substernal Goiter

Miriam N. Lango

Introduction

Prior to the 20th century, thyroid surgery was associated with a high operative mortality rate. The meticulous surgical technique advanced by Kocher in the late 1890s transformed thyroidectomy into a safe operative procedure associated with a 1% mortality rate. Although generally safe and effective, surgery for massive and substernal goiter remains subject to potentially significant surgical complications.

Approximately 5% of the population in the United States is estimated to have benign enlargement of nodules within the thyroid gland, known as a goiter. Iodine deficiency has been associated with the development of goiter, but this cause of goiter is now uncommon in the developed world. The vast majority of goiters are not associated with abnormal thyroid hormone function, and most are asymptomatic. However, massive enlargement can occur in which the gland extends around the pharynx or extends below the level of the thoracic inlet into the chest. In 1939 Crile described substernal goiters as those extending to the aortic arch. Recently In 2008, Huins et al. described, a three-tiered system derived from a large meta-analysis which classified substernal goiters in relation to the aortic arch, pericardium, and atrium.[1]

Massive and substernal goiters are often technically demanding procedures, due to the gland's vascularity and its proximity to the larynx, trachea, and the recurrent laryngeal nerves controlling vocal cord movement. In addition, the exposure needed to identify and preserve important structures is hampered when the goiter extends below the level of the thoracic inlet into the enclosed space of the chest. Nevertheless, even large goiters can usually be delivered out of the chest through an incision low in the neck using technical maneuvers.[2]

However, extension inferior to the aortic arch more often necessitates additional exposure.[1]

Substernal goiters may come to clinical attention as a visible mass or as a result of goiter-related symptoms: a compressive pressure–type sensation, shortness of breath on lying down, and problems swallowing. Indeed, substernal goiters are more often symptomatic than massive goiters limited to the neck. Substernal goiters may not be visible on inspection because most of the gland is in the mediastinum (Figs. 81.1 to 81.3). Patients develop symptoms due to cumulative growth within the confines of the thoracic inlet and chest cavity, compressing or displacing the trachea, esophagus, and mediastinal blood vessels. Enlargement is typically slow and progressive over many years. Sudden, rapid enlargement of a long-standing goiter suggests the development of cancer but could also be due to abrupt bleeding into the gland.

Surgery for goiter is the definitive treatment for massive or substernal goiter but is associated with a number of potential complications. The surgery is highly effective in ameliorating goiter-related symptoms, but diligent surgical execution is needed to optimize favorable outcomes. Strategies to limit intraoperative bleeding, enhance exposure, and facilitate atraumatic surgical dissection will diminish intraoperative complications.

Key Operative Learning Points

1. Assess the level of patient-reported symptoms, prior to surgery. Consider using a thyroid-specific tool, such as the short version of the thyroid-related patient-reported outcome (ThyPRO) tool[3] prior to surgery; this tool may also be administered several months after surgery. Rapid enlargement associated with pain and dysphagia suggests the development of an aggressive malignancy.

2. Preoperative evaluation[4] should include serum thyroid-stimulating hormone (TSH) and imaging. Both an ultrasound and a computer tomography (CT) scan should be obtained. The CT scan with intravenous contrast will determine the substernal extent of the goiter and its relationship with large blood vessels and identify posterior mediastinal extension associated with displacement of the recurrent laryngeal nerve. The appearance may also suggest the presence of an infiltrative

malignancy that could alter the treatment plan.

3. Continuous laryngeal nerve monitoring that tests the functional integrity of the recurrent laryngeal nerve by means of continuous intraoperative vagal nerve stimulation is particularly useful in the management of large substernal goiters. During these cases the recurrent laryngeal nerve may not be readily identified because it is hidden behind a large obstructing goiter and subject to traction injury. Evidence for the use of continuous laryngeal nerve monitoring is mounting, but this technology does not yet represent standard of care.[5]

4. Instrumentation used for minimally invasive thyroid surgery is useful in substernal goiter surgery, which usually requires dissection in narrow spaces with limited exposure; having the proper instrumentation may obviate the need for manubrium or sternal osteotomies, which may be required in revision cases or those involving substernal thyroid cancer (Fig. 81.4).

Preoperative Period

History

1. History of present illness
   a. History of anterior neck mass
      1) Duration of mass, interval enlargement
   b. Patient symptoms
      1) Direct compression of the trachea or esophagus by a substernal goiter can cause dysphagia to solids, positional dyspnea, and dysphonia. Positional dyspnea and orthopnea are frequently associated with substernal goiter with tracheal compression on cross-sectional imaging.
   c. History of snoring, daytime somnolence, sleep apnea
   d. Factors predisposing to thyroid cancer, such as history of neck radiation, or family history of thyroid cancer

FIG. 81.1 A large substernal goiter is not necessarily associated with an obvious abnormality in the neck visible by inspection alone.

FIG. 81.2 The cervical incision must be large enough to accommodate delivery of the gland. A continuous laryngeal nerve monitor stimulates *(yellow wire)* the ipsilateral vagus nerve, monitoring the functional integrity of the recurrent laryngeal nerve during the procedure.

2. Past medical history

a. A complete past medical and surgical history must be obtained from the patient. Prior imaging and biopsies should be reviewed. A history of hypertension and prior neck surgery should be noted.

Physical Examination

1. Respiratory distress? Stridor? Hoarseness?
2. Venous congestion of neck/facial venous collaterals
3. Neck
   a. Size and location of the goiter
      1) Consistency: Is the mass firm or hard?
      2) Is it tethered to the overlying skin; is the skin indurated?
      3) Does it extend to the clavicle?

FIG. 81.3 The massive substernal component was delivered prior to definitive identification of the recurrent laryngeal nerve. In the absence of amplitude or latency changes, safe delivery without traction injury was accomplished.

FIG. 81.4 Specialized equipment can be helpful. A custom, long McCabe is superior to the classic McCabe dissector, a Schnidt, or a right-angle clamp in reaching into deep narrow spaces. A suction dissector may be used like a Kittner sponge but is less abrasive.

4) Does it move with swallowing? Is the inferior extent palpable with swallowing?

5) Is the trachea palpable, and is it deviated?

6) World health organization (WHO) classification (Table 81.1): Patients with goiters visible on casual inspection may have few goiter-related symptoms. Substernal goiters associated with patient symptoms may not necessarily be appreciated on clinical examination alone (see Fig. 81.1).

b. Palpable cervical lymphadenopathy and neck levels involved

4. Larynx: Examination of the larynx should also assess the pharynx for compression, as well as vocal cord mobility.

TABLE 81.1

World Health Organization Classification of Goiter

Grade 0	Impalpable/invisible
Grade 1a	Palpable but invisible even in full extension
Grade 1b	Palpable in neutral position/visible in extension
Grade 2	Visible no palpation required to make diagnosis
Grade 3	Visible at a distance

WHO, World Health Organization.

5. Pemberton maneuver: The maneuver is performed by having the patient raise both arms against the face for several minutes to see if the patient develops reversible facial flushing or cyanosis, sometimes associated with shortness of breath or stridor. A positive Pemberton sign indicates superior vena cava syndrome causing diminished venous outflow from and venous congestion of the head and neck due to goiter-related compression of the vessels in the mediastinum. Patients may also have enlargement of venous collaterals in the chest and neck.

Imaging

Ultrasound of the neck

Prior to thyroidectomy, patients should undergo a formal ultrasound of the neck and thyroid gland to assess the risk of malignancy in the goiter. In the presence of abnormal adenopathy or invasive features, a fine-needle aspiration biopsy may be warranted.

CT of the neck/chest

A CT scan of the neck and chest is recommended if substernal extension is suspected.[6] Evaluation of the caudal extent of the goiter will facilitate surgical planning and enable added thoracic exposure should it prove to be necessary.[1]

Caudal growth of a goiter in the visceral space initially involves extension into the pretracheal space into the anterior mediastinum or retroesophageal extension into the posterior mediastinum. Significantly, posterior mediastinum extension is rare in the absence of concomitant anterior mediastinum involvement.[7] Goiter extension into the posterior mediastinum suggests anterior displacement of the recurrent laryngeal nerve. A meta-analysis linked extension to specific structures with the need for additional procedures (Table 81.2). Goiter extension above the fourth vertebrae or above the level of the aortic arch can usually be managed transcervically. Posterior mediastinum extension of the goiter necessitates a thoracotomy for exposure and extirpation.

The degree of tracheal compression, described as the percentage reduction in tracheal diameter, should be noted. Any assessment of substernal goiter should include a description of the degree of

tracheal compression is described as the greatest percentage reduction in tracheal diameter. Compression greater than 35% is considered prognostic, with near-universal relief of preoperative positional dyspnea.[4]

Indications

1. Substernal goiter

Historically, the presence of a substernal goiter has been considered a sufficient indication for surgery. However, specific preoperative factors predict greater improvements in patient symptoms. Improvement or resolution of positional dyspnea varies with the degree of preoperative tracheal compression. Greater than 35% narrowing of the tracheal lumen has been associated with resolution of positional dyspnea in 57% to 95% of patients; lesser narrowing is less reliably associated with improvement in positional dyspnea postoperatively.[4] Thyroid gland weight greater than 100 g or thyroid lobe greater than 75 g has also been associated with an improvement in patient symptoms,[4] but this information is not available prior to surgery. Older adult or infirm patients with lesser narrowing may be observed for progression, whereas younger or more symptomatic patients may be offered surgery promptly.

TABLE 81.2

Classification and Approach for Retrosternal Goiters

Grade	Anatomic Location	Approach
1	Above aortic arch/above T4 vertebra	Cervical
2	Aortic arch to pericardium	Manubriotomy
3	Below right atrium	Full sternotomy

Reproduced with permission Huins CT, Georgalas C, Mehrzad H, et al.: A new classification system for retrosternal goitre based on a systematic review of its complications and management. *Int J Surg* 6(1):71-76, 2008.

Contraindications

1. Patient refusal of consent

2. Unresectable aggressive or anaplastic thyroid carcinoma

3. Major medical comorbidities

Preoperative Preparation

1. TSH
2. Anesthesia and medical consultations
3. Recurrent laryngeal nerve monitoring
4. Thyroid-specific instrumentation (see Fig. 81.4)
5. Type and screen
6. Vessel sealing devices (optional)

Operative Period

Anesthesia

General anesthesia

Positioning

Supine with neck extension

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin or alternative for those allergic

Monitoring

Laryngeal nerve monitoring

The role of laryngeal nerve monitoring in thyroid surgery remains an active area of investigation. Moreover, laryngeal nerve monitoring may be done intermittently or in real time, using vagal nerve stimulation during the thyroidectomy. A study suggested intermittent laryngeal nerve monitoring results in higher rates of laryngeal nerve palsies.[8] Such monitoring might be particularly valuable in cases in which the recurrent laryngeal nerve is obscured

by a large obstructing goiter and subject to traction injury. Electromyographic signals suggesting no changes in the amplitude or latency of recurrent laryngeal nerve signals during surgical maneuvers to deliver a large substernal goiter provide real-time feedback regarding the function of the recurrent laryngeal nerve.

Instruments and Equipment to Have Available

1. Standard thyroidectomy set
2. Extra long McCabe dissector (see Fig. 81.4)
3. Suction dissector (see Fig. 81.4)

Thyroid sets developed for minimally invasive thyroid surgery are also useful for substernal goiter surgery. Some of these are commercially available. In general, longer instruments are needed than those needed for standard thyroidectomy. Standard McCabe dissectors are relatively short (14 cm); longer versions of this instrument can be custom ordered at a reasonable cost and are extremely useful in these complex procedures (see Fig. 81.4). The tip of the right angle clamp common on many surgical trays may not fit in the tight space between the thyroid goiter and the thoracic inlet. The tip of a McCabe dissector is shorter, and the angle of the tip is wider, making it more suited to dissection in this region. The use of a suction dissector developed for endoscopic sinus surgery is less traumatic for blunt dissection during thyroid surgery than the use of Kittner[9] (see Fig. 81.4). The suction dissector is used to expose planes around the goiter, making tunnels into the mediastinum, whereas the long McCabe ("the Longo") facilitates dissection of vessels between the tunnels. Endoscopic visualization is not usually needed, but a good headlight is mandatory.

Key Anatomic Landmarks

Anatomic landmarks for the recurrent laryngeal nerve:

The recurrent laryngeal nerve may be found in the triangle marked by the carotid artery laterally, the trachea, and the lower pole of the

thyroid gland (Fig. 81.5).[10]

The recurrent laryngeal nerve crosses the inferior thyroid artery to enter the larynx posterior to the inferior thyroid artery.

Goiters extending into the posterior mediastinum enlarge caudally posterior to the inferior thyroid artery along or behind the esophagus, displacing the recurrent laryngeal nerve in an anterior direction (see Fig. 81.5).

The vast majority of goiters involving the posterior mediastinum also involve the anterior mediastinum.[7]

Prerequisite Skills

1. Mastery of nonsubsternal thyroid surgery. Substernal goiter surgery is complex, and outcomes after surgery are better when surgery is performed by experienced, high-volume thyroid surgeons.

Operative Risks

1. Airway compromise during intubation
2. Intraoperative hemorrhage
3. Recurrent laryngeal nerve injury
4. Hypoparathyroidism and hypocalcemia
5. Tracheal or esophageal injury

Surgical Technique

After a systematic workup, the patient is brought to the operating room.

Intubation

Communication between the otolaryngologist and the anesthesiologist is a prerequisite for safe airway management in a patient with an obstructive lesion. Most patients with large goiters can be safely intubated. Tracheal deviation does not hamper passage of an endotracheal tube, although intubation over a flexible fiberoptic

bronchoscope can help to guide advancement and placement of the endotracheal tube with severe deviation. With substantial tracheal compression, a smaller-caliber endotracheal tube may be necessary. An awake or emergency tracheotomy is rarely necessary. Nevertheless, it is prudent for the surgeon to be present during induction of anesthesia.

FIG. 81.5 Left hemineck.

The rln enters the larynx posterior to the inferior thyroid artery. Most goiters extend into the anterior, rather than posterior mediastinum. Goiters extending into the posterior mediastinum expand caudally along the esophagus, posterior and deep to the inferior thyroid artery. *cc,* Common carotid; *ct,* cricothyroid muscle; *icm,* inferior constrictor muscle; *ita,* inferior thyroid artery; *rln,* recurrent laryngeal nerve; *t,* trachea. Reproduced with permission Asgharpour E, Maranillo E, Sanudo J, et al.: Recurrent laryngeal nerve landmarks revisited. *Head Neck* 34[9]:1240-1246, 2012.

Thoracic consultation

The vast majority of substernal goiters may be removed transcervically, without need for additional exposure afforded by

osteotomy of the manubrium or sternum. Nevertheless, adhesions from prior surgery or locally invasive thyroid cancer or ectopic thyroid tissue may require added exposure. Patients with a history of sternotomy for cardiac surgery should never undergo repeat sternotomy without the ability for cardiopulmonary bypass, because atrial injury becomes a factor. A large meta-analysis has also linked the need for thoracic exposure based on caudal extent of the goiter (see Table 81.1).[1] Extension of the goiter to the pericardium suggests the need for a manubriotomy, whereas extension to the atrium suggests the need for a sternotomy, often involving the first two or three rib insertions (Fig. 81.6).

Surgical technique

The skin incision is made, and skin flaps are raised. The strap muscles are separated in the midline (see Figs. 81.1 and 81.2). In cases of massive extension the strap muscles may be sectioned and reapproximated with mattress suturing at the conclusion of the case. Typically, the superior pole is dissected out first. The superior vascular pedicle is ligated. Retropharyngeal extension of the goiter may be encountered but is less common than substernal extension. Extracapsular dissection will limit bleeding during this part of the procedure.

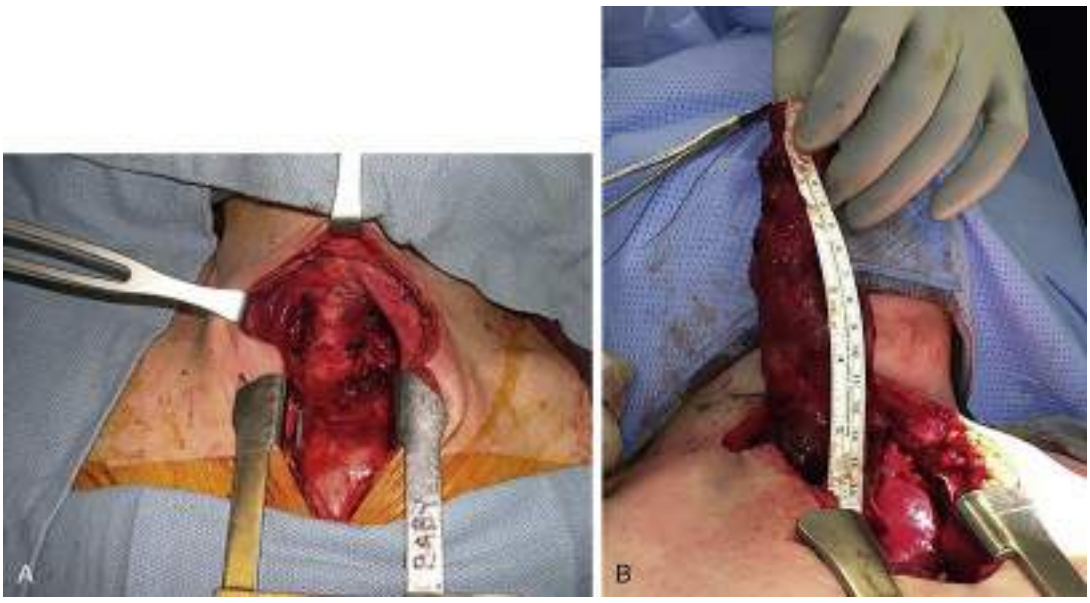

FIG. 81.6 **A** and **B,** Increased exposure afforded by median

sternotomy, allowing increased access to the region surrounding the great vessels, enabling safe complete resection.

The recurrent laryngeal nerve is usually in its normal anatomic position, even in cases involving large substernal goiters. After the goiter is mobilized off the pharynx and larynx, the recurrent laryngeal nerve may potentially be identified if the larynx is relatively high in the neck, just lateral to Berry's ligament, which is sectioned prior to mobilization of the substernal component. However, if the larynx is relatively low relative to the thoracic inlet, it will be difficult to identify the recurrent laryngeal nerve prior to delivering the substernal component into the neck. Dissection of the substernal component can be challenging due to limited exposure afforded by the thoracic inlet. This is particularly the case if there has been prior surgery and the goiter is scarred to the tissues around the thoracic inlet. Instruments used for minimally invasive thyroid surgery can be very useful.

Palpation into the chest with finger dissection assists with delivery of the substernal component into the neck. If the gland cannot be mobilized and delivered, thoracic surgery consultation for added exposure is mandatory. Thus the substernal component of the gland is often delivered into the neck without dissecting the recurrent laryngeal nerve prior to this maneuver. Moreover, mobilization of the gland out of the chest is frequently associated with substantial bleeding. This may be minimized by ligating the inferior thyroid pedicle. However, in the presence of a large substernal goiter, the inferior thyroid pedicle may not be well visualized prior to delivering the gland out of the neck. Upon delivering the gland out of the chest, hemostasis must be undertaken with care. Application of manual pressure to the bleeding surface of the thyroid and other areas is followed by meticulous hemostasis. Many nerve injuries occur during the process of obtaining hemostasis.

In the vast majority of cases the recurrent laryngeal nerve remains posterior to the thyroid gland; in cases with goiter extension into the posterior mediastinum, the recurrent laryngeal nerve is displaced in an anterior direction. In these cases, finger dissection and mobilization will be associated with a severe traction injury to the

nerve. A high index of suspicion will prevent this complication. After hemostasis is achieved, the strap muscles are reapproximated which the neck is closed in layers. A drain may be used and hastens resolution of postoperative edema in the neck.

Common Errors in Technique

1. Improper equipment
2. Intraoperative bleeding
3. Incomplete removal of the goiter
4. Inadvertent entry into the airway or esophagus
5. Failure to identify or protect the recurrent laryngeal nerve

Postoperative Period

Postoperative Management

1. Assessment of the adequacy of the airway—evaluate for shortness of breath and stridor
2. Assessment of vocal cord mobility by means of laryngoscopy
3. Thyroid hormone supplementation—necessary for total thyroidectomy
4. Postoperative calcium—rule out postoperative hypoparathyroidism
5. Pain medication as needed

Complications

Intraoperative Complications

1. Hemorrhage
2. Recurrent laryngeal nerve injury
3. Airway entry

Because goiters are engorged with enlarged blood vessels, intraoperative bleeding is not uncommon. Early ligation of the superior and inferior thyroid pedicles will diminish blood loss. Intraglandular dissection should be avoided. Hemorrhage from the posterior aspect of the thyroid bed following delivery of the substernal component is managed by pressure or packing and careful identification and ligation of the bleeding sites. A preoperative type and screen is mandatory; transfusion is used when necessary. Injury to the recurrent laryngeal nerve usually results from excessive traction on the nerve during mobilization. The use of continuous laryngeal nerve monitoring identifies this type of injury and enables the surgeon to modify the approach. However, nerve monitoring cannot prevent inadvertent transection or thermal-related injury. If a loss of signal is encountered, deferring management of the contralateral lobe should be considered. Entry into the airway or esophagus is rare but should be repaired if feasible. A Penrose or suction drain may help to prevent the accumulation of subcutaneous air.

Postoperative Complications

1. Hemorrhage
2. Hoarseness/voice change
3. Hypoparathyroidism
4. Stridor
5. Wound infection

Suspected hemorrhage after surgery should be managed with surgical exploration and evacuation of the hematoma. If hemorrhage is associated with rapid enlargement of a hematoma and dyspnea, the wound should be opened at the bedside to relieve pressure on the airway. Formal exploration may be undertaken in the operating room after the patient is safely intubated. Hoarseness may be related to the endotracheal tube or nerve injury. Vocal cord mobility should be evaluated with laryngoscopy. Calcium may be repleted with or without vitamin D. The management is similar to hypoparathyroidism following total thyroidectomy.

Patients undergoing surgery should be extubated in the operating

room when possible. Stridor may be related to vocal cord paralysis or alternatively tracheomalacia. Reintubation may be needed, but an assessment of vocal cord mobility should be undertaken, if possible. Wound infection after thyroidectomy is rare and usually represents a small unrecognized tracheal or esophageal perforation. This can be managed with antibiotics and placement of a drain into the wound; often a Penrose drain will suffice.

Alternative Management Plan

1. Thyroid hormone administration
2. Radioiodine treatment
3. Surveillance or supportive care

Discussion

Evidence-Based Medicine Question

How effective is thyroidectomy in relieving goiter-related symptoms?

Thyroidectomy is effective in relieving positional dyspnea in 82% of patients with goiter and 88% of patients with substernal goiter. Heavier glands predict greater response to surgery, although such measurements cannot be made prior to surgery. Substernal thyroidectomy has been associated with resolution of pulmonary hypertension and heart failure. Dysphagia associated with compression of the esophagus or pharynx is also caused by other processes. Resolution of dysphagia less reliably follows after thyroidectomy. Patient-reported outcomes have detected improvements in swallowing-related symptoms 1 year after surgery, but recurrent laryngeal nerve injury negates any benefit from surgery on outcome.[4]

Editorial Comment

Fortunately most patients with massive or substernal goiter are asymptomatic, which allows them to attain their size without treatment.

Substernal goiters are frequently found as an incidental finding on routine imaging for another problem, such as metastatic workup or motor vehicle accident. Some patients may have significant compression of the trachea, esophagus, or great vessels. The majority of symptomatic patients can expect relief of symptoms after surgical removal of the goiter.

Alfred Simental, Jr.

Access the review questions online at http://www.expertconsult.com

Review Questions

1. Preoperative surgical evaluation of a patient suspected of having a substernal goiter includes all of the following *except*:

   a. TSH

   b. **Chest radiograph**

   c. CT scan of the chest

   d. Thyroid ultrasound

   e. Laryngoscopy

2. Potential immediate complications of a total substernal thyroidectomy include all of the following except:

   a. Postoperative hemorrhage

   b. Vocal cord paralysis

   c. Hypoparathyroidism

   d. Wound infection

   e. **Hypothyroidism**

3. Contraindications for substernal thyroidectomy include all of the following except:

   a. Medically inoperable patient

   b. Refusal of consent

   c. Unresectable anaplastic thyroid carcinoma

   d. **Presence of unilateral vocal cord paralysis**

e. Uncontrolled hyperthyroidism

4. Of the following preoperative factors, which is least associated with an improvement of symptoms after thyroidectomy?

   a. Preoperative tracheal compression

   b. Preoperative positional dyspnea

   c. **Preoperative dysphagia**

   d. Resected gland weight greater than 100 g

   e. Resected lobe weight greater than 75 g

Invasive Thyroid Cancer

Daniel Kwon, and Steve Lee

Introduction

Thyroid cancer is a curable disease with increasing incidence and treatment strategies. This corresponds with the widespread use of screening modalities and improved health care availability. With more cases being detected in early stages, the incidence of invasive thyroid cancer is relatively low, ranging from 5% to 25%.[1,2] Despite the low incidence, invasive thyroid cancer has significant prognostic implications, with nearly half of deaths from thyroid cancer being attributable to local disease, typically due to airway obstruction and bleeding.[3] Extrathyroidal extension (ETE) in well-differentiated thyroid cancer is a surrogate indicator for loss of normal cellular architecture and poor prognosis. However, in contrast to invasive anaplastic thyroid cancer, tumors of papillary or follicular histology with ETE often retain a favorable prognosis and can successfully be managed surgically.[4,5] Invasive thyroid cancer is a challenging surgical problem that requires complete preoperative evaluation, comprehensive surgical planning, and often a multispecialty surgical team to manage the wide range of surgeries that are required for complete tumor extirpation while minimizing morbidity.

Key Learning Points

1. Patients with a high risk of invasive thyroid cancer should be identified and have cross-sectional imaging preoperatively.

2. ETE into muscle or other connective tissue may be adequately treated with wide local excision.

3. The recurrent laryngeal nerve (RLN) should be resected if invaded and preoperative assessment revealed ipsilateral paralysis. Conversely, efforts should be made to spare the nerve if preoperatively it was determined to be functional.

4. Shave resection may be acceptable for limited invasion into the larynx, trachea, and esophagus but with increased rates of local recurrence.

5. Transmural invasion into the viscera of the neck typically requires more aggressive margin-negative resection.

Preoperative Period

History

1. History of present illness

   a. Evaluate onset, growth, and pain.

      1) Rapidly growing tumors may represent a more aggressive histology and behavior.

      2) Pain or stiffness in the neck may be a feature of invasion.

      3) If a diagnosis of malignancy has not yet been confirmed, index of suspicion must be high for goiters with an aggressive clinical history.

   b. Is there a history of voice changes?

      1) Complaints of voice changes are often the earliest symptom of invasion and should alert the surgeon to evaluate further for laryngotracheal or nerve invasion.

      2) Voice change is not very sensitive for detecting vocal fold paralysis.

   c. Does the patient have complaints of dysphagia, dyspnea, cough, or hemoptysis?

      1) May represent intraluminal invasion of neck viscera

      2) However, may also be secondary to compression as in benign goiters

3) Absence of symptoms does not make invasion less likely, because the majority of invasive thyroid cancers are asymptomatic.

d. Is there a history of previous thyroid cancer?

1) Recurrent cancer in the original thyroid bed has a high risk of invasion

2. Risk Factors

a. Age

1) There is a higher incidence of ETE in older patients with thyroid cancer.

b. Size of the mass

1) Primary cancer >4 cm have increased incidence of invasion

c. Histology

1) Papillary thyroid carcinoma is the most common histologic type.

2) ETE is often associated with subtypes such as insular, tall cell, and trabecular carcinomas.

3) Anaplastic or poorly differentiated cancers are nearly uniformly invasive but have a different decision-making tree due to their poor prognosis

3. Past medical history

a. History of previously treated thyroid cancer

1) Central neck recurrence after thyroidectomy is often invasive due to anatomic proximity, as well as disruption of natural tissue planes.

Physical Examination

1. Complete examination of the head and neck

a. Examine the thyroid for fixation to underlying structures and overlying skin and assess movement with swallowing.

b. Palpate the neck to evaluate for lymph node metastases.

c. Assessment of cranial nerves

2. Laryngeal function should be routinely assessed.

a. Voice assessment is required in all patients being seen for thyroid cancer.

b. Best practice includes visualization of the larynx because laryngeal paralysis often does not produce noticeable voice changes.

1) Mirror laryngoscopy or flexible laryngoscopy should be used to document vocal fold mobility.

c. Preoperative ipsilateral vocal fold paralysis is highly predictive of invasive thyroid cancer, and these patients should receive advanced cross-sectional imaging.

Diagnostic Studies

1. Fine-needle aspiration (FNA)

a. FNA is an important initial diagnostic tool for workup in the evaluation of thyroid tumors.

b. Regional metastases and recurrent masses should be biopsy-proven prior to surgical treatment.

2. Laboratory studies

a. Of limited clinical value in evaluating the extent of invasive thyroid cancer

b. Rising thyroglobulin or thyroglobulin antibodies may indicate recurrent or metastatic disease.

3. Imaging

a. Ultrasound

1) Performed routinely for all thyroid cancer evaluations

2) May identify invasion into surrounding structures, although studies have shown a wide range of sensitivity and specificity

3) Operator dependent

4) May be useful for surgical planning if performed by the operating surgeon

b. Computed tomography (CT) and magnetic resonance imaging (MRI)

1) Should be done for all patients suspected of invasive thyroid cancer

2) CT and MRI have similar rates of sensitivity and specificity in detecting extent of tumor and invasion.

3) CT is rapid, widely available, and easily read by most surgeons.

4) Use of iodinated contrast may interfere with postoperative radioactive iodine (RAI) treatment for up to 6 to 8 weeks and should be used judiciously.

c. Positron emission tomography (PET)

1) May identify metastatic or recurrent disease in radioiodine negative tumors

2) Evaluation of distant extent of disease (Fig. 82.1) may alter treatment decisions at the primary site.

Indications

1. Surgical resection remains the hallmark of treatment for thyroid cancer, invasive or otherwise.

2. Optimal resection should result in negative margins with wide resection of tumor and involved structures

a. Structures with low morbidity on resection such as strap muscles

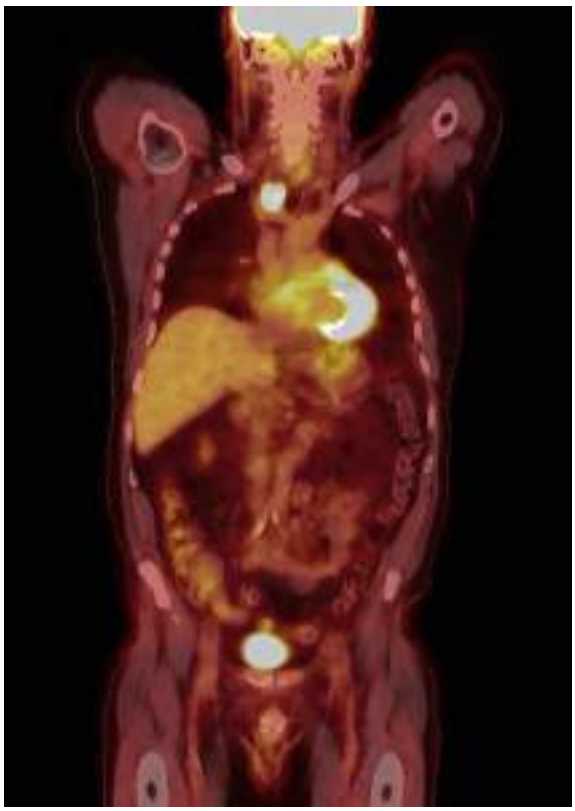

FIG. 82.1 PET evaluation of primary and distant sites, showing hypermetabolic activity in the right thyroid.

b. Preoperative nerve infiltration causing dysfunction

c. Transmural invasion of larynx, trachea, or esophagus

3. Shave resection may provide similar survival with decreased morbidity.

a. Partial-thickness invasion into larynx, trachea, or esophagus

b. Nerve encasement with normal preoperative function

Contraindications

1. Morbidity or surgical sequelae of resection unacceptable to patient

2. Major organ resection should be avoided, if possible, in the case of incidental finding of invasion if patient has not been counseled preoperatively.

3. Limiting morbidity and surgical risk in widely metastatic or unresectable, poorly differentiated thyroid carcinoma

Preoperative Preparation

1. Discussion/informed consent with patient regarding treatment goals and extent of resection
    a. Many studies fail to demonstrate survival difference between aggressive and conservative surgery.
    b. Local control rates vary and conservative surgery may require repeated surgery and eventual salvage.
2. The surgeon should be prepared for the wide range of surgical resections and reconstructions that may be required.
    a. When transmural invasion is suspected, reconstructive options should be available, including microvascular surgery and thoracic surgery support.

Operative Period

Anesthesia

1. Surgery for invasive thyroid cancer generally requires general anesthesia with endotracheal intubation.

2. Thyroid cancer with limited extension could theoretically be done with sedation and local anesthesia, but this is not typical.

3. Esophageal temperature probe or nasogastric tube (NGT) placement is helpful to easily identify the esophagus intraoperatively, as well as use for stenting and feeding in the case of esophagectomy or pharyngectomy.

Positioning

1. Neck should be placed in slight extension with shoulder roll

2. Reverse Trendelenburg or elevated head of bed to promote venous drainage away from the neck

Perioperative Antibiotic Prophylaxis

1. Major head and neck surgery warrants a preincisional antibiotic dose, typically a first-generation cephalosporin for gram-positive coverage.

2. If upper aerodigestive tract breach is expected, coverage for anaerobic bacteria should be added with metronidazole or clindamycin.

Monitoring

1. Intraoperative laryngeal nerve monitoring may be used.
   a. Utility and benefit in routine thyroidectomy are controversial.
   b. May provide information regarding functional status of the nerve intraoperatively in the case of surgery of invasive disease and may help to guide extent of surgery and treatment of the contralateral side
   c. Should not substitute direct identification and preservation by the surgeon

Instruments and Equipment

1. Basic open neck surgery instruments
   a. Thyroid or neck dissection sets
   b. Fine-tipped dissectors or McCabe dissection for nerve dissection

2. Vascular instruments should be available or open if vascular involvement is suspected.

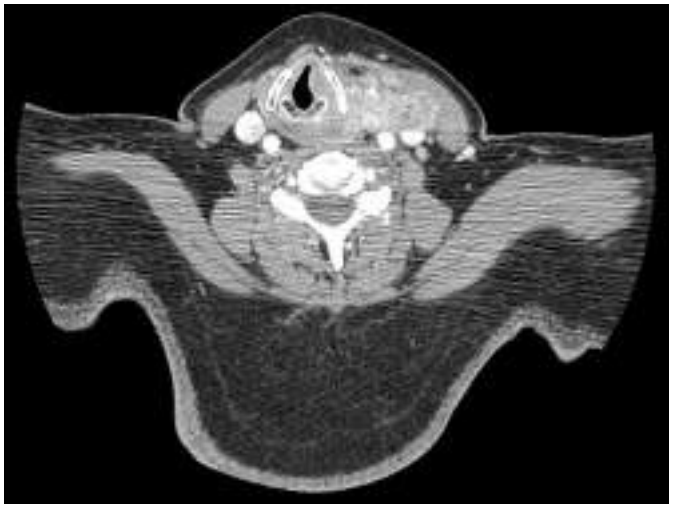

FIG. 82.2 CT imaging demonstrating laryngeal invasion into the left paraglottic space from around the lateral edge thyroid cartilage.

Key Anatomic Landmarks

1. RLN
   a. The right RLN course is often more tangential due to its course around the subclavian artery when compared with the left side.
   b. The RLN enters the larynx just deep to the inferior laryngeal constrictor, behind the cricoarytenoid joint, where it is closely associated with branches of inferior thyroid artery.
   c. RLN invasion is most common at its entry into the larynx due to its relative fixed position.
   d. The expected position of the RLN may be distorted in cases of thyroid malignancy.
2. Larynx
   a. Invasion occurs through direct extension through the thyroid and cricoid cartilage or via the paraglottic space around the lateral edge of the thyroid cartilage (Fig. 82.2).
   b. Extension into the hypopharynx may occur through the piriform sinus, which is closely associated with the lateral edge of the thyroid cartilage.

3. Trachea

a. Invasion occurs from direct extension from the thyroid or paratracheal lymph node metastases.

b. Adherence and superficial invasion into the peritracheal fascia and perichondrium occur first.

c. Transmural invasion typically occurs between the cartilaginous rings with feeding vessels that traverse the soft tissue.

1) Often has submucosal spread before intraluminal extension (Fig. 82.3)

4. Esophagus

a. Invasion may be due to direct extension or paratracheal lymph node metastases.

b. The esophagus is generally resistant to invasion and invasion typically involves outer muscular layers without intraluminal invasion.

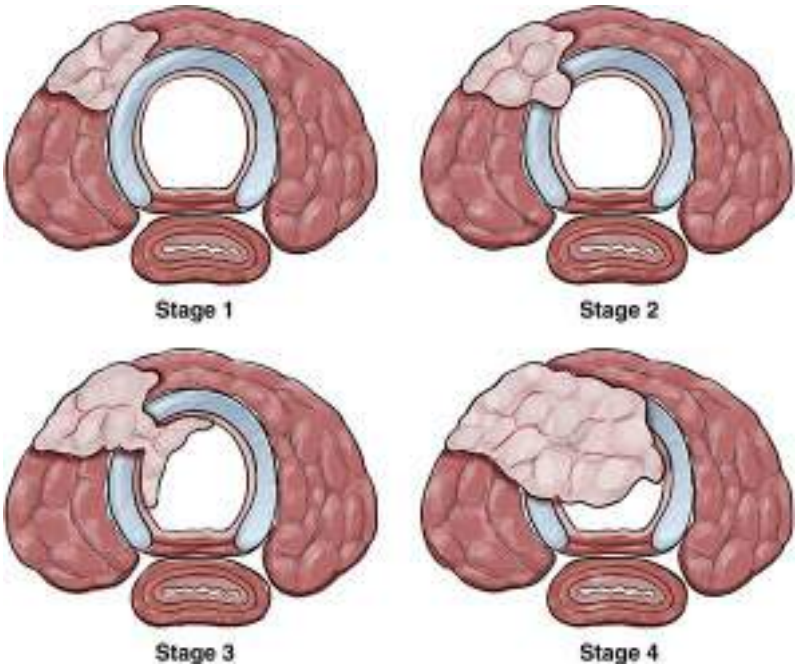

FIG. 82.3 Grading of tracheal invasion from thyroid cancer.

5. Vascular structures

a. Internal jugular vein IJV is most commonly involved from metastatic lymph node spread rather than primary tumor and should be suspected in bulky lateral lymphadenopathy (Fig. 82.4)

b. When carotid artery involvement is suspected, evaluation of circle of Willis must be done with angiography

Prerequisite Skills

1. Intimate knowledge of deep neck anatomy and open neck surgical technique

2. Thyroidectomy (see Chapter 78)

3. Neck dissection (see Chapters 64–67)

4. Partial and total laryngectomy (see Chapters 12, 13, 16, 17)

5. Sleeve resection of trachea (see Chapter 22)

6. Pharyngectomy (see Chapter 40)

7. The surgeon should have personal expertise or readily available assistance from surgeons specializing in thoracic surgery, vascular surgery, or microvascular reconstruction if extensive invasion is suspected of confirmed.

Operative Risks

1. Vocal cord paralysis

   a. If the nerve is functional preoperatively, all efforts should be made to dissect and preserve the RLN.

2. Airway obstruction

3. Pharyngeal or esophageal fistula

4. Dysphagia

5. Hypocalcemia

6. Vascular injury

Surgical Technique

1. Surgical approach

   a. Anterior horizontal incision in line of relaxed skin tension if possible

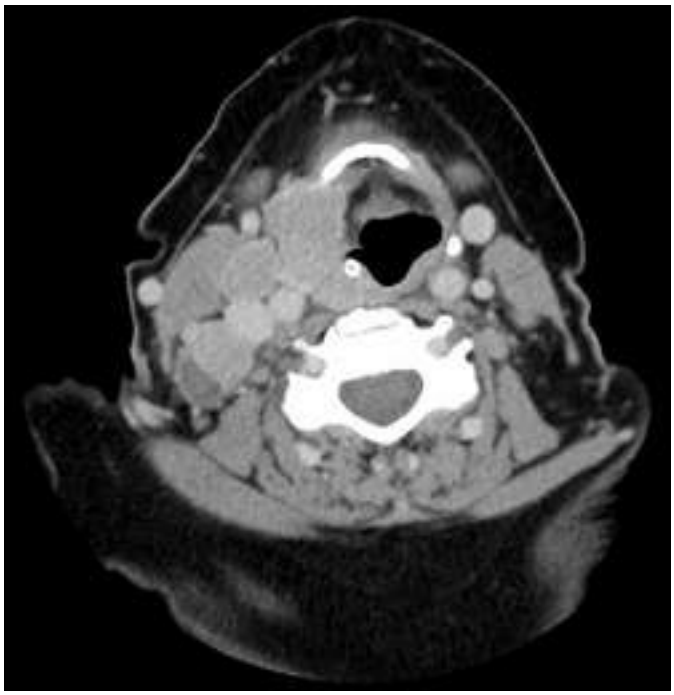

FIG. 82.4 Bulky metastatic cancer in the right lateral neck involving sternocleidomastoid muscle with obliteration of right neck vasculature.

   b. Incision should be extended as needed to incorporate large cancers or allow for lateral neck dissection

      1) McFee incision

      2) Hockey stick or apron incision

   c. Strap muscles may be transversely transected for exposure and should be reapproximated with sutures if uninvolved with tumor on closure.

   d. Median sternotomy may be necessary for substernal extension or for tracheal resection (Fig. 82.5).

      1) Unlike benign thyroid goiters with a substernal component, malignancies with ETE often do not mobilize and require wide

exposure.

2. Muscle and skin invasion

a. Invasion into overlying strap muscles is the most common manifestation of ETE and is often found incidentally.

b. Bluntly dissect strap muscle off thyroid capsule with Freer, Kittner sponge, or dissecting forceps until invasion is identified.

c. Simple wide resection with a cuff of normal muscle is adequate.

3. Nerve invasion

a. The RLN should always be identified and dissected.

1) Avoid unnecessary devascularization, tension, or pressure on RLN during surgery.

2) Preoperative paresis or paralysis may be due to compression.

b. Tumor may be shaved from the RLN if laryngeal function was normal preoperatively

c. RLN should be resected with tumor specimen en bloc if there is documented preoperative paralysis with confirmed invasion.

d. RLN should immediately be repaired if sacrificed.

1) Primary end-to-end neurorrhaphy

a) For small segments with tension-free approximation

b) Microscopic magnification should be used.

c) Nerve ends should be carefully cleaned and prepared.

d) 9-0 nonabsorbable sutures through epineural sheath to coapt nerve fascicles

2) Interposition graft

a) If tension-free approximation not possible

b) Similar neurorraphy technique

c) Ansa cervicalis, great auricular nerve, sural nerve are all good potential donor sites

3) Cross-grafting

a) Motor branch of ansa cervicalis may be anastamosed to

distal RLN stump if proximal stump is unavailable

FIG. 82.5 Total thyroidectomy requiring medial sternotomy.

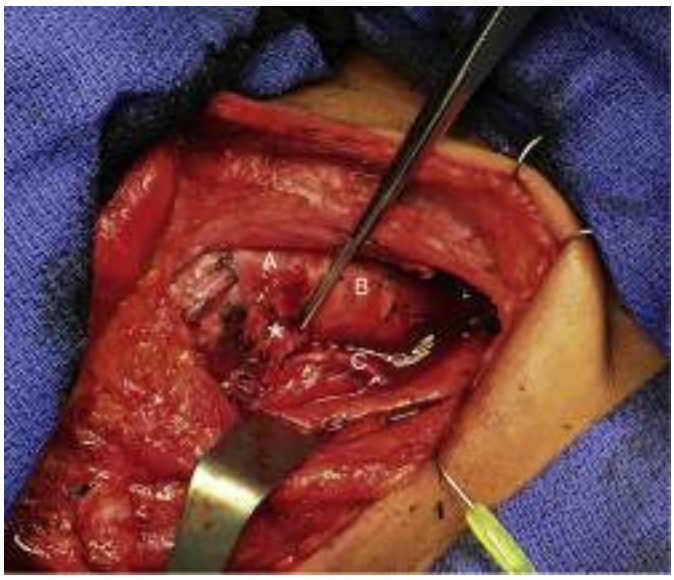

FIG. 82.6 Right thyroid gland (retracted laterally in clamps) with invasion *(asterisk)* and adherence to laryngotracheal complex. **A,** Cricoid, **B,** trachea, **C,** recurrent laryngeal nerve.

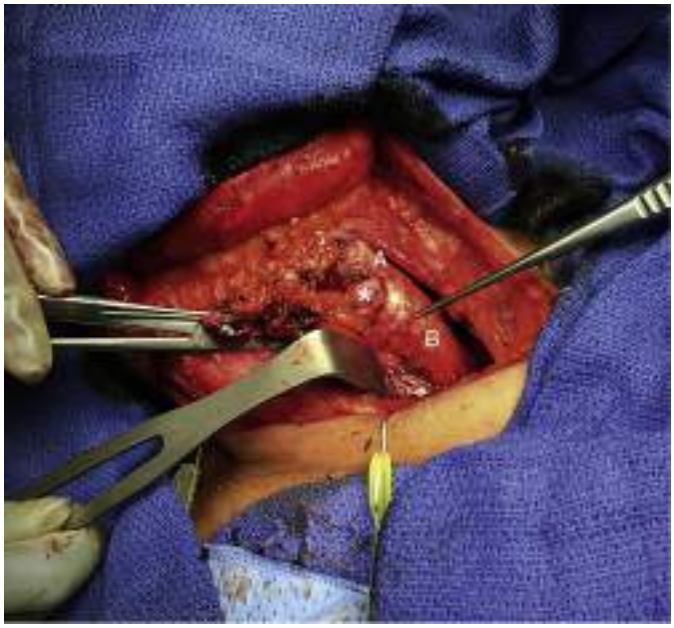

FIG. 82.7 Shave excision *(asterisk)* of thyroid cancer with right-sided laryngeal invasion. **A,** Cricoid, **B,** trachea.

e. Adjunctive laryngeal rehabilitation may be done immediately or at a later time, as necessary.

1) Vocal cord injection

2) Medialization thyroplasty

3) Arytenoid adduction

4) Neuromuscular pedicle

4. Laryngeal invasion

a. Direct laryngoscopy rather than simple mirror examination should be done when laryngeal invasion is suspected preoperatively.

b. Resection of macroscopic tumor off of the thyroid cartilage, cricoid, and cricothyroid membrane (shave resection) may be considered in superficially invasive or adherent tumors (Figs. 82.6 and 82.7).

1) Impossible to assess true disease extension

2) Invasive tumors are more likely poorly differentiated and may be less responsive to RAI.

3) Shave resections have been associated with poorer prognosis and need for repeat surgery.

c. Negative margin resection may require laryngectomy.

1) Vertical partial laryngectomy (see Chapter 13)

a) May be extended as needed if able to preserve one cricoarytenoid unit

b) Tracheostomy required

c) Reconstruction may be done with cartilage grafting and strap muscle flap.

2) Cricoid resection

a) Up to one-third of cricoid ring

i) Cartilage reconstruction to prevent airway stenosis

b) Resection margins involving greater than one-third of cricoid or extension below cricoid cartilage require total laryngectomy.

2) Total laryngectomy (see Chapter 16)

a) Indicated for extensive laryngeal involvement or when partial laryngectomy is impractical

b) May be combined with tracheal resection

5. Tracheal invasion

a. Bronchoscopy

1) Should be done prior to resection when tracheal invasion is seen on imaging

2) Intraluminal findings are a late finding of tracheal invasion, and normal mucosal examinations on bronchoscopy do not rule out involvement of the trachea

b. Shave excision

1) Sharply separate tumor from the airway leaving the mucosa of the airway intact.

2) Typically does not need reconstruction

3) May be used as in the larynx for ETE adherence or superficial invasion

4) Impossible to assess extent of true disease

5) Higher rates of recurrence and need for additional surgery

c. Tracheal resection

1) Circumferential tracheal resection

a) Involved tracheal rings are completely excised en bloc with the cancer.

i) Up to seven to eight tracheal rings may be resected safely.

b) Blunt mobilization of the trachea done anteriorly with limited lateral dissection to preserve lateral blood supply

c) Inferior mobilization carried down to carina

d) Larynx may be released from the hyoid superiorly

e) Neck flexion may aid in releasing tension.

f) Tension-free anastomosis of the trachea should be done with monofilament sutures.

g) Extraluminal knots should be used to reduce risk of stenosis.

h) Circumferential resection preferred due to propensity of intraluminal invasion to spread circumferentially along tracheal ring

2) Window tracheal resection

a) Only involved anterior tracheal excised with tumor with various options for repair

i) Resulting defect may be patched with pedicled or free tissue transfer, often sternocleidomastoid muscle

ii) Sliding tracheoplasty involves wedge resection of lateral portion of window to allow for tension-free primary closure

iii) Window may be stomatized for tracheostomy and staged closure

b) Risks underestimating lateral spread of intraluminal invasion

c) May have less morbidity than circumferential excision

6. Esophageal and pharyngeal invasion

a. Esophagoscopy

1) May be done before or at time of surgery to assess the lumen

2) Low yield due to low rate of intraluminal extension

b. Resection of muscular layer

1) Simple wide excision of muscularis layer of esophagus with tumor

2) Bougie, NGT, or esophageal temperature probe may aid in identifying esophagus and avoiding mucosal defect

3) Reconstruction is typically not required.

c. Full-thickness resection

1) Wide, full-thickness excision of involved intraluminal disease

2) Small defects in the pharynx or cervical esophagus may be closed primarily in a multilayered fashion.

3) Larger defects may require a supporting myofascial flap or myocutaneous flap.

4) Involvement of thoracic esophagus or large circumferential defects may require a gastric pull-up.

7. Vascular invasion

a. Preoperative CT or MRI angiography should be completed with formal angiography to access cerebral collateral flow if resection of carotid artery is planned.

b. IJV

1) Vessel should be dissected, isolated, and controlled distal and proximal to site of invasion

2) Perform wide resection en bloc with the cancer.

a) For extensive involvement, sacrifice of IJV should be done.

b) For focal invasion, noncircumferential resection may be done.

i) May be repaired primarily for small defects

ii) Patch angioplasty with autologous vein graft or synthetic material

3) Suture ligation should be done meticulously to avoid uncontrollable bleeding, especially in the skull base.

4) Unilateral involvement with patent contralateral IJV requires no reconstruction.

5) If bilateral sacrifice is necessary or if contralateral IJV flow is absent, one or both veins should be repaired with an autologous vein graft.

a) Saphenous or femoral vein may be used

b) Staged resection of IJV may be done to allow for development of collateral flow

c. Carotid artery

1) Distal and proximal control of the carotid artery should be done with atraumatic vessel loops.

2) In most cases, tumor is able to be dissected or peeled from carotid while maintaining the integrity of the vessel

3) Sacrifice of common or internal carotid should only be done in the following circumstances

a) Invasion is circumferential (Fig. 82.8) or no dissection plane possible

b) Cancer = involving the carotid artery is the only barrier to achieving complete resection of disease

c) Preoperative imaging and counseling have been done with the patient with acceptable risk of neurovascular injury with temporary disruption of cerebral blood flow

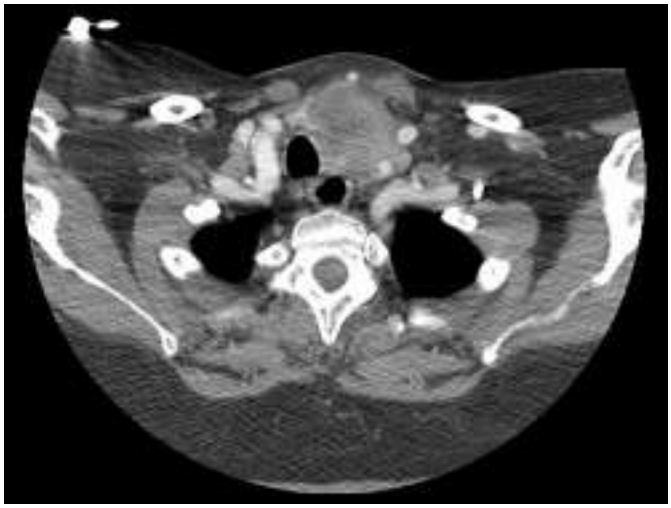

FIG. 82.8 Left thyroid cancer demonstrating encasement of the left common carotid artery on CT.

4) Limited proximal common carotid resection may maintain cerebral perfusion through external carotid artery backflow

   a) Carotid resection and common carotid artery to Internal carotid artery bypass is often done with polytetrafluoroethylene material or autologous grafts.

5) If aerodigestive tract resection or communication is involved in the same operation, meticulous protection and separation are essential to avoid carotid blowout.

   a) Local versus regional muscle flaps may be sutured to the prevertebral fascia to separate lateral neck from central visceral compartment

Common Errors

1. Inadequate preoperative index of suspicion and evaluation of the patient

   a. Invasion discovered intraoperatively and surgeon unprepared for necessary surgery

   b. Incorrect surgical planning

   c. Patient counseling incomplete

2. Incomplete evaluation of extent of invasion in the trachea and larynx

3. Failure to have appropriate subspecialty surgical support available

Postoperative Period

Postoperative Management

1. Intensive care unit level of care for airway monitoring and ventilation management in cases of major laryngeal, tracheal, and vascular resection and reconstruction

2. Surgical drains for any extensive resection, entry into viscera, or neck dissection

3. Monitoring for hypocalcemia

   a. Serum parathyroid hormone (PTH) should be drawn postoperative if available; alternatively serial serum calcium levels may be monitored.

   b. Calcium supplementation for low PTH <20 pg/mL or downtrending calcium levels

4. Hypothyroidism

   a. Thyroid hormone replacement is necessary in all patients receiving total thyroidectomy.

   b. Thyroid hormone withdrawal or liothyronine may be used in anticipation of RAI.

   c. thyroid-stimulating hormone should be suppressed.

5. Adjuvant treatment

   a. RAI therapy (I-131)

      1) Indicated for iodine avid cases of gross ETE, known residual disease, metastatic disease

      2) An important adjunct treatment if shave resection was used

      3) Maybe have limited efficacy in poorly differentiated histology

   b. External beam radiation

      1) May be considered for:

a) High-grade histology (unlikely to uptake iodine)

b) Unresectable gross disease

c) Cases with extensive invasion

2) Associated with improved locoregional control

c. Chemotherapeutic agents

1) Tyrosine kinase inhibitors have been shown to slow or halt progression of disease in iodine-refractory thyroid cancers

2) A variety of antineoplastic agents have been described or are being studied with some promise.

Complications

1. Fluid Collection

a. Hematoma

b. Seroma

c. Infection/abscess

1) Usually indicates leak from luminal structure (trachea, esophagus, pharynx)

d. Wound-healing issues

2. RLN injury

a. May be temporary or partial due to dissection or complete in the case of sacrifice

b. Priority of rehabilitation should be airway first, then swallowing, and lastly phonation

c. If bilateral paralysis or paresis is present, tracheostomy may be necessary

3. Hypoparathyroidism

a. Common when total thyroidectomy is done with extensive paratracheal or lateral neck dissection

b. Monitor postoperative serum PTH and calcium.

c. A patient with a laryngectomy will not be able to verbalize symptoms.

4. Anastomotic leak

a. Can be evidenced by signs of neck infection

1) Increased pain

2) Erythema and edema of skin

3) Neck swelling

4) Suture line dehiscence and discharge

b. Surgical drain fluid may change in quality.

1) Can be tested for amylase if diagnosis is equivocal

c. Can usually be managed conservatively with surgical drain, antibiotics, or packing

d. Feeding tube should be placed if the leak is from pharynx or esophagus

e. Breakdown of airway anastomosis can be life threatening

5. Airway stenosis

a. Typically occurs at the site of anastomosis

b. Antacid medications, antibiotics, and steroids may be used immediately postoperatively to help to avoid inflammation and scarring.

c. Serial laryngoscopy and bronchoscopy should be done to monitor healing.

d. Endoscopic balloon dilations are effective in treating and preventing stenosis.

6. Carotid blowout

a. May be the result of repair breakdown, infection, or recurrent disease

b. High index of suspicion when patient presents with heralding "sentinel bleed"

c. If the diagnosis is made before a catastrophic bleed, treatment

includes:

1) Emergent surgical sacrifice

2) Endovascular stenting or embolization

Alternative Management Plan

1. Unresectable disease or unsuitable patients may elect to have palliative external beam radiation therapy (EBRT) with or without chemotherapy.

2. Tyrosine kinase inhibitors

Discussion

Evidence-Based Question

What should the extent of surgery be for invasive well-differentiated thyroid carcinoma involving the laryngotracheal complex?

Several series have been published supporting the use of shave resection, citing similar survival rates.[6-8] Proponents of shave resection argue that for short segments of superficial tracheal invasion, shave resection may completely excise the disease and the morbidity of circumferential or window resection is unwarranted given the lack of survival difference. However, the evidence currently available is derived from relatively small series with no prospective randomized trials. It is difficult to interpret these series due to inherent heterogeneity in terms of patient selection, histology, stage, iodine avidity, the use of adjuvant treatment, and number of reoperations for local recurrence. Shave excision precludes assessment of the depth of invasion, which is an important prognostic factor for survival.[2,9,10] Okazi et al. reported a series of 21 cases receiving circumferential tracheal resection for invasive thyroid cancer with pathology revealing extension deep to the peritracheal fascia in 19 cases. Not surprisingly, studies have shown high rates of local recurrence in patients receiving shave excision.[8,10] These patients often require additional adjuvant treatment, reoperation, and often eventual salvage laryngotracheal resection. In general, a central goal of treatment in thyroid cancer is local control in the central

compartment. The risks and morbidity of more complete margin-negative resections versus shave resections involving the larynx and trachea must be weighed. Considerations should include the overall status of disease, patient preference, surgeon experience, and treatment goals.

Editorial Comment

The diagnosis of thyroid cancer continues to rise to an estimated 62,000 cases in the United States in 2016. Fortunately invasive thyroid cancer remains relatively uncommon but is responsible for considerable morbidity. Historically, tracheal or esophageal invasion was felt to represent unresectable cancer, and gross tumor was often left behind. With the participation of head and neck oncologic surgeons, thyroid cancer can be treated with aggressive surgical techniques typically reserved for other head and neck cancers, such as laryngeal squamous cell carcinoma. Although considered morbid, treatments such as tracheal resection, esophagectomy, and laryngectomy can confer excellent survival and disease-free control.

Review Questions

1. What is the best imaging modality to evaluate extent and location of tumor invasion into surrounding structures?

   a. Ultrasound

   b. **CT**

   c. MRI

   d. PET

2. What is the recommended management of an RLN adherent to papillary thyroid cancer in a patient with normal preoperative voice and laryngeal function?

   a. En bloc resection of the nerve with end-to-end anastomosis

b. En bloc resection of the nerve with interposition nerve graft

c. **Attempts at nerve preservation with sharp dissection of tumor off the nerve**

d. En bloc resection of the nerve with ansa to RLN cross-graft

3. What surgical option allows the best chance of local control in tracheal invasion?

a. Window resection

b. Shave resection followed by EBRT

c. Shave resection followed by RAI

d. **Circumferential tracheal resection**

Intraoperative Parathyroid Hormone Monitoring

Jeffrey Steitz, and Jeffrey Bumpous

Introduction

Parathyroid hormone (PTH) is secreted from the parathyroid glands and is primarily responsible for calcium homeostasis. The mechanism by which this occurs is through renal tubular reabsorption, bone resorption, and formation of calcitriol from calcidiol in the renal tubular cells. The hormone is synthesized as an inactive polypeptide chain, which is then cleaved at the N-terminal in the parathyroid glands to an active form. The half-life of the hormone ranges from 2 to 4 minutes, making it useful for serologic analysis by rapid immunoassay following excision of an abnormally functioning gland.

Primary hyperparathyroidism is a disorder of the parathyroid glands in which excess PTH is secreted. This most commonly results from a single parathyroid adenoma (80% to 85%) or less frequently from four-gland hyperplasia (10% to 15%) or double adenoma (4% to 6%). Rarely, primary hyperparathyroidism can be caused by parathyroid carcinoma (0.1% to 1%).[1] Historically, primary hyperparathyroidism has been treated with a four-gland exploration with removal of abnormal-appearing parathyroid tissue and biopsy verification of normal parathyroid tissue in the case of adenoma versus three and a half gland excision in cases of hyperplasia. However, bilateral neck exploration has a higher incidence of temporary and permanent hypocalcemia, which may lead to longer hospital stays and increased morbidity from symptomatic hypocalcemia. With the advent of improved imaging techniques and radioguided parathyroidectomy, minimally invasive techniques have decreased the morbidity associated with this condition and led to overall better outcomes.

Preoperative imaging with a sestamibi scan has excellent sensitivity in the case of a single parathyroid adenoma. However, in patients who have underlying four-gland hyperplasia or double adenoma, sensitivity decreases significantly to 30% to 44%. This decreased sensitivity may lead to treatment failure and subject patients to an additional surgery. Intraoperative PTH monitoring is a valuable adjunct in the approach to minimally invasive parathyroidectomy. It allows for the rapid detection of PTH prior to and following excision of abnormal-appearing parathyroid tissue. This decreases the need for bilateral neck exploration as well as the overall risk of postoperative hypocalcemia, hematoma, and recurrent laryngeal nerve injury; it also shortens the operative time. Intraoperative PTH monitoring is a rapid assay performed at three intervals throughout the surgery: before incision and at 10 and 15 minutes after excision. If the PTH level drops at least 50% from the highest preincision or preexcision levels, the procedure can safely be concluded without further neck exploration (Table 83.1).[2,3]

In addition to providing immediate feedback during parathyroid surgery, intraoperative PTH monitoring has been used to predict the likelihood of hypocalcemia following total thyroidectomy. Hypocalcemia is the most frequent complication following total thyroidectomy, with a reported incidence of 20% to 50%. Debilitating and permanent hypocalcemia, though less common, can still occur in close to 2% of patients. Historically patients are admitted to the hospital following total thyroidectomy for the monitoring of hypocalcemia, since symptoms can occur within 24 to 48 hours and can be life threatening. Research in the use of PTH levels following total thyroidectomy is ongoing and a consensus on the timing of blood draw and appropriate levels for discharge has not been clearly elucidated. In general, PTH assay results drawn within 6 hours after total thyroidectomy have been found to be the most reliable. Cutoff values for PTH that accurately predict hypocalcemia unfortunately do not exist. Studies have shown that patients who went on to develop hypocalcemia had 70% to 80% declines in PTH as opposed to 20% to 30% declines in patients who remained normocalcemic.[4,5]

Key Operative Learning Points

1. Intraoperative PTH monitoring is a valuable adjunct in minimally

invasive parathyroidectomy, especially in the setting of negative preoperative imaging studies.

2. A blood sample can be easily and rapidly collected from the internal jugular vein, peripheral vein, or an arterial line.

3. PTH should be sampled at three separate points: before incision and at 10 and 15 minutes following excision. A greater than 50% decrease in the highest PTH value following excision correlates with complete removal of abnormal parathyroid tissue.

Preoperative Period

History

1. History of present illness
   a. See Chapter 108 (Parathyroidectomy for Primary Hyperparathyroidism and Non-Localizing Hyperparathyroidism)
2. Past medical history
   a. Medical illness
      1) Bone pain or history of pathologic fracture
      2) History of renal calculi or other renal disorder
      3) Underlying psychologic illness or depression
      4) Generalized weakness, abdominal pain, muscle spasm
   b. Surgery
      1) Previous thyroid or parathyroid surgery
      2) Any other neck surgery
   c. Family history
      1) History of familial hypercalcemia should raise concern for multiple endocrine neoplasia (MEN) syndrome or familial hypocalciuric hypercalcemia
   d. Medications
      1) Calcium supplements

2) Lithium: may cause hypercalcemia

3) Antiplatelet drugs

4) Herbal products

5) Alcohol

TABLE 83.1

Intraoperative Parathyroid Hormone Assay and Expected Values After Assay Performed

Intraoperative Parathyroid Hormone Assay Performed	Expected Value
Preincision	Varies depending on level of patient hyperparathyroidism
10 minutes postexcision	In successful surgery, a decrease of greater than 50% or at least a trend downward in preincision PTH levels is seen
15 minutes postexcision	With successful surgery, a decrease of greater than 50% in preincision PTH levels is seen

PTH, Parathyroid hormone.

Physical Examination

1. See Chapter 108 (Parathyroidectomy for Primary Hyperparathyroidism and Non-Localizing Hyperparathyroidism).

Imaging

No imaging is required.

Ultrasound

Thyroid ultrasound can be useful for the localization of parathyroid adenoma; however, its utility is limited, especially in the setting of thyroid nodule or multinodular goiter.

Technetium-99 Sestamibi Scan

The sestamibi scan has consistently been shown to be a highly sensitive study in single parathyroid adenoma. However, in the setting of parathyroid hyperplasia or double adenoma the sensitivity significantly decreases to 30% to 44%.

Single photon emission computed tomography (SPECT)

Dual-energy X-ray absorptiometry (DEXA) Scan

The DEXA scan is a useful adjunct in patients with primary hyperparathyroidism who are at high risk for operative intervention. Its utility lies in the diagnosis of osteoporosis or osteopenia, conditions that can lead to a pathologic fracture. In patients without any underlying bone abnormality, some high-risk patients with subclinical hyperparathyroidism can be safely observed.

Indications

1. Intraoperative PTH assessment in parathyroid adenoma, double adenoma, or hyperplasia

2. Postoperative prediction of hypocalcemia following total thyroidectomy. This can be useful in otherwise low-risk patients to determine the likelihood of symptomatic hypocalcemia in the perioperative period.

Contraindications

1. Significant medical comorbidities with elevated perioperative risk

Patients with significant comorbidities that preclude operative intervention can be monitored for complications associated with hyperparathyroidism, including but not limited to arrhythmias, renal disease, and pathologic fracture.

Preoperative Preparation

1. Assessment of preoperative PTH levels

2. Assessment of preoperative calcium levels

3. Discontinuation of antiplatelet drugs if possible

Operative Period

Anesthesia

General: Although this procedure can be done with awake sedation, general anesthesia is preferred for patient comfort and protection of the airway if there is active bleeding.

Monitored anesthesia care (MAC)

Local anesthesia

Positioning

Supine. In addition to supine positioning, proper neck extension and shoulder-roll placement are especially important in dissection of the lower neck.

Prone

Lateral recumbent

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin: We prefer cefazolin 1 mg if the patient weighs less than 75 kg or 2 mg if the patient weighs more than that.

Second-generation cephalosporin: Clindamycin if the patient is allergic to penicillin

Monitoring

None

Recurrent laryngeal nerve monitor: Can be a useful adjunct in the identification and preservation of the recurrent laryngeal nerve, especially in revision surgery

Instruments and Equipment to Have Available

1. Basic head and neck surgery set

2. Nerve integrity monitor (NIM) endotracheal tube if monitoring of the

recurrent laryngeal nerve is planned

3. In drawing blood for intraoperative PTH assessment, we authors use a 10-mL syringe with an 18-gauge needle placed into the internal jugular vein.

Key Anatomic Landmarks

1. See Chapter 108 (Parathyroidectomy for Primary Hyperparathyroidism and Non-Localizing Hyperparathyroidism) for anatomic landmarks useful in parathyroidectomy.

2. The internal jugular vein lies within the carotid sheath lateral to the thyroid gland.

Prerequisite Skills

1. Parathyroidectomy or total parathyroidectomy; see Chapter 108 (Parathyroidectomy for Primary Hyperparathyroidism and Non-Localizing Hyperparathyroidism).

Operative Risks

1. Intraoperative hemorrhage from the internal jugular vein

2. Venous thrombosis/thrombophlebitis

3. Damage to the recurrent laryngeal nerve

4. Devascularization of normal parathyroid tissue

Surgical Technique

- See Chapters 108 and 102 regarding surgical management in parathyroidectomy and total thyroidectomy.

In performing thyroid and parathyroid surgery, the surgeon should be comfortable in managing the vascular pedicles of the glands. Dissection laterally from the thyroid gland leads to the structures of the carotid sheath. In preparation for venipuncture, the internal jugular vein should

be dissected bluntly from the carotid sheath with the assistance of a bipolar cautery. Alternatively a peripheral or arterial line can be used for assays.

- PTH assays should be performed at four intervals:
  - Preincision: from a peripheral source
  - At 10 minutes postexcision: from the internal jugular vein or peripherally
  - At 15 minutes postexcision: from the internal jugular vein or peripherally
- Should the PTH level drop to greater than 50% of the highest preincision value, the procedure can safely be concluded. Should the PTH drop less than 50%, four-gland exploration may need to be performed to rule out double adenoma or four-gland hyperplasia. See Chapter 108 for discussion of four-gland exploration.
- Hemostasis from internal jugular vein venipuncture

Bleeding from the internal jugular vein at the venipuncture site can easily be controlled with digital pressure for 3 to 5 minutes. Alternatively, thrombin-soaked Gelfoam can also be applied. Rarely, suture repair or ligation may have to be performed.

Common Errors in Technique

1. Laceration of the internal jugular vein during venipuncture
2. Failure to recognize underlying renal disease

PTH is a rapidly metabolized hormone with a half-life of 2 to 4 minutes in a normal person. Underlying renal disease can be common in patients with hyperparathyroidism and may prolong the half-life of PTH.

Postoperative Period

Postoperative Management

1. Routine postoperative care for patients undergoing parathyroidectomy

or thyroidectomy (see Chapters 102 to 106 and 108 to 110)

2. In patients who undergo PTH assay following total thyroidectomy, should the PTH level drop significantly, the patient should be monitored in the hospital for hypocalcemia. In contrast, low-risk patients without a significant decrease in PTH may be discharged on a case-by-case basis.

3. After parathyroidectomy, should the PTH fail to drop more than 50% and four-gland exploration is performed, monitoring for hypocalcemia as an inpatient will be required.

Complications

1. Hemorrhage from the venipuncture site in the internal jugular vein

This can occur if the venipuncture needle lacerates the internal jugular vein, leading to a larger rent in the vessel. If pressure does not control the hemorrhage, primary repair can be performed with a 5-0 or smaller vascular prolene suture. Rarely, if the laceration in the vein becomes enlarged by attempts at control and is unsalvageable, the internal jugular vein can be sacrificed. This can be done with 2-0 silk ties or medium hemoclips.

2. For complications related to parathyroidectomy and thyroidectomy, see Chapters 102 to 106 and 108 to 110.

Alternative Management Plan

1. Minimally invasive radioguided parathyroidectomy

Use of radiolabeled tracer in parathyroid surgery detected by the gamma probe is another useful adjunct in minimally invasive surgical approaches to the parathyroid gland. This does not exclude intraoperative PTH assay and can be used in conjunction with it.

2. Four-gland exploration

Historically four-gland exploration was the standard for primary hyperparathyroidism. There is unfortunately an increased risk of complications and the need for repeat surgery in the event of four-gland hyperplasia.

Discussion

Evidence-Based Medicine Question

Why perform intraoperative assays at 10 and 15 minutes postexcision?

Once the intraoperative PTH assay was developed and validated, several criteria were developed to determine the most sensitive and accurate times for assay. The accepted criterion is known as the Miami criterion and has a sensitivity and overall accuracy of 97%. Additionally the positive predictive value is 99% and negative predictive value 88%. The criterion itself is an equal to or greater than a 50% decrease from the highest preexcision PTH value at 10 minutes. When several criteria were compared, the Miami criterion showed significantly fewer false-negative results (2.6% vs. 6% to 24%), making it the most accepted method. PTH assays done at longer time intervals (>15 minutes) have been shown to increase operating time as well as the likelihood of false-negative results.

Editorial Comment

The PTH assay has greatly influenced modern parathyroid surgery, resulting in shorter operative times and greater surgical success. Outpatient thyroid surgery has also used rapid PTH assays to predict potential hypocalcemia in postoperative patients.

Alfred Simental, Jr.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. A PTH assay should be performed at all of the following times during minimally invasive parathyroidectomy EXCEPT

   a. Preincision

   b. 10 minutes postexcision

   c. **2 hours postexcision**

   d. 15 minutes postexcision

2. Postexcision levels of PTH should drop by what percentage to be considered safe to conclude the operation?

   a. ≥10%

   b. ≥30%

   c. ≥75%

   d. **≥50%**

3. Following total thyroidectomy, a PTH level drawn within what time frame can be useful to determine likelihood of postoperative hypocalcemia?

   a. **At 6 hours**

   b. At 10 minutes

   c. At 4 hours

   d. At 24 hours

Parathyroidectomy for Primary Hyperparathyroidism and Nonlocalizing Hyperparathyroidism

Joshua S. Park, and Alfred Simental Jr.

Introduction

The parathyroid glands are usually found adjacent to the thyroid gland and produce parathyroid hormone (PTH), which increases serum calcium levels by enhancing bone resorption, increasing calcium reabsorption in the distal tubules of the kidneys, and converting calcidiol to the active calcitriol form of vitamin D, which stimulates intestinal calcium absorption. About 85% of the population have two superior (4th pouch) and two inferior (3rd pouch) parathyroid glands, embryologically originating from the dorsal portion of the respective pharyngeal pouches. Supernumerary (more than four) parathyroid glands may occur in up to 15% of the population, and 1% to 3% of parathyroid glands are ectopic.[1]

Primary hyperparathyroidism (PHPT) affects up to 0.5% of the US population and is 4 times more common in females. When sporadic, PHPT is most commonly associated with parathyroid adenoma (80% to 90% of cases) (Fig. 84.1), glandular hyperplasia (6% to 15%) (Fig. 84.2), double adenomas (2% to 5%), and carcinoma (<5%).[1] Familial conditions such as multiple endocrine neoplasia (MEN) type 1, MEN type 2A, and familial isolated hyperparathyroidism are also associated with PHPT. Radiation exposure and genetic defects in cyclin D1 (PRAD) oncogene, MEN1, and Cyclin dependent kinase inhibitory B (CDKN1B) have been identified as risk factors for the development of adenomas and hyperplasia, but there are many yet unknown factors that cause PHPT. Parathyroidectomy is the only curative treatment for patients with PHPT.

Key Operative Learning Points

- Superior parathyroid glands are most commonly located on the posterolateral aspect of the upper two-thirds of the thyroid lobes. Their location can be estimated 1 cm above and below the intersection between the recurrent laryngeal nerve (RLN) and the inferior thyroid artery.
- Inferior parathyroid glands are most commonly found in the thyrothymic tract at the level of the inferior aspect of the thyroid lobes.
- The RLN is almost always anterior to the superior parathyroid glands and usually posterior to the inferior parathyroid glands.
- Focused approaches to parathyroidectomy are made possible by preoperative localization of the hyperfunctioning parathyroid gland and intraoperative PTH monitoring.

Preoperative Period

History

1. History of present illness
   a. Most patients with PHPT are asymptomatic, but many have nonspecific symptoms such as fatigue, weakness of the proximal extremities, diffuse bone pain, anorexia, and constipation.
   b. Symptoms of hypercalcemia
      1) Urinary system: Polydipsia, polyuria, nephrolithiasis
      2) Skeletal system: Osteopenia, osteoporosis, or osteitis fibrosa cystic, which presents with bone pain, pathologic fractures, and/or "brown tumors"
      3) Gastrointestinal system: Peptic ulcer disease (PUD), pancreatitis, cholelithiasis
      4) Cardiovascular system: Hypertension, arrhythmias, embolic events
      5) Neurologic system: Depression, anxiety, cognitive dysfunction,

psychosis

c. Symptoms of coexistent thyroid disease

1) Compressive symptoms such as dysphagia, hoarseness, cervical pressure, globus sensation

2. Past medical history

a. Previous treatment of PHPT

b. History of radiation therapy to the neck

c. Medical illnesses, to determine candidacy for surgery

d. Past surgical history, especially operations on the neck

3. Family history: Thyroid or parathyroid disease, familial isolated hyperparathyroidism, MEN type 1 or 2A, or familial hypocalciuric hypercalcemia

4. Medications

a. Anticoagulants and antiplatelet medications

b. Lithium or thiazide diuretics

1) May cause mild hypercalcemia and hyperparathyroidism, so discontinue for at least 1 month before confirming PHPT.

c. Allergies to antibiotics

Physical Examination

1. Neck

a. Examination findings are nonspecific

b. Assess for thyroid nodules and cervical adenopathy.

c. A palpable mass in the neck in the patient with hypercalcemia may indicate parathyroid carcinoma.

2. Laryngoscopy

a. Assess preoperative RLN function.

b. Essential prior to reoperation

Laboratory

1. Most cases of PHPT are diagnosed following an incidental finding of elevated serum calcium.

2. Calcium, total vitamin D, and PTH should be measured together.

3. Measure 24-hour urine calcium excretion in order to distinguish PHPT from familial hypocalciuric hypercalcemia.

4. Other laboratory abnormalities in PHPT include hypophosphatemia and mild hyperchloremic acidosis secondary to renal involvement.

5. Use creatinine and blood urea nitrogen (BUN) to rule out renal insufficiency.

6. Patients who have had gastric bypass surgery should have calcium challenge to assure absorptive ability.

Imaging

1. Preoperative imaging/localization results in

   a. Increased operative success

   b. Decreased surgical risk/extent of dissection

   c. Decreased operative time

FIG. 84.1 Parathyroid adenoma.

FIG. 84.2 Parathyroid hyperplasia. Surgical clips have been placed on the parathyroid glands.

2. Imaging is particularly important prior to reoperation.

3. Imaging guides the operative approach.

4. Imaging has no role in the diagnosis of PHPT.

5. Imaging options:

   a. Ultrasound

      1) Parathyroid adenomas have a homogeneous hypoechoic appearance on ultrasound.[1]

      2) Ultrasound has emerged as the preferred initial preoperative localization method for many surgeons and endocrinologists.

      3) Ultrasound can screen for concomitant thyroid lesions that require surgical intervention, though the sensitivity of ultrasound is diminished in those with concurrent thyroid disease.

      4) As in other applications, the major limitation of sonography is that accuracy is operator-dependent.

   b. Technetium-99m sestamibi scintigraphy (Fig. 84.3)

1) Sestamibi scintigraphy has been the traditional standard for preoperative localization.

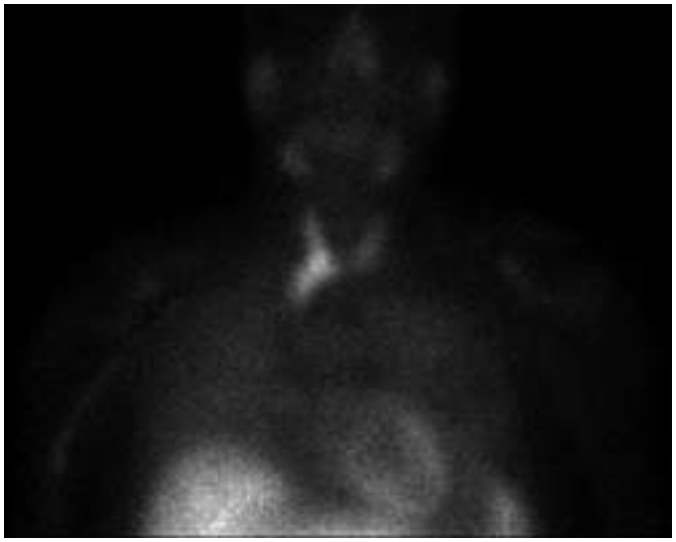

FIG. 84.3 Sestamibi scintigraphy.

This scan shows increased activity on the right. In the presence of hypercalcemia, this finding suggests a parathyroid adenoma.

2) Planar images[2] are captured after the injection of the radiotracer technetium-99m-methoxyisobutylisonitrile (MIBI), which is taken up preferentially by the mitochondria of the cells of the hyperfunctioning parathyroid gland(s).

6. Patients with familial hyperparathyroidism, MEN type 1, and MEN type 2A only need ultrasound to screen for coexistent thyroid disease because they will undergo four-gland exploration.

Invasive Localization

1. Invasive localization techniques may be employed if previous imaging is nonlocalizing or conflicting.

2. Selective venous sampling and arteriography effectively localize pathologic parathyroid glands.

a. Associated with risks such as hematoma of the groin, possible embolic events, and contrast-induced anaphylaxis or acute kidney

injury

3. Fine-needle aspiration of a parathyroid mass under ultrasound guidance can confirm location by measuring PTH in aspirate.

Indications

1. Symptomatic PHPT, including parathyroid crisis

2. Familial PHPT

3. Suspicion for parathyroid cancer

4. Presence of thyroid disease that can be surgically treated at the same time as PHPT

5. Asymptomatic PHPT patients in whom at least one of the following is true[3]:

   a. Age less than 50 years

   b. Serum calcium greater than 1 mg/dL above the upper limit of normal

   c. Bone mineral density T score less than –2.5

   d. Vertebral fracture

   e. Creatinine clearance less than 60 mL/minute or reduced more than 30% for age

   f. Twenty-four-hour urine calcium greater than 400 mg/dL

   g. Nephrolithiasis or nephrocalcinosis on imaging

Contraindications

1. Contralateral RLN injury

2. Symptomatic cervical disc disease

3. Other comorbidities that preclude surgery

Preoperative Preparation

1. Discontinue antiplatelet and anticoagulation medications

2. An important factor for surgically curing PHPT and minimizing morbidity is correctly determining the extent of the surgery that should be performed

a. Minimally invasive parathyroidectomy (MIP), which generally consists of successful preoperative localization, cervical block anesthesia, a smaller incision, and intraoperative PTH monitoring, results in complication and cure rates equal to or better than traditional bilateral neck exploration (BNE)[4] and may reduce costs.

1) The success rate of parathyroidectomy for PHPT, via either MIP or traditional BNE, approaches 95% to 97% in experienced, high volume surgical centers.

b. Video-assisted (endoscopic) parathyroidectomy is a minimally invasive technique that has excellent safety and outcomes.

1) It is performed under local or general anesthesia with intraoperative PTH monitoring in patients with positive preoperative localization of a single adenoma.

2) Video augmentation with 30-degree endoscopes provides optimal illumination and magnification.

3) Potential benefits include improved cosmesis and reduced postoperative cervical discomfort.

c. Bilateral cervical exploration remains the first-line option for certain subsets of the PHPT population:

1) Patients with nonlocalizing, equivocal, or contradicting preoperative imaging

2) Suspected multiglandular disease; most hereditary forms of PHPT cause multiglandular disease:

a) MEN type 1

i) Subtotal parathyroidectomy, which consists of the removal of three and a half glands, or total parathyroidectomy with autotransplantation

ii) Thymectomy is also performed, since the thymus is the most common site of supernumerary parathyroid

glands, which are common in MEN type 1.

iii) It is important to diagnose MEN preoperatively because undiagnosed patients may undergo MIP instead of BNE, likely resulting in operative failure.

b) MEN type 2A

i) Usually BNE with resection of enlarged glands, but some prefer subtotal or total parathyroidectomy

c) Familial isolated hyperparathyroidism

i) Subtotal or total parathyroidectomy and thymectomy

d) Familial neonatal hyperparathyroidism

i) Treat urgently with total parathyroidectomy and thymectomy.

3) Failure of intraoperative PTH to normalize after unilateral exploration

4) Concurrent indication for thyroidectomy

d. Despite the high success rate of parathyroidectomy, the surgeon's experience and expertise are invaluable in parathyroid surgery.

1) When a minimally invasive procedure is chosen as the initial approach, the surgeon must know when and how to convert the procedure to a BNE.

a) The most common reasons for conversion are incorrect preoperative localization, failure of normalization of intraoperative PTH, and intraoperative evidence of multiglandular disease.

Operative Period

Anesthesia

- Parathyroid surgery is generally performed under general endotracheal anesthesia.
- MIP, in cases involving a well-localized single adenoma in patients

without a history of neck surgery, may be completed using a superficial cervical plexus block with conscious intravenous sedation.

- Similar cure and complication rates while reducing postoperative pain and nausea
- Significant risk for conversion to general anesthesia, most commonly due to intraoperative discovery of concurrent thyroid pathology or multiglandular parathyroid disease

Positioning

- Position the patient in the supine position, and tilt the head of bed to 30 degrees in reverse Trendelenburg to enhance venous drainage from the head and neck.
- Augment slight neck extension by placing a small roll under the scapulae.

Perioperative Antibiotic Prophylaxis

- Perioperative antibiotics are not required in clean neck surgeries such as parathyroidectomy and can be limited to a single preincision dose.

Monitoring

- Routine anesthesia monitoring
- Generally no neural intraoperative monitoring is necessary, but may be used depending on surgeon preference.

Instruments and Equipment to Have Available

- Basic head and neck set
- Ultrasonic scalpel for thyroidectomy
- Monopolar and bipolar cautery

- Kittner/peanut sponges for blunt dissection, retraction, and protection of nerves from thermal energy
- Babcock forceps are helpful in grasping and retracting thyroid tissue.
- McCabe dissector
  - Its curved, precise, nonlocking tips are excellent for identification and dissection of nerves.
- Surgical clips should be available.
- Mahorner, Lone Star, or Weitlaner self-retaining retractors may be helpful if an assistant is not available.

Key Anatomic Landmarks

- RLN
  - The right RLN originates from the vagus nerve at the level of the subclavian artery and transversely travels toward the trachea, entering the tracheoesophageal groove before eventually entering the larynx near the first tracheal ring.
  - The left RLN originates from the vagus nerve at the level of the aortic arch and travels more directly cranially toward the tracheoesophageal groove to enter the larynx.

Prerequisite Skills

- Intricate knowledge of surgical instrument use and meticulous soft tissue/neural dissection
- Experience with thyroid surgery

Operative Risks

- Injury to the RLN
  - The nerve does not always need to be identified and traced but should be visualized and consciously protected if exploration involves the paraesophageal and retroesophageal spaces.

- RLN monitoring via electromyography may aid in nerve localization but has not altered the incidence of postoperative vocal fold paresis.

- Incidental excision of normal parathyroid gland tissue
  - Verify parathyroid tissue by frozen section and then mince the tissue into 1 mm pieces and autotransplant into sternocleidomastoid or strap muscles.

Surgical Technique

- Draw preoperative PTH level.
  - Collect blood samples from peripheral venous or arterial access because central venous samples may result in falsely elevated PTH levels if drawn ipsilateral to an adenomatous gland.
- After injecting local anesthetic, make a Kocher skin incision between the cricoid and suprasternal notch, ideally in a relaxed skin crease.
  - In BNE, place a 3- to 5-cm incision in the midline.
  - In MIP, the incision can be smaller and lateralized to the suspected side.
- Raise subplatysmal flaps transversely.
- Divide the median raphe longitudinally to reveal and split the strap muscles in the midline, retracting laterally from the thyroid gland, which is retracted medially.
  - Thyroid vein ligation aids mobilization of the thyroid lobe.
- Rotate the thyroid medially in order to visualize the entire posterior aspect of the gland and identify parathyroids on the posterior capsular surface.
- Continue dissection in order to visualize the carotid artery, paratracheal region, and retrothyroid space.
- Identify RLN and trace it inferiorly to the carotid artery and superiorly to the cricothyroid muscle.
- Search for parathyroid glands (Video 84.1).
  - Utilize visualization and palpation to detect the glands.

- Normal parathyroid glands are about the size of a grain of rice or lentil and weigh 30 to 50 mg.
- Do not remove normal parathyroid glands, even if an enlarged parathyroid is not found.
- Regardless of pathology, parathyroid glands can vary in color.
  - Normal parathyroid glands are usually light brown compared to adipose tissue, which is yellow.
  - A white, firm parathyroid gland should raise suspicion for carcinoma.
- Non malignant parathyroid glands have greater mobility than thyroid nodules and perithyroidal lymph nodes.

- In MIP, attempt to find the enlarged gland that was identified on preoperative imaging.
- In BNE, surgeon preference determines the order in which the search is conducted, but it should be systematic and consistent.
- Locating superior parathyroid glands
  - Embryologically, the superior parathyroid glands arise from the fourth branchial pouch and migrate caudally with the thyroid lobe.
  - Most commonly found on the posterolateral surface of the upper two-thirds of the thyroid lobe, in proximity to the cricothyroid junction
    - This position is approximated about 1 cm above and below the intersection of the RLN and the inferior thyroid artery
  - Less common locations include the piriform sinus, tracheoesophageal groove, and the paraesophageal/retroesophageal spaces (Fig. 84.4)
- Locating inferior parathyroid glands
  - The inferior glands are derived from the dorsal wing of the third branchial pouch and have greater variability in location due to the longer path of embryologic descent, which is paired to the thymus.
  - Most commonly found in the anterior mediastinal compartment,

often associated with the thymus or the inferior portion of the thyroid lobe

- Missing inferior glands should be sought near the thymus and superior mediastinum (see Fig. 84.4).

- Adjunctive intraoperative techniques can help localize an occult gland
  - Radio-guided probe: Technetium-99m–labeled sestamibi is injected 2 hours prior to surgery to allow concentration into the hyperfunctioning gland; a handheld gamma probe is used to guide incision placement, depending on greatest radioactivity, and to survey the postexcisional surgical site for remnant parathyroid tissue.
    - Limited by its inability to exclude multiglandular disease, and the fact that thyroid nodules may take up the technetium-99m and cause false positive results

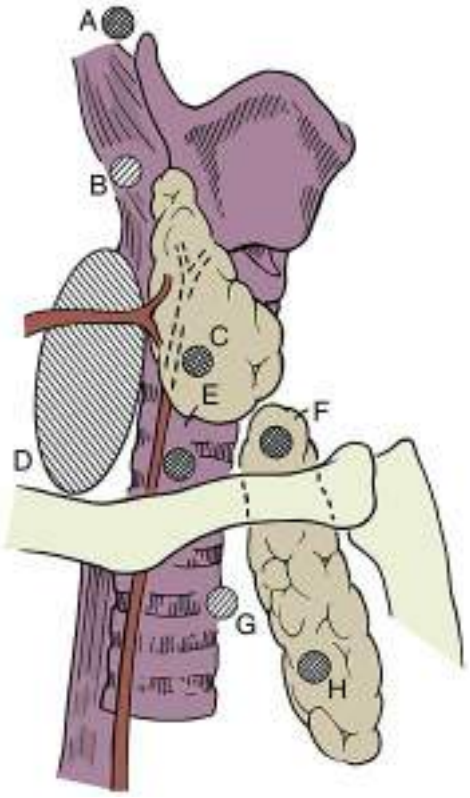

FIG. 84.4 Ectopic locations of the superior (B, partially descended; D, tracheoesophageal groove; G,

mediastinal) and inferior (A, undescended; C, intrathyroid; E, mediastinal outlet; F, intrathymic; H, anterior mediastinal) parathyroid glands.

- Methylene blue: Intravenous injection can augment visual localization
  - Typically reserved for reoperative cases, in large part due to the risk of neurotoxicity
- Jugular vein sampling of PTH levels may help lateralize the hyperfunctioning gland.

- Once an enlarged parathyroid gland is identified, dissect it circumferentially from surrounding structures before sealing the vessels (Video 84.2).
  - Parathyroid adenoma and hyperplasia are shown in Figs. 84.1 and 84.2, respectively.
- Excise the parathyroid gland and send for frozen section analysis in order to confirm that it was indeed parathyroid tissue that was removed.
- Deciding whether to discontinue exploration should only occur after identification of at least one abnormal and one normal gland or use of PTH.
- Intraoperative PTH monitoring may also guide the decision to conclude surgery.
  - The short half-life of PTH (3 to 5 minutes) allows for rapid assay techniques that can be completed within 20 minutes.
  - Intraoperative PTH monitoring allows for less extensive surgeries,[4] reduces costs, and results in excellent outcomes, even for reoperative parathyroidectomy and surgery performed for patients with nonlocalizing scans.
  - The Loma Linda University protocol requires the measurement of four intraoperative PTH levels: preincision, and 10-, 15-, and 20-minute postexcision levels.
    - A PTH decrease of greater than 50% compared to the preincision level within 10 minutes after gland excision suggests the patient is

cured.

- The 15- and 20-minute levels should continue to significantly drop, as leveling off in the slope of decline is worrisome for persistent disease.

- The incision may be closed while awaiting the results of the PTH assay, but the patient should remain under anesthesia until satisfactory levels are reached.
- An unchanged PTH level likely signifies the failure to remove abnormal parathyroid tissue.
- PTH levels do not need to be drawn after the removal of each parathyroid gland if BNE had been planned.

- If further surgical dissection is warranted based on PTH testing, then explore the ipsilateral side to find the other parathyroid gland on that side.
  - Enlargement of this second gland is further evidence of multiglandular disease.
    - In this case, explore all four glands and perform subtotal parathyroidectomy.
    - Surgical clips should be placed to aid in localization of parathyroid glands left in situ, especially in cases of suspected hyperplasia (see Fig. 84.2).
- Over 95% of adenomatous parathyroid glands are removed transcervically, but a median sternotomy may be necessary if a mediastinal enlarged gland is inaccessible through the neck.
- Conclude the procedure by reapproximating the strap muscles and platysma with interrupted absorbable sutures, and close the skin with a running subcuticular absorbable suture or adhesive Steri-Strips.

Common Errors in Technique

- Poor hemostasis resulting in staining of the surgical field
  - The plane between the strap muscles and thyroid capsule is particularly vascular.

- Use careful blunt dissection during exploration.

- Insufficient visualization of common parathyroid gland locations.
  - Enhance medial retraction of the thyroid lobes by ligating the middle thyroid veins.
  - Open the fascial sheath (pretracheal fascia) to access the paraesophageal and retroesophageal spaces.
- Devascularization or removal of normal parathyroid glands.
  - These should be identified intraoperatively and the glands autotransplanted.

Postoperative Period

Postoperative Management

1. Mild analgesics are generally adequate following parathyroid surgery.

2. The first postoperative visit, which should occur within 2 weeks of surgery, includes laboratory tests such as calcium, PTH, and vitamin D.

   a. TSH may be checked as well, since parathyroidectomy is a risk factor for thyroid dysfunction.

3. PTH and calcium should be measured again 6 months after surgery to confirm a cure.

4. Bone mineral density should be measured about 18 months after surgery.

Complications

1. Operative failure

   a. The goal of parathyroid surgery is to induce eucalcemia that lasts at least 6 months after the operation.

   b. Persistent or recurrent hyperparathyroidism is the most common complication, occurring in up to 5%.

   c. Given the increased difficulty and complication rates associated with

re-exploration of the neck, extensive preoperative evaluation is appropriate.

1) The PHPT diagnosis should first be confirmed via serum testing, ruling out other causes of hypercalcemia.

2) Reoperative parathyroid surgery is associated with a higher rate of supernumerary and ectopic glands.

a) Optimally, two preoperative imaging techniques should be utilized to congruently localize the hyperfunctioning gland.

b) MRI and 4-D CT are useful for localizing ectopic glands and identifying mediastinal disease if previous imaging studies are nonlocalizing.

c) Invasive venous sampling and arteriography, which are employed more commonly in these patients compared to those without prior cervical surgery, are effective secondary options.

3) Assess RLN function with laryngoscopy.

d. Reoperative surgery

1) Even in reoperation, the most common cause of hyperparathyroidism is a single adenoma, so a focused approach may be appropriate with positive localization.

2) The incision can be placed medially, which offers a direct approach, or laterally, which helps avoid the previous surgical field.

3) The search for abnormal glands is carried out in a fashion opposite to first-time operations.

a) Dissection should start laterally and work medially in an attempt to avoid scarred regions.

e. Reoperation results in similar success rates as initial procedures when performed by experienced surgeons.

2. Cervical hematoma

a. Evacuation of a cervical hematoma is required in less than 1% of all parathyroidectomy patients.

3. Hypocalcemia

   a. Presents with paresthesias and numbness but can progress to life-threatening tetany, seizures, and arrhythmias.

   b. Treatment involves oral calcium and calcitriol; intravenous calcium may be administered if the patient remains symptomatic despite oral supplementation.

4. RLN injury

   a. If suspected, assess vocal folds with direct laryngoscopy.

   b. Bilateral RLN injury presents with difficulty breathing and stridor shortly after extubation.

      1) If immediate reintubation is unsuccessful, emergent tracheostomy should be performed.

   c. Unilateral RLN injury can usually be managed with speech therapy and medialization of the vocal fold.

5. Wound infection

   a. Remove sutures and perform incision and drainage.

   b. Provide a short course of systemic antibiotics.

6. Thyroid dysfunction

   a. Occurs due to manipulation of the thyroid gland during surgery

   b. Presents with hyperthyroidism in the immediate postoperative phase, but hypothyroidism may result long term

Alternative Management Plan

- Parathyroidectomy is the only cure for PHPT, but there are alternative options for poor surgical candidates.
  - Bisphosphonates may be used to protect bone mineral density.
  - Calcimimetics such as cinacalcet can help decrease PTH secretion, thereby decreasing serum calcium.
  - Angiographic ablation, ethanol ablation, and laser ablation may result in transient or durable reduction in serum calcium.

- Aggressive hydration may help decrease serum calcium but will not prevent osteoporosis.

- Nonsurgical patients with PHPT should be regularly monitored for serum calcium, bone mineral density, and renal function.[3]

Discussion

Evidence-Based Medicine Question: What Is the Best Method for Preoperative Localization?

Sestamibi scintigraphy (see Fig. 84.3) has been the traditional method for preoperative parathyroid imaging. Sensitivity for correct lateralization of the hyperfunctioning gland with this modality varies widely, but most report rates above 70%. Unfortunately, this leaves a significant cohort with nonlocalizing scans, even when the etiology is a single adenoma. When performed by experienced surgeons, ultrasound may be more sensitive than planar sestamibi,[5] even in the presence of multiglandular disease. Therefore, some believe that sonography is more convenient, less invasive, and results in health care savings compared to scintigraphy. However, sonography is limited by operator dependence, and patient factors such as gland size, body mass index, and serum calcium can further impact its accuracy.[5] Sonography and planar sestamibi scintigraphy are less reliable in those with multiglandular disease, smaller parathyroid adenomas, and coexisting thyroid pathology. A combination of these two relatively inexpensive, minimally invasive techniques likely results in the best outcomes, since concurrence between ultrasound and planar sestamibi results indicates excellent accuracy.

Sestamibi single-photon emission computed tomography (SPECT) produces three-dimensional images that enhance the detection of multiglandular disease and ectopic parathyroid glands, but may miss multiglandular disease in a significant number of cases. Sestamibi SPECT combined with CT provides excellent localization, but is expensive and requires significant radiation exposure.[2] Four-dimensional CT with intravenous contrast has the ability to accurately localize the abnormal gland to the correct quadrant. Magnetic resonance imaging (MRI) is

another option that is most appropriate if ultrasound and sestamibi scintigraphy do not provide definitive localization. Abnormal parathyroid glands usually appear hypointense on T1 and hyperintense on T2.

Editorial Comment

Parathyroidectomy remains the only definitive treatment for PHPT and with proper experience and planning is expected to yield a high success rate with a low complication rate. A robust knowledge of thyroid and parathyroid embryology and anatomy will aid the surgeon. Fortunately, advances in imaging and intraoperative serology have aided the surgeon in improving success and decreasing operative time.

Review Questions

1. Which of the following is the best method for diagnosis of PHPT?

   a. Confirm elevated calcium on single occasion and subsequently measure PTH

   b. Confirm elevated calcium, vitamin D, and PTH

   c. **Confirm simultaneously elevated calcium and PTH on two separate occasions and determine elevated 24-hour urine calcium excretion**

   d. Confirm elevated calcium on two separate occasions, measure PTH, and determine location of parathyroid adenoma by sonography

   e. Confirm elevated calcium and abnormal sestamibi scintigraphy

2. In which of the following scenarios is preoperative localization of the abnormal parathyroid gland(s) most useful?

   a. Patient with confirmed MEN type 1

   b. Elderly asymptomatic patient with normal bone mineral density but elevated serum calcium

c. Patient with elevated calcium and PTH and low 24-hour urine calcium

d. **Patient who has undergone previous parathyroidectomy but has persistent hyperparathyroidism**

e. Patient with PHPT and concurrent Hashimoto's thyroiditis

3. Which of the following is *false* with regard to intraoperative identification of parathyroid glands?

a. Parathyroid glands can vary widely in color

b. Parathyroid glands normally weigh 30 to 50 mg

c. Superior parathyroid glands are most commonly found on the posterolateral surface of the upper two-thirds of the thyroid lobes

d. Inferior parathyroid glands can be associated with the thymus

e. **The RLN is usually posterior to the superior parathyroid glands**

4. Which of the following is *false* regarding intraoperative PTH monitoring?

a. The short half-life of PTH makes this technique possible

b. MIP should be performed with intraoperative PTH monitoring regardless of preoperative localization

c. **Minimal change in PTH 20 minutes after excision of a parathyroid gland indicates hyperplasia**

d. A PTH decrease of greater than 50% compared to the highest pre-excision level within 10 minutes suggests that the correct gland was removed and that surgery can conclude

e. Intraoperative PTH monitoring has been shown to reduce costs

5. A 55-year-old male patient diagnosed with PHPT undergoes unilateral neck exploration and excision of one parathyroid gland. However, he presents 2 months later with persistently elevated serum calcium and worsening bone pain, fatigue, and memory problems. Which of the following is *least* appropriate?

a. Lab tests to confirm diagnosis of PHPT

b. Laryngoscopy

c. Attempt to localize the abnormal parathyroid gland(s) with both sonography and sestamibi scintigraphy

d. Offer arteriography if imaging techniques are nonlocalizing

e. **Plan for BNE and total parathyroidectomy regardless of imaging in order to avoid a potential third neck surgery**

Parathyroidectomy for Secondary Hyperparathyroidism

Pedro Andrade Filho

Introduction

Secondary hyperparathyroidism (SHPT) is a consequence of the decreased concentration of ionized calcium in the blood, which may have many causes. SHPT is characterized by increased compensatory parathyroid hormone (PTH) secretion due to the malabsorption of intestinal calcium mainly caused by chronic renal disease. For this reason, SHPT is often referred to as renal SHPT, but it may be due to other chronic conditions that result in low serum calcium. Increased parathyroid function is stimulated by calcium deficiency (presenting with normocalcemia or hypocalcemia); thus the parathyroid gland has no functional autonomy. Other causes of SHPT include long-term lithium therapy, osteomalacia, rickets, malabsorption diseases, severe Crohn disease, celiac disease, and vitamin D deficiency. Gastric bypass or weight reduction (bariatric) surgery may also result in SHPT. Renal SHPT is initially treated medically, although parathyroidectomy (PTX) remains an efficient and definitive treatment option for this condition, since it may bridge the time until kidney transplantation can be performed.

In theory, if the feedback mechanism involving the level of blood calcium and PTH is interrupted, it could result in regression of the parathyroid glands. For patients with chronic kidney disease–mineral and bone disorder (CKD-MBD), the feedback mechanism is interrupted by successful renal transplantation. The hypertrophic gland transformation occurs over years of progressive kidney disease. The sustained hypersecretion of PTH is associated with an increase in the size of the parathyroid gland, leading to diffuse parathyroid hyperplasia.

Subsequently, some cells inside the parathyroid gland can proliferate in a monoclonal growth pattern, which results in an advanced type of nodular hyperplasia.[1] During the process of parathyroid hyperplasia, both calcium-sensing receptors (CaSRs) and vitamin D receptors (VDRs) are progressively downregulated.[2] As a result, the parathyroid glands with nodular hyperplasia become increasingly unresponsive to active treatment with vitamin D.

Whether a regression of parathyroid hyperplasia can occur after medical treatment with calcitriol or vitamin D3 remains uncertain. Also, regression of parathyroid hyperplasia has been reported in rare cases of spontaneous infarction of the glands.[3] Also, enhanced apoptosis of parathyroid cells has been observed in diffuse hyperplasia following kidney transplantation, which suggests the possibility of the long-term regression of an individual gland.[4]

The use of a new generation of vitamin D analogues and calcimimetics as well as changes in diet and modified dialysis techniques has led to a reduction in fractures and PTX for renal SHPT in patients with CKD-MBD. However, the required medications can be expensive, and the cost of 9 months of calcimimetic treatment may exceed that of surgical therapy.[5]

The elevation of PTH takes time; when it reaches values higher than 495 pg/mL, there is a 25% increased risk of mortality.[6] The response to vitamin D is reduced by 50% at PTH levels above 750 pg/mL.[7] Therefore early surgery can potentially offer an improved quality of life and possibly a higher long-term rate of survival.[5-7]

Key Operative Learning Points

1. The surgical strategy should focus on a correct balance between the extent of parathyroid resection with prevention of recurrence while also minimizing permanent hypoparathyroidism.

2. The common surgical procedures are subtotal parathyroidectomy (SPTX) and total parathyroidectomy (TPTX). SPTX and TPTX can be coupled with parathyroid autotransplantation (AT) and bilateral cervical thymectomy (BCT) (Table 85.1). The surgeon's preference and transplantation status influence the type of operation performed.

3. BCT is considered an essential part of any effort to remove supernumerary glands or ectopic parathyroid nests, thus reducing persistent and recurrent SHPT.

4. Proper timing of the decision for surgery is essential in order to avoid a procedure done too early in the development of renal SHPT, which would prove unnecessary, or one that is done too late, which would pose increasing risks and complications due to the patient's worsening comorbidities. Therefore integrated, multidisciplinary care is vital to detect the best surgical timing as well as careful postoperative care to control for metabolic alterations.

5. A comprehensive approach to the treatment and prevention of progressive renal SHPT is crucial, starting with early monitoring for biomarkers (PTH, Ca, and phosphorus), dietary modifications, mode of renal replacement therapy, and drug therapy.

Preoperative Period

History

1. History of present illness

   a. Many patients with renal SHPT may be asymptomatic but may present with nonspecific symptoms, such as bone or joint pain, cutaneous itching, and fatigue. However, abnormalities may be already detectable by laboratory or radiographic studies. Patients may present with elevated serum phosphate levels, reduced vitamin D production, and low or normal serum calcium levels; as a result, PTH levels would be markedly elevated.

   b. What serologic parameters indicate changes in renal SHPT, and is it possible to avoid progressive PTH elevation?

      At the beginning of CKD stage III (estimated glomerular filtration rate [GFR] <60 mL/min), PTH levels start to increase. According to the recommendations of the kidney disease outcomes quality initiative (KDOQI), PTH should be kept between 150 and 300 pg/mL to avoid the complete suppression of osteoclasts and prevent adynamic bone disease[8] (Table 85.2). Current therapeutic strategies

include the modification of calcium and phosphorus balance by restricting the intake of dietary calcium and phosphorus and their removal during hemodialysis as well as the administration of phosphate binders, vitamin D receptor activators (calcitriol and newer vitamin D analogues), and a calcimimetic. When PTH levels cannot be maintained within the target ranges, the surgical option should be considered so as to avoid the progression of ectopic calcification.

TABLE 85.1

Acceptable Surgical Procedures for Secondary Hyperparathyroidism and Outcomes

Procedure	Recurrence/Persistence (%)	Hypoparathyroidism (%)	Reference/Type Study/Level of Evidence
SPTX with or without BCT	20	0	Rothmund et al. (1991)/RCT/1b
SPTX with or without BCT and with AT	4.8	2.4	Gasparri et al. (2001)/CRS/3
SPTX with or without BCT and without AT	0	0	Schneider (2012)/CRS/3

AT, Autotransplantation; *BCT,* bilateral cervical thymectomy; *SPTX,* subtotal parathyroidectomy.

TABLE 85.2

Target Ranges for Monitoring of Secondary Hyperparathyroidism

Stage of CKD	GFR	Corrected Calcium (mg/dL)	Phosphorus (mg/dL)	iPTH (pg/mL)	Monitoring of iPTH	Monitoring of Calcium and Phosphorus
3	30–60	Normal limits	2.7–4.6	35–70	1 year	1 year
4	15–29	Normal limits	2.7–4.6	70–110	3 months	3 months
5	<15	8.4–9.5	3.5–5.5	150–300	3 months	1 month

CKD, Chronic kidney disease; *GFR,* glomerular filtration rate; *iPTH,* intact parathyroid hormone.

c. Why do PTH levels continue to increase despite dietary restriction and the administration of phosphate binders, calcimimetics, and vitamin D analogues?

As the process of low-level secretion of extracellular Ca-stimulating PTH continues, the parathyroid glands are gradually transformed from normal glands into glands manifesting diffuse hyperplasia, then nodular hyperplasia, and finally multiple adenomas. The glandular growth/hyperplasia is hyperactive, irregular, asymmetrical, and asynchronous; this process is related to the time on dialysis until the parathyroid gland finally becomes autonomous. At that point there is no longer any response to medical treatment.

This is an important part of disease progression, because even after kidney transplantation the hypersecretion of PTH and hypercalcemia can persist. This condition, called tertiary hyperparathyroidism, can jeopardize the transplant surgery and long-term viability of the transplanted kidney.

Although PTH levels can be suppressed by continuous treatment with phosphate binders, vitamin D analogues, and/or calcimimetics, a progressive reduction in the expression of CaSRs and VDRs can occur. This can ultimately result in resistance to medical management, at which point PTX might be required.

d. Which patients may benefit from PTX?

Surgical intervention should be considered in symptomatic patients who present with bone or muscle pain, muscle weakness, irritability, pruritus, bone loss, the exacerbation of anemia due to resistance to erythropoietin, or worsening cardiomyopathy. There are patients who develop resistance or intolerance to medical therapy; they too should be considered candidates for surgical intervention.

Patients may present with painful pink or purple firm nodules or plaques surrounded by livedo reticularis that progress to deep painful ulcers covered with black eschar; such patients must be screened for surgery immediately. Sepsis from infections in skin ulcers can cause up to 80% mortality.

This condition is known as calciphylaxis, which may be bilateral and symmetrical, affecting the thighs, abdomen, and buttocks. It occurs in only 4% of patients undergoing surgery.[9] Where it appears that vascular calcification is driven by PTH, calcimimetic (as cinacalcet) is the preferred treatment for the control of PTH levels, as demonstrated by the evaluation of cinacalcet hydrochloride therapy to lower cardiovascular events (EVOLVE) trial.[10] PTX is a surgical option for controlling elevated PTH levels and has been effective in isolated cases. In patients with calciphylaxis who have received urgent surgical treatment with TPTX, median survival was significantly prolonged. However, the risks associated with surgery, especially in medically complicated patients, make this a second-line treatment following failed medical management. Calciphilaxis is more commonly observed in women, patients with diabetes mellitus, obesity, hypoalbuminemia,

and/or liver cirrhosis as well as in patients taking warfarin and those with a systemic inflammation or malignant disease.

e. What PTH level indicates the need for surgical intervention?

Intact PTH levels should be higher than 500 pg/mL and refractory to medical treatment.

2. Past Medical History

a. Most of these patients have significant worsening of the CKD; therefore the following questions must be addressed:

1) Is this patient on dialysis? If so, how long has this been the case?

2) What is the patient's general state of health?

3) Has the patient had any previous hospitalizations related to SHPT?

b. Medical illness

The following must be investigated as they may influence surgery: anemia, heart disease, hypertension, diabetes mellitus, hyperlipidemia, previous thrombosis, gastrointestinal malabsorption, and voice changes.

c. Surgery

1) Evaluation of any previous neck surgery or thyroid/parathyroid surgery is mandatory. Postoperative complications are higher and success rates lower if there was previous cervical exploration.

d. Family history

1) There are some studies showing that the loss of heterozygosity (LOH) in 3q was detected more frequently in uremic parathyroid hyperplasia in comparison with LOH in 11q13 and 1q in parathyroid adenomas and LOH in 1q and 6q in familial hyperparathyroidism. It has been reported that LOH in 11q13 and the X-chromosome is present in uremic parathyroid hyperplasia.

e. Medications

1) The use of anticoagulants or antiplatelet medication should be discontinued several days prior to surgery to reduce

complications from bleeding.

2) Prolonged diuretic (especially thiazides) or lithium use is a cause of SHPT, which can lead to hyperplasia or persistent hypercalcemia.

Physical Examination

1. Head and Neck

a. Inspection of the neck and thyroid gland to evaluate

1) Symmetry, size, firmness, fixation, and associated lymph nodes as well as evidence of previous neck surgery

b. Laryngoscopic evaluation

Vocal fold function should be assessed, especially in repeat surgery or in the case of associated thyroid masses.

Laboratory

1. Patients may present with elevated serum phosphate, reduced vitamin D, and low or normal serum calcium levels and, as a result, elevated PTH levels.

2. The KDOQI of the National Kidney Foundation recommends the following target levels for renal SHPT patients who are on dialysis:

a. Serum calcium level between 8.4 and 9.5 mg/dL

b. Serum phosphate level of 3.5 to 5.5 mg/dL

c. Intact PTH (iPTH) of 150 to 300 pg/mL

3. Although there are no specific indications for PTX listed in the KDOQI guidelines, PTX is considered in severe renal SHPT refractory to medical treatment. PTX effectively and quickly lowers calcium, PTH, and phosphorus levels and also helps to prevent cardiovascular complications and ectopic calcifications. Postoperative bone biopsy has shown suppression of bone resorption and initiation of bone formation. Up to 32% of patients with prolonged renal failure require PTX despite expensive medical treatment.[5]

Imaging

1. Preoperative routine evaluation includes the following:

   a. Ultrasonography (US) of the neck

      1) To localize the parathyroid as well as to evaluate any concomitant thyroid disease or nodules that may point to the presence of an intrathyroidal parathyroid gland (Fig. 85.1)

   b. Technetium-99m (^{99m}Tc) sestamibi scintigraphy with or without single-photon emission computed tomography (SPECT)

      2) This is usually not ordered but may be helpful in identifying ectopic glands and facilitating surgical planning. The combination of US and 99mTc sestamibi scintigraphy can provide more accurate results. Because hyperplasia is the predominant physiologic mechanism, the presence of ectopic glands creates surgical challenges more frequently (4 times higher) as compared with primary hyperparathyroidism.

   c. Four-dimensional contrast-enhanced CT (4D CT)

      3) Used mainly in preparation for reoperation to provide precise anatomic information regarding orthotopic or ectopic glands, multiglandular disease, and coexisting pathology such as thyroid nodules or lymph nodes. Disadvantages include cost and radiation exposure.

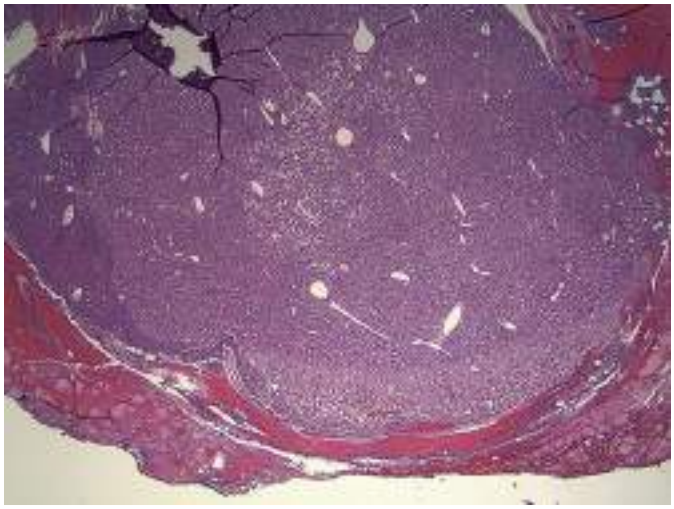

FIG. 85.1 Photomicrograph showing an intrathyroid parathyroid gland.

d. Magnetic resonance imaging (MRI)

4) This is helpful in the visualization of mediastinal hyperplastic parathyroid glands. Abnormal glands, identified on adipose tissue–saturated T2-weighted (hyperintense) imaging, can be distinguished from the surrounding mediastinal adipose tissue using this modality, and gadolinium may help to enhance the abnormal glands. MRI is not as helpful in visualizing cervical glands.

e. C-methionine positron emission tomography and computed tomography (PET CT) or 18 fluorodeoxyglucose (FDG) PET CT—or even selective venous catheterization with PTH assessment—appear to be reserved for special indications such as reoperation.

Indications

1. Severe renal SHPT

a. Hyperphosphatemia refractory to medical management with PTH levels exceeding 800 pg/mL or extraosseous calcifications with PTH greater than 500 pg/mL as well as severe radiologically or histologically proven osteopathy

2. Calciphylaxis

3. Intractable pruritus

4. Symptomatic patients or patient's preference

5. Nodular hyperplastic parathyroid

Contraindications

1. High-risk medical comorbidities

2. Pre-existing recurrent nerve paralysis

3. Previous neck surgery or explorations constitute a relative contraindication; surgery in this setting should be performed only by

experts in parathyroid surgery.

Preoperative Preparation

1. Dialysis patients should undergo dialysis 12 to 24 hours or at the latest 36 hours prior to surgery so as to minimize the administration of heparin.

2. Cardiologic evaluation is desirable because renal SHPT patients (around 80%) frequently have coexisting hypertension, diabetes, and cardiac disease.

3. Electrolyte abnormalities should be corrected as much as possible. Be aware of hypocalcemia, hyperphosphatemia (main cause of pruritus), hypermagnesemia, and hyperkalemia. The consequences of hypermagnesemia include hypoventilation, central nervous system (CNS) depression, hypotension, and shock. Hyperkalemia is an important electrolyte disorder to consider in contemplating general anesthesia and the potential use of muscle relaxants, which may increase serum calcium and result in various cardiac arrhythmias. Electrocardiography (ECG) in hyperkalemic patients can show a high T wave, extended P-R interval, and widened QRS complex. Elective surgery is ideally performed with a potassium value below 5.5 mEq/L.

4. Anticoagulant medications should be discontinued if possible.

5. All tissue removed at previous surgeries should be acquired and reviewed by in-house experts.

Operative Period

Anesthesia

1. General anesthesia is preferred owing to the need for bilateral exploration, tracheal manipulation, and potentially longer surgical times.

2. PTX can be performed under local anesthesia in selected high-risk patients to minimize the risk of general anesthesia.

Positioning

1. Supine with a small shoulder roll, slightly extending the neck

2. The arms should be tucked in at the patient's side with the elbows padded to protect the ulnar nerve.

Perioperative Antibiotic Prophylaxis

1. Antibiotics are not mandatory in clean surgical cases. A single perioperative dose of a broad-spectrum antibiotic may be considered.

Monitoring

1. Intraoperative PTH monitoring is advocated for routine use during PTX in order to ensure adequate resection goals with final PTH levels less than 300.

2. Intraoperative nerve monitoring (IONM) of the recurrent laryngeal nerve with special endotracheal tubes that have electromyographic (EMG) capability may be helpful in reoperations.

Required Instruments and Equipment

1. Standard thyroid set

2. Bipolar/monopolar cautery

3. McCabe surgical dissecting clamp

4. Endotracheal tubes with EMG capability may be recommended in reoperations and at the discretion of the surgeon.

5. Intraoperative PTH monitoring: PTH half-life is approximately 2 to 5 minutes and 10 minutes of removing all hyperactive parathyroid tissue; the PTH levels should then fall by more than half. By testing PTH levels before removing the hyperactive parathyroid glands (usually before starting the surgery and before tying off the blood supply to the gland) and then again after removal of the abnormal gland, the surgeon can determine the presence of additional hyperfunctioning glands. Although there are different criteria for a successful operation, most surgeons look for at least a 50% drop in PTH levels to consider the patient cured. PTH is

tested following the removal of the glands after 10, 15, and 20 minutes. Ideally the 20-minute, postexcision PTH level should be below 300. It can take anywhere from 10 to 40 minutes to get the results from each PTH testing. The patient usually remains in the operating room during this time.

Key Anatomic Landmarks

1. Laryngotracheal complex: The recurrent laryngeal nerve enters the larynx between the cricoid cartilage and the first tracheal ring. Any dissection below the cricoid cartilage requires expert knowledge of the anatomy of the recurrent laryngeal nerve to avoid injury.

2. Recurrent laryngeal nerve: The superior glands usually lie posterior to the plane of the nerve while the inferior glands lie anterior to the nerve in most cases.

3. Thyroid gland: Most parathyroid glands lie directly posterior to or around the capsule of the thyroid gland; identification and mobilization of the gland are required in four-gland explorations.

4. Inferior thyroid artery: Parathyroid glands are often located near the junction of the inferior thyroid artery and the recurrent laryngeal nerve. The proper identification of the artery prevents inadvertent nerve injury.

5. Carotid arteries: These constitute the lateral boundaries of dissection.

Prerequisite Skills

1. Proficiency in thyroid surgery

2. Knowledge of thyroid and parathyroid embryology

Operative Risks

1. Injury to the recurrent laryngeal nerve

   a. Temporary hoarseness occurs in less than 5% of cases and typically resolves within a few weeks. However, hoarseness may take up to 6 months to fully recover when the parathyroid gland is juxtaposed or posterior to the nerve. In less than 1% of cases, the nerve may be

permanently injured.

2. “Hungry-bone syndrome” is defined as severe hypocalcemia requiring a prolonged postoperative hospital or readmission and can occur in some 28% of patients after PTX, developing within the first 18 postoperative hours.

3. Parathyromatosis is a condition of persistent HPT caused by diffuse functional ectopic parathyroid tissue, which is often spilled at the time of parathyroid gland removal.

4. Hematomas may occur, usually within the first 4 hours of surgery, although bleeding can happen up to a week later, especially in patients with a bleeding disorder or those who are taking anticoagulants. This occurs in less than 1% of cases and usually requires surgical evacuation to prevent serious compressive sequelae.

5. Infections are extremely rare and should raise the concern of incidental injury to the trachea or esophagus. Generally opening the wound and placing a Penrose drain should suffice as initial management.

6. Inadequate parathyroid resection and persistence of the disease

Surgical Technique

1. After intubation, blood should be drawn for baseline testing of PTH levels before removing the hyperactive parathyroid glands; this is best achieved before starting the operation and with minimal manipulation of the neck.

2. The skin is marked for thyroid surgery, followed by infiltration of the skin with local anesthesia (epinephrine). A 3- to 4-cm Kocher incision is placed into a line of relaxed skin tension approximately 2 fingerbreadths above the suprasternal notch. Dissection continues through the platysma muscle and the subplatysmal flaps are elevated. All four glands should be exposed for surgical decision. The location of the superior parathyroid gland is sought on the posterior and lateral aspects of the thyroid gland. The middle thyroid veins are ligated and the gland is rotated. The superior gland should be located near the superior pole of the thyroid, often deep to the plane of the recurrent laryngeal nerve and superior to the intersection of the recurrent laryngeal nerve and the inferior thyroid

artery. Blunt dissection of the fibroareolar tissue to expose the thyroid gland using a Kittner or peanut dissector with a Freer elevator is recommended. Diligent hemostasis is mandatory. It is preferable to identify the recurrent laryngeal nerve before any gland is removed. If additional exposure is needed, the superior thyroid artery can be ligated as it enters the superior aspect of the thyroid; the thyroid gland can then be further rotated anteromedially. The inferior parathyroid is usually medial and anterior to the recurrent laryngeal nerve, often overlying the trachea or tracheoesophageal groove in the region of the intersection of the recurrent laryngeal nerve and the inferior thyroid artery. Dissection along the nerve down the tracheoesophageal groove and along the esophagus toward the mediastinum may be required to find the abnormal gland. The search for the inferior gland should include the thyrothymic adipose tissue and the superior aspect of the thymus. The use of BCT may also be required. After visualizing all four glands, the surgeon will choose one of the following approaches:

a. TPTX without AT

b. TPTX with AT

c. PTX

The optimal surgical treatment of SHPT has not been clearly defined but may be influenced by the likelihood of subsequent renal transplantation. SPTX involved the resection of 3½ parathyroid glands with a remnant left in situ (between 50 and 70 mg of the gland) (Figs. 85.2 and 85.3). TPTX is the resection of all four parathyroid glands (Fig. 85.4) and is often accompanied by AT of a portion of a normal-appearing gland, usually into the forearm or in the neck, but can also include cryopreservation and delayed AT. The technique of parathyroid AT includes mincing (Fig. 85.5), thin-sectioning, and homogenization into a paste form. A frozen-section biopsy specimen is obtained to confirm that it is parathyroid tissue before reimplantation is performed with the residual gland (usually a remnant of 50 mg). The reimplantation can use neck musculature such as the sternocleidomastoid muscle (SCM) or involve the forearm in the brachioradialis muscle. Small pockets are created in the muscle (Fig.85.6), followed by insertion of the minced gland and closure and marking with a surgical clip or permanent suture. Cervical thymectomy may be required, especially because ectopic or supernumerary glands can be found in up to 37% of the cases. The tissue

overlying the trachea just inferior to the thyroid down to the innominate artery/aortic arch inferiorly, the trachea posteriorly, and the bilateral carotid artery medially should be removed. The appropriate surgical approach will vary from patient to patient and will fall into one of these acceptable surgical treatments.

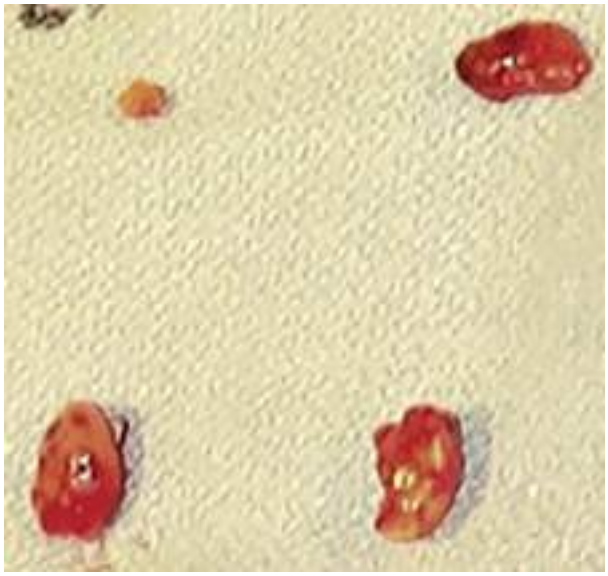

FIG. 85.2 Subtotal parathyroidectomy (removal of 3½ glands).

Common Errors in Technique

1. Excessive bleeding

   a. A blood-free field is mandatory. If blood is present it will stain the lymph nodes and adipose tissue located in the paratracheal space, making it more difficult to identify the parathyroid tissue.

   b. Bleeding also increases the risk of inadvertent injury to the recurrent nerve or esophagus.

2. Excessive parathyroid gland remnant. In SPTX, the remnant piece of parathyroid may necessitate reoperation for recurrent disease, which is associated with a higher rate of complications. For this reason, the remnant parathyroid gland is marked with a surgical clip (for later identification) and should be left away from the RLN and preferably anterior to the RLN. Approximately 50 to 70 mg should be preserved in

order to avoid damage to the blood supply. Devascularized glands rapidly become dusky and should be removed and reimplanted after frozen section confirms the presence of parathyroid tissue.

3. In TPTX with AT, the parathyroid can be implanted in the forearm to alleviate the risks of reoperative neck surgery. Reimplantation will not prevent immediate postoperative hypocalcemia. Autotransplantation to a forearm location may be technically challenging in patients with one or more pre-existing arteriovenous fistulas or grafts in the upper extremities.

4. Poor cosmesis

   a. Incisions should be carefully placed into lines of relaxed skin tension for camouflage.

   b. Subcuticular closure is preferred to prevent track marking.

   c. The strap muscle and platysma should be approximated to prevent adhesion of the trachea to the underlying skin.

Postoperative Period

Postoperative Management

1. Pain control

   a. Usually small doses of narcotics can be given for 1 to 2 days.

   b. Patients should quickly be transitioned to a nonnarcotic pain medication such as naproxen sodium or acetaminophen.

2. Postoperative dialysis

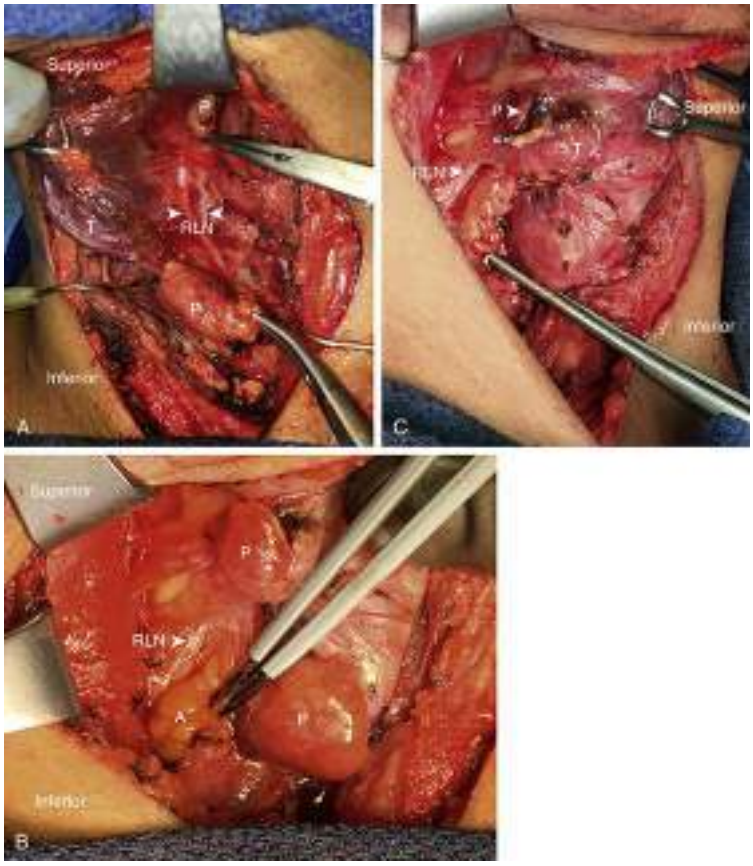

FIG. 85.3 **A,** Subtotal parathyroidectomy; Superior and inferior left parathyroid gland. **B,** Superior and inferior right parathyroid gland. **C,** Between one half and one quarter of the right superior gland was kept in place and marked with a surgical clip. *A,* Adipose Tissue; *P,* parathyroid; *RLN,* recurrent laryngeal nerve; *T,* thyroid gland.

FIG. 85.4 Total parathyroidectomy (four-gland excision).

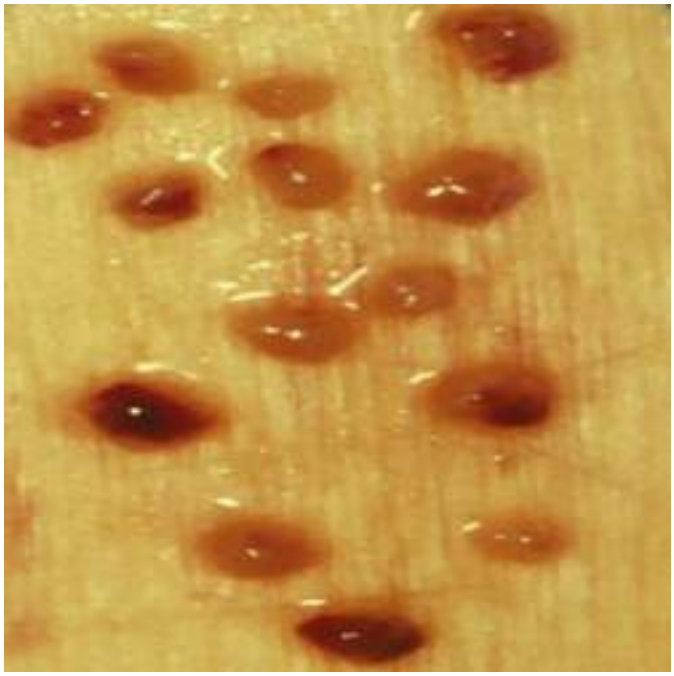

FIG. 85.5 Remnant of gland minced into pieces smaller than 1 mm^3 using scalpel or scissors and ready for transplantation into striated muscle.

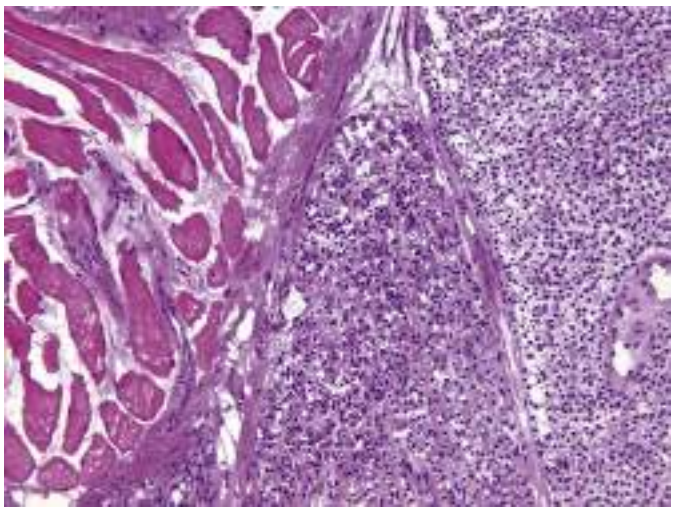

FIG. 85.6 Parathyroid tissue transplanted into the striated muscle tissue.

3. Calcium replacement

   a. SHPT patients are best managed by a minimum of overnight observation and should be started on empiric oral calcium and vitamin D supplementation. Hungry-bone syndrome is a risk for hypocalcemia despite persistently elevated PTH.

   b. Calcium should be checked every 12 hours after total PTX. In the first 72 hours, patients may need intravenous (IV) calcium in addition to high doses of oral calcium and calcitriol, which will be decreased during the subsequent weeks.

Complications

1. Hypocalcemia is the most common postoperative complication following PTX in renal SHPT. Up to 85% of the patients will experience hypocalcemia. Prophylactic calcium and calcitriol can be started before or after surgery. The National Kidney Foundation recommends the following postoperative treatment of hypocalcemia:

The blood level of ionized calcium should be measured every 12 hours for the first 48 to 72 hours after surgery and then twice daily until the patient is stable. If the blood levels of ionized or corrected total calcium fall below normal (<0.9 mmol/L or <3.6 mg/dL corresponding to corrected total calcium of 7.2 mg/dL), a calcium gluconate infusion should be

initiated at a rate of 1 to 2 mg elemental calcium per kilogram body weight per hour and adjusted to maintain an ionized calcium in the normal range (1.15 to 1.36 mmol/L or 4.6 to 5.4 mg/dL). The calcium infusion should be gradually reduced when the level of ionized calcium attains the normal range and remains stable. When oral intake is possible, the patient should receive calcium carbonate 1 to 2 g 3 times a day as well as calcitriol of up to 2 μg/day, and these therapies should be adjusted as necessary to maintain the level of ionized calcium in the normal range.

2. Hyperparathyroidism after PTX. Postoperative PTHs should ideally be less than 300 pg/dL. Persistent or recurrent hyperparathyroidism occurs in 2% to 30% of cases even in the hands of experienced surgeons after either SPTX or TPTX plus AT. Persistence should be rare and recurrence is lower after TPTX without transplantation. SPTX has a higher chance for hyperparathyroidism than TPTX plus transplantation.

3. Recurrent laryngeal nerve injuries are extremely rare, occurring in less than 1% of cases, and most of these injuries are transient neuropraxias.

4. Hematomas, wound infection, dehiscence, and death are also extremely rare.

Alternative Management Plan

1. Arteriographic embolization and percutaneous ethanol ablation resulting in transitory hypoparathyroidism has been described in the past; however, this is not commonly recommended.

2. Aggressive vitamin D and calcium replacement to inhibit PTH secretion

3. Administration of cinacalcet (Sensipar) can be used in refractory cases or medically fragile patients who cannot undergo surgery.

Discussion

Evidence-Based Medicine Question

Is there any marker that predicts the success of PTX?

Intraoperative PTH monitoring has been considered the gold standard for intraoperative monitoring and is necessary during function-controlled PTX. This type of monitoring predicts the cure and is very helpful in persistent or recurrent disease. The benefits extend beyond the economic savings resulting from limited exploration and reduced operating times. Surgery is considered successful when PTH levels drop to a level less than 300 pg/mL in cases of STPX at the end of the procedure.

Editorial Comment

Surgery for SHPT has become more common with improvements in dialysis and cardiac care in patients with renal failure. Surgery should be tailored according to transplantation status and requires more experience than that called for by typical parathyroid surgery. In contrast to patients with primary hyperparathyroidism, surgery for SHPT should not routinely be performed as an outpatient procedure, as the risk of significant hypocalcemia is a valid concern.

Alfred Simental, Jr.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. The following are acceptable surgical options for renal SHPT except

   a. 3½ PTX

   b. TPTX

   c. TPTX + autotransplantation

   d. **Cervical thymectomy alone**

2. What is the most preventable cause of postoperative death in PTX?

   a. Cardiac complication

   b. **Acute hypocalcemia**

   c. Infection

   d. Hyperkalemia

3. Which is the predominant parathyroid pathology seen in patients with secondary hyperparathyroidism?

   a. Carcinoma

   b. **Hyperplasia**

   c. Adenoma

   d. Apoplexy

4. If your surgical decision is SPTX, which gland should be left in situ?

   a. Closer to the recurrent laryngeal nerve

   b. Deep in the carotid sheath

   c. Retropharyngeal

   d. **Any easily retrievable parathyroid gland (more anterior plane)**

Reoperative Parathyroidectomy

Christopher Azbell, and Jeffrey Bumpous

Introduction

Parathyroidectomy for primary hyperparathyroidism has a success rate of 90% to 95% among experienced surgeons. However, management of persistent hyperparathyroidism following surgery can be challenging. Careful preoperative analysis of factors that lead to the failure of the initial surgery must be performed prior to reoperative parathyroidectomy. After confirmation of the diagnosis of persistent hyperparathyroidism, all prior operative reports, pathology reports, and imaging studies should be reviewed in detail. Planning for reoperation should include obtaining new imaging, when indicated, and formulating a methodical operative plan. Surgery can be complicated by tissue fibrosis, edema, inflammation, and loss of surgical landmarks.[1] Reoperative parathyroidectomy is still associated with lower success rates and increased postoperative hypocalcemia and recurrent laryngeal nerve injury.[2-4]

Key Operative Learning Points

1. Careful confirmation of the diagnosis of primary hyperparathyroidism is essential before planning the operation.

2. Localizing imaging, including a parathyroid nuclear scan with single photon emission comptuted tomograph (SPECT), and when negative, four-dimensional (4D) computed tomography (CT) and/or selective venous angiography and parathyroid hormone (PTH) sampling, are important potential adjuncts to preoperative identification of single gland disease in the reoperative scenario.

3. A detailed discussion with the patient regarding the risks of reoperative surgery is necessary.

Preoperative Period

History

1. History of present illness
   a. Signs or symptoms of hypercalcemia
      1) Nephrolithiasis
      2) Severe osteoporosis
      3) Pancreatitis
      4) Abdominal pain
      5) Extremity (bone and muscle) pain
      6) Depression, anxiety, fatigue
   b. How are symptoms now different from symptoms prior to the initial surgery?
2. Prior surgical treatment
   a. Surgical approach (unilateral vs. bilateral)
   b. Specimens removed (assessment of size, weight and number of glands removed or biopsied, thyroid removal). This helps to avoid unnecessary exploration in regions devoid of parathyroid tissue.
   c. Complications encountered: The presence of pre-existing vocal fold paralysis would greatly influence the random exploration of the paratracheal region on the ipsilateral side of the functioning vocal fold to prevent tracheostomy.
3. Past medical history
   a. Obtain preoperative and postoperative calcium and PTH levels. The diagnosis of primary hyperparathyroidism should be independently reconfirmed.
   b. Obtain detailed operative and pathology reports from all prior

surgeries.

c. Personal history

1) Endocrinopathies, including thyroid disorders or carcinoma, pheochromocytoma

2) Renal disease (increased chance that subtotal parathyroidectomy is necessary for cure)

3) Hypothalamus-pituitary axis disease

d. Family history of endocrinopathies (multiple endocrine neoplasia syndromes, familial hyperparathyroidism)

e. Medications

1) Exogenous calcium/vitamin D supplementation

2) Anticoagulants

3) Diuretics (especially thiazides)

4) Use of lithium

5) Allergies

Physical Examination

1. Neck

a. Palpation of any midline or lateral neck masses (unlikely, but if present raise the concern of coexistent thyroid pathology or parathyroid carcinoma)

b. Palpation of thyroid

c. Examination of prior surgical incision

2. Flexible laryngoscopy

a. Assess recurrent laryngeal nerve function (fiberoptic laryngoscopy is preferable)

Imaging

1. Ultrasound of the neck: identifies concomitant thyroid disease and

potentially abnormal parathyroid glands

2. Parathyroid uptake scan [technetium 99 metastable (Tc99m) Sestamibi SPECT preferred]: greater than 80% success in localizing side of overactive parathyroid

3. Dexa bone density scan: Patients with severe osteoporosis, especially with pathologic fractures, must strongly be considered for reoperation, even if persistently nonlocalizing.

4. Possible 4D CT scan of neck and chest in patients that are not localizing by ultrasound or nuclear medicine scans

5. Selective venous angiography and PTH sampling

Indications

1. Persistent symptomatic hypercalcemia within 6 months following prior parathyroidectomy

2. Recurrent primary hyperparathyroidism greater than 6 months following parathyroidectomy

3. Recurrent parathyroid carcinoma

4. Parathyromatosis (seeding from prior surgery/spillage)

5. Bone mineral density greater than 2 standard deviations below gender- and age-matched group (z score <–2.0)

6. Recurrent nephrolithiasis

Contraindications

1. Asymptomatic disease with borderline hyperparathyroidism

2. Recurrent laryngeal nerve injury contralateral to parathyroid adenomas (relative)

3. Significant medical comorbidities increasing risk of anesthesia

4. Cause other than hyperparathyroidism for hypercalcemia is confirmed

5. Diagnostic uncertainty (should be resolved prior to repeat surgery)

Preoperative Preparation

1. Detailed explanation of risks and benefits to reoperation

2. Obtain baseline PTH.

3. Review imaging and have relevant imaging available.

Operative Period

Anesthesia

General

Awake sedation

Local

Positioning

Supine: The patient is positioned with a shoulder roll to extend the neck and better expose the anterior midline cervical structures.

Prone

Lateral recumbent

Perioperative Antibiotic Prophylaxis:

First-generation cephalosporin (Kefzol)

Second-generation cephalosporin

Clindamycin if allergic to penicillin

Monitoring

None

Neural integrity monitor (NIM) electromyogram (EMG) endotracheal tube—optional on physician preference and experience

Instruments and Equipment to Have Available

1. Major head and neck set

2. Bipolar cautery: necessary for careful dissection in previously dissected tissues

3. Pass probe for confirmation of recurrent laryngeal nerve identification (If NIM is used)

4. Intraoperative PTH assay

5. Relevant imaging

Key Anatomic Landmarks

1. Recurrent laryngeal nerve: The nerve ascends in the tracheoesophageal groove bilaterally, entering the larynx at the inferior border of the inferior pharyngeal constrictor. It is typically located more laterally in the left neck.

2. External branch of superior laryngeal nerve: This branch supplies the cricothyroid muscle. It descends along the inferior constrictor muscle within 1 cm of the superior pole of thyroid. In approximately 20% of cases, the nerve may be closely adherent to the superior pole.

3. Superior parathyroid glands: Derived from the fourth branchial pouch, they are found along the posterolateral aspect of the superior thyroid pole, deep (posterior) to the plane of the recurrent laryngeal nerve.

4. Inferior parathyroid glands: The inferior parathyroids, like the thymus, are derived from the third branchial pouch. They are more variable in position because of their longer descent but are typically found along the posterolateral aspect of the inferior thyroid pole, superficial (anterior) to the plane of the recurrent laryngeal nerve (i.e., anterior superior mediastinum in the thymic remnant).

Prerequisite Skills

1. Localization and preservation of recurrent laryngeal nerve
2. Experience in thyroid and parathyroid surgery

Operative Risks

1. Paralysis or paresis of recurrent laryngeal nerve
2. Postoperative hypocalcemia
3. Intraoperative hemorrhage from innominate artery
4. Esophageal perforation

Surgical Technique

1. Skin incision
2. Raising supraplatysmal flaps
   a. Exposure superiorly to level of thyroid notch
   b. Exposure inferiorly below level of inferior thyroid pole
   c. Placement of retractors
3. Medial approach
   a. Divide midline raphe of strap muscles.
   b. Gentle lateral retraction of ipsilateral strap muscles
   c. Divide fascia from thyroid capsule using bipolar cautery.

4. Lateral approach (especially in localizable disease by imaging in which the patient has had prior midline approach. The senior author prefers the lateral approach for unilaterally localizable disease.)
   a. Define lateral border of strap muscles.
   b. Retract strap muscles contralaterally, exposing ipsilateral thyroid lobe.
   c. Divide fascia from thyroid capsule using meticulous bipolar cautery dissection.
5. Localization of parathyroid glands

a. Careful identification of recurrent laryngeal nerve

b. Use of gamma probe to identify parathyroid adenoma (useful adjunct in re-exploration if the offending gland is localizable on Tc99m Sestamibi imaging)[5]

c. Search regions where unrecognized parathyroid glands are usually found.

d. Ensure adequate exposure of paratracheal region, including identification of carotid artery laterally and thyroid/trachea medially, followed by medialization of thyroid gland and exposure of the posterior surface where parathyroid glands are often found (Fig. 86.1).

6. Reimplantation of glands where vascularity is questionable, functional glands have previously been explanted, intraoperative PTH is low (<10 pg/dL)

Common Errors in Technique

1. Inadequate preoperative localization

2. Failure to identify recurrent laryngeal nerve

3. Insufficient four gland exploration

4. Incorrect diagnosis of primary hyperparathyroidism (i.e., familial hypocalciuric hypercalcemia, a calcium-sensing receptor [CaSr] genetic abnormality). In cases of hypercalcemia and normal PTH, consideration of other causes of hypercalcemia must be entertained; 24-hour urine calcium may be helpful in this instance. Furthermore, in cases of mildly elevated PTH and normal total calcium, ionized calcium levels should be obtained and if elevated are indicative of primary hyperparathyroidism.

FIG. 86.1 Reoperative inferior parathyroid. Parathyroid located in paratracheal groove after adequate mobilization and medial retraction of thyroid gland. Right lateral approach for reoperative parathyroidectomy using methylene blue as an intraoperative adjunct and demonstrating a right superior parathyroid adenoma and a normal inferior gland. *P,* Parathyroid; *T,* thyroid.

5. Failure to preserve adequate volume of functional parathyroid tissue or consider reimplantation of a portion of a gland into a well-vascularized recipient bed

Postoperative Period

Postoperative Management

1. Obtain ionized calcium and parathyroid hormone levels postoperatively.

2. Discharge patient on day of surgery for limited unilateral surgeries.

3. Twenty-three–hour observation overnight for more extensive four gland explorations

4. Pain management

5. Careful patient and family education regarding the symptoms of hypocalcemia (leg cramps, perioral hyperesthesia/tingling) and the need

for serious attention to those symptoms

6. Assess and manage vitamin D deficiency as a factor that may prolong hypocalcemia and “bone hunger.”

Complications

1. Injury to recurrent laryngeal nerve. Unilateral injury can be observed initially, with expected improvement in several months. Bilateral injury may require a tracheostomy.

2. Postoperative hypocalcemia. Calcium supplementation with calcium gluconate and vitamin D. Rare use of exogenous parathyroid hormone in refractory cases (costly and requires parenteral administration)

3. Hemorrhage. Postoperative hemorrhage requires surgical exploration, with identification and ligation of the bleeding vessels.

4. Persistent hyperparathyroidism (normocalcemia and persistently elevated PTH in particular represents a challenging scenario, which can represent secondary hyperparathyroidism, metabolic bone disease with or without vitamin D deficiency, or persistent primary hyperparathyroidism. If the ionized calcium is elevated in the presence of elevated PTH, persistent primary hyperparathyroidism is much more likely.)

Alternative Management Plan

1. Observation and serial calcium and PTH levels

2. Calcimimetic agents (cinacalcet) in patients that are symptomatic and otherwise not surgical candidates

Discussion

Evidence-Based Medicine Question

What are the most important imaging modalities when preparing for reoperative parathyroid surgery?

Answer

It is clear that reoperative surgery represents a challenge due to the increased risk of ectopic gland location, likelihood of multiple gland disease, and the presence of postsurgical scarring from the initial surgical exploration. Nuclear medicine examination with Sestamibi scanning is paramount in identifying metabolically active parathyroid tissue. This allows for the identification of ectopic parathyroid tissue in more than 80% of cases. High-resolution imaging with CT or magnetic resonance imaging has also shown a high degree of sensitivity in detecting abnormally enlarged paratracheal, paraesophageal, and superior mediastinal masses that may represent overactive parathyroid tissue.

Editorial Comment

Parathyroid surgery for primary hyperparathyroidism has a high success rate on initial surgery, but reoperative surgery faces special challenges that may include abnormal patient anatomy, scarring from previous surgery, and concomitant thyroid pathology. Detailed review of previous reports and operative attempts, as well as repeat attempts at localization, is essential in maximizing success. When possible, reoperative surgery should be performed by experienced parathyroid surgeons in the presence of intraoperative parathyroid hormone monitoring.

Review Questions

1. Which of the following is NOT a symptom of persistent hypercalcemia?

a. Pancreatitis

b. **Perioral numbness**

c. Abdominal pain

d. Fatigue

2. The external branch of the superior laryngeal nerve innervates which muscle?

   a. Lateral cricoarytenoid

   b. Posterior cricoarytenoid

   c. Vocalis

   d. **Cricothyroid**

3. Which of the following is a relative contraindication to repeat parathyroidectomy?

   a. Symptomatic hypercalcemia 1 year after a previous parathyroid adenoma excision

   b. Retroesophageal mass with increased uptake seen on SPECT/CT

   c. **Elevated serum calcium and decreased urinary calcium in a patient with a family history of similar finding**

   d. A new parathyroid mass in a patient with a history of parathyroid carcinoma

4. The inferior parathyroid glands are derived from which embryonic structure?

   a. **Third branchial pouch**

   b. Fourth branchial pouch

   c. Fifth branchial pouch

   d. Ventral diverticulum of the tongue

Office-Based Procedures

Trevor Hackman

Introduction

The breadth of office-based procedures continues to expand within the field of otolaryngology. Office-based procedures allow for prompt, low-cost diagnosis and management of many otolaryngological conditions. Fine needle aspiration (FNA) is a well-established procedure, which provides prompt and accurate diagnosis of neck pathology, including saliva gland and thyroid masses. The application of ultrasound guidance improves accuracy as well as diagnostic yield. In addition, the application of technologic advances and adaptive surgical techniques has improved patient outcomes and expanded the breadth of procedures possible in clinical settings, avoiding the risks and costs of general anesthesia for otherwise minor procedures. Sialendoscopy is a procedure well suited for the transition to the clinic setting for management of salivary gland pathology. The indications for and performance of ultrasound-guided FNA and in-office salivary gland procedures are reviewed in this chapter, including operative setup, procedural details, and complications.

Key Operative Learning Points

1. FNA is a highly accurate procedure for classifying the histology of cervical masses (salivary, thyroid, adenopathy).

2. Ultrasonography enhances the accuracy of the physical examination and FNA.

3. In-office salivary gland procedures, including sialendoscopy, provide excellent minimally invasive gland-sparing therapy without the need for general anesthesia.

Preoperative Period

History

1. History of present illness

   a. Duration of the mass in the neck may impact the decision to pursue further evaluation

      1) A persistent or slowly progressive mass in the neck lasting for more than 3 weeks should be screened for malignancy.

   b. Does the patient have any associated symptoms or high-risk behavior?

      1) Does the patient display fevers, chills, malaise, weight loss, otalgia, odynophagia, dysphagia, hoarseness, or hemoptysis? Does the patient have a history of smoking/alcohol use or hazardous exposure?

   c. How long has the patient experienced problems with the saliva gland?

      1) Acuity of symptoms relates to gland health—ongoing periodic swelling (reversible damage) versus persistent enlargement (end-stage fibrosis).

   d. How many glands are affected?

      1) Multiple gland involvement is likely inflammatory/autoimmune (radioactive iodine induced sialadenitis or Sjogren's syndrome). Solitary gland symptoms are more suggestive of focal obstruction (sialolithiasis or stricture).

   e. What symptoms is the patient experiencing?

      1) Obstructive symptoms—Swelling of the gland, pain, salty discharge, prandial association

      2) Inflammatory symptoms—Dry eyes, dry mouth, multigland involvement, history of radioactive iodine, chronic swelling

   f. Is there a prandial relationship to these symptoms?

1) Sialadenitis is exacerbated by the salivary stimulus of a meal. Pain with mastication and swelling that persists for more than a few hours, or occurs upon arousal from sleep, is more indicative of temporomandibular joint disorders.

2. Past medical history

a. Prior treatment: Antibiotic therapy, sialogouges, steroid therapy

b. Medical illness: Renal calculi; Sjogren's syndrome, diabetes mellitus, severe dehydration

c. Surgery: Parathyroidectomy, renal lithotripsy

d. Family history: Autoimmune diseases

e. Medications

1) Antihypertensive medications

2) Antiplatelet medications

Physical Examination

1. Neck

Examination of the neck may reveal a fixed or a mobile mass.

2. Oral cavity

Examination of the oral cavity may reveal turbid discharge from the salivary ducts, palpable submucosal masses consistent with calculi, or oral cavity lesions. If calculi are palpated, the location and the size of the calculi should be noted.

3. Salivary glands

Examination may reveal a swollen or firm salivary gland, draining sinus, and nodularity to the skin (seen with Sjogren's syndrome).

4. Pharynx/larynx

Examination may reveal a primary malignant lesion within the oropharynx, hypopharynx, or larynx responsible for the mass in the neck.

Imaging

Ultrasonography (Fig. 87.1) of the salivary glands may reveal salivary gland masses, calculi, abnormal architecture of the gland, cyst formation (seen in Sjogren's syndrome, HIV, atypical infections), ductal dilation (seen with salivary stricture or sialolithiasis), honeycomb appearing parenchyma (seen with lymphoma and Sjogren's syndrome). In the neck, ultrasound can visualize vital neck anatomy (thyroid, lymph nodes, and vessels), characterize palpable mass in the neck, or visualize nonpalpable malignant adenopathy. Using characteristic imaging criteria, thyroid and neck masses can be radiographically triaged for biopsy (see Chapter 78 and Chapter 64).

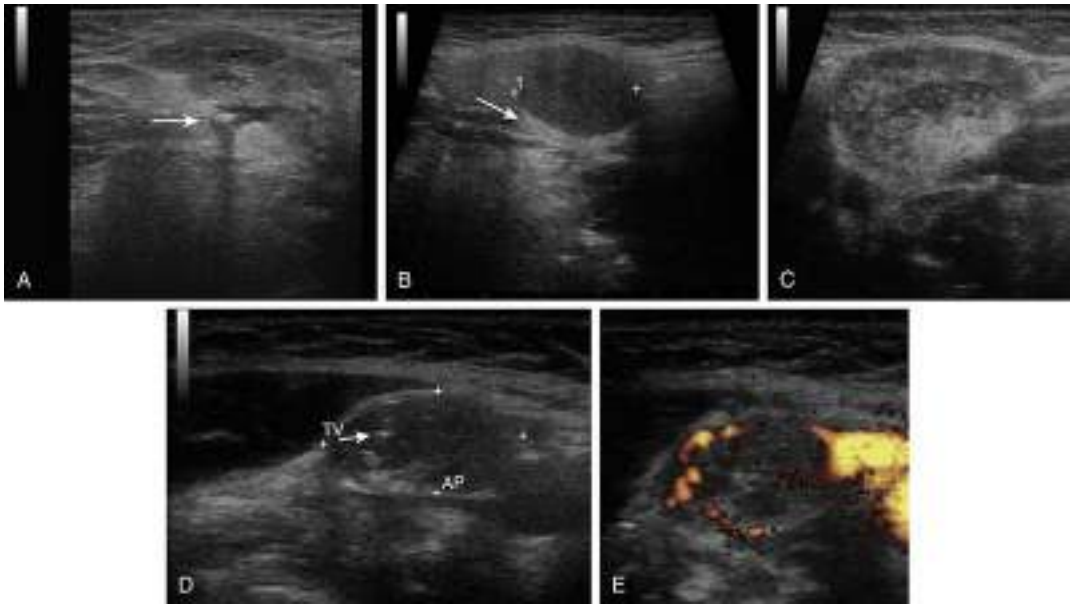

FIG. 87.1 Ultrasound Images.

A, Submandibular stone—hyperechoic signal *(arrow)* with shadow artifact. **B,** Pleomorphic adenoma—hypoechoic mass with posterior enhancement *(arrow)*. **C,** Cystic degeneration from Sjogren's syndrome. **D,** Necrotic adenopathy with loss of hilum and microcalcification. **E,** Pripheral vascularity seen in malignant adenopathy. *TV,* transverse; *AP,* anterior/posterior.

1. Computed tomography (CT)

CT scan may reveal salivary calculi, markedly dilated ducts, saliva

gland masses, and a mass in the neck and thyroid. When performed with contrast, the CT scan may reveal primary aerodigestive tract lesions and malignant adenopathy (>1 cm, round, necrosis), reveal pharyngeal space lesions (deep lobe parotid tumors), and help classify vascular lesions.

2. CT angiography

Useful when the clinician suspects a vascular tumor (carotid body) or anticipates trauma to the carotid artery

3. Magnetic resonance imaging

Useful when the clinician suspects soft tissue masses (superficial or deep lobe parotid lesions), vascular lesions (glomus tumors, paragangliomas), or neural tumors (schwannomas, neurofibromas)

4. Angiography

May be required for evaluation of carotid body tumors and preoperative embolization. If carotid artery injury or sacrifice is anticipated, angiography may be used to direct therapy (embolization/stenting) or assess for circle of Willis communication (balloon occlusion).

Indications

1. Mass in the neck, thyroid, or saliva glands refractory to conservative therapy

Ultrasound and FNA allow for imaging characterization and pathologic assessment of the lesion. The ultrasound enhances accuracy of the biopsy and may help distinguish malignant from benign lesions. FNA directs future management/treatment. Even when lymphoma is suspected, FNA provides an initial diagnostic assessment of the concerning adenopathy, which will prevent the clinician from inadvertently performing an excisional or incisional biopsy of metastatic adenopathy and contaminating the neck. With enough passes,[1-2] lymphoma may be identified by FNA alone and confirmed with flow cytometry, obviating the need for a surgical procedure and expediting patient care. With the exception of Hodgkin's lymphoma, which may show a polymorphous lymphoid population on cytology, lymphoma will often reveal a monoclonal population on cytology, confirming the clinical

diagnosis of lymphoma. In some cases, patients may still require incisional or excisional biopsy to further categorize the type of lymphoma, but following this algorithm, at least other malignancies have been excluded prior to violating the neck.

2. Recurrent acute and chronic sialadenitis

Sialendoscopy with or without sialolithotomy effectively relieves salivary gland obstruction related to high viscosity salivary debris, sialolithiasis, or salivary stricture. Patients with chronic progressive salivary dysfunction from autoimmune disease (Sjogren's syndrome) and radioactive iodine therapy for thyroid cancer also respond symptomatically to sialendoscopy. Ultrasonography is also useful in localizing nonpalpable salivary calculi, directing incisions in the floor of the mouth for salivary calculi, and managing complex salivary strictures (visualization of balloon dilator position, transfacial access to dilated proximal parotid duct for Seldinger technique anterograde dilation). Typically calculi less than 3 mm are amenable to endoscopic retrieval. Larger calculi greater than or equal to 4 mm often require the addition of a cutdown and ductotomy or fragmentation of the calculi.

3. Transcutaneous injections and vocal fold motion

In addition to the imaging and biopsy guidance afforded by ultrasonography, the ultrasound can also be effective for targeting Botox injections into the salivary glands for sialorrhea or into the muscles of mastication for refractory temporomandibular joint pain with associated muscle hypertrophy (temporalis and masseter). Ultrasound may also be used to map difficult laryngeal anatomy and direct injections into the subglottis (steroid for subglottic stenosis) and vocal folds for augmentation, and direct Botox for spasmotic dysphonia. In many patients, vocal fold and/or arytenoid motion may be seen through the cricothyroid or thyrohyoid membranes.

Contraindications

1. Patients with strong vasovagal reactions

Patients who report vigorous vasovagal reactions are not suitable for in-office minor procedures. FNA may be possible, but patients require preprocedural counseling, and the clinician should be prepared to handle

an episode.

2. Antiplatelet therapy or bleeding disorders

Patients with bleeding disorders are best managed in an operating room setting. Those on antiplatelet therapy should discontinue therapy prior to elective procedures. FNA may still be performed safely in these patients, as the bore of the needle is narrow in caliber. Patients should be prepared for likely bruising at the biopsy site.

Preoperative Preparation

1. External surfaces should be cleansed with alcohol prior to the procedure.

2. Discontinue antiplatelet drugs if possible prior to invasive salivary procedures.

3. In the case of FNA, slides should be prepared and labeled and containers ready.

4. When performing intraoral procedures, a suction should be made available.

Operative Period

Anesthesia

1. Local: Although these procedures can be performed in the operating room, the administration of local anesthesia is sufficient for FNA and most salivary procedures in the vast majority of patients. From a practical standpoint, these procedures are performed in the office, and therefore avoidance of sedation expedites patient throughput, decreases the need for additional patient monitoring, and allows patients to transport themselves to and from clinic. Injectable 1% lidocaine with 1:100,000 epinephrine into the skin site overlying the FNA improves patient comfort with the FNA, particularly when multiple passes are planned. For sialendoscopy, an intraductal irrigation with a 2% lidocaine solution is sufficient anesthesia for diagnostic endoscopies and sialolith wire basket retrievals. The clinician should be careful to limit the volume

and pressure of the irrigation, as high-pressure irrigation will result in cell/duct damage, diffusion of local anesthetic into the soft tissues, and patient discomfort. It is recommended to limit the volume of lidocaine irrigation to less than 5 cc. If further irrigation is required, due to length of the procedure, the clinician should then transition to sterile saline.

2. Awake sedation: This may improve patient tolerance with FNA in select cases, but requires the physician obtain sedation privileges and that the clinic setting is appropriately outfitted for sedation. One of the challenges with sedation can be the depth of sedation: too little and the patient will move, deleteriously affecting efficacy of the procedure; too much and the respiratory drive and airway protection may be suppressed. Therefore, sedation is not recommended for sialendoscopy but may be a feasible route for select cases of FNA, such as the otherwise healthy adult or child whose anxiety over needles prevents a purely local anesthetic approach.

3. General: Reserved for pediatric patients and those with developmental delays who are unable to cooperate and remain still for an FNA, for patients with large parotid calculi requiring transfacial cutdown procedures, and those unable/unwilling to undergo salivary procedures under local anesthesia.

Positioning

1. Chair: The patient is positioned ideally in an adjustable procedure chair. For FNA procedures, the clinician may elect to stand and have the patient sitting upright, or sit and position the patient supine. In cases where the patient becomes vasovagal, the clinician should have the ability to place the patient in a supine or slightly Trendelenburg position. For salivary procedures, the patient is ideally positioned in the upright sitting position to allow for optimal patient control of secretions and ergonomic positioning for the physician, particularly while performing endoscopy and viewing the monitor.

2. Prone

3. Lateral recumbent

Perioperative Antibiotic Prophylaxis

1. None: Not required unless the patient has a prosthetic implant (heart valve) and sialolithotomy is planned

2. Second-generation cephalosporin

3. Clindamycin

Monitoring

1. None

Instruments and Equipment to Have Available

1. FNA
   a. Ultrasound
   b. Fine-bore needles (23 to 25 gauge), 1 to 1.5 inch length
   c. 10-mL Luer-lock syringes
   d. Glass slides
   e. 95% alcohol or a spray fixative
   f. Alcohol swabs
   g. 1% lidocaine with 1:100, 000 epinephrine, or alternative local anesthesia
   h. IV extension tubing (optional). The tubing is ideal for ultrasound-guided suction aspiration technique, as the operator holds the needle at the hub and therefore has markedly improved dexterity. (Fig. 87.2)
   i. Balanced salt solution (optional) for rinsing the needle

FIG. 87.2 Procedural Equipment.

A, Equipment for a standard ultrasound guided fine needle aspiration. **B,** Basic equipment for in office sialendoscopy. **C,** Accessory sialendoscopy equipment —*1*. Conical and tapered dilators; *2*. Lacrimal probes; *3*. Forceps and sharp scissors.

2. Sialendoscopy.

   a. Salivary dilators/probes

      1) Conical dilators, Marchal dilators, tapered dilators, Bougie dilators

   b. Sialendoscopes: Diagnostic (0.8 mm) and interventional scopes (0.4 mm working channel; 0.6 mm working channel)

   c. Sterile normal saline

   d. 2% lidocaine solution

   e. IV extension tubing

   f. Light cord; HD video camera attachment and video tower

   g. Yankauer suction and tubing

   h. Injectable local anesthesia (noted previously)

3. Sialolithotomy

a. Items listed under sialendoscopy

b. 0.4 mm and 0.6 mm wire baskets

c. Endoscopic graspers

d. 11 or 15 blade scalpel

e. Fine-toothed forceps

f. Salivary stents

Key Anatomic Landmarks

1. Wharton's duct papilla: Located in the anterior floor of the mouth bilaterally, just lateral to the frenulum, the papilla is a raised area of mucosa, which contains the punctal orifice of the submandibular duct.

2. Stensen's duct papilla: Located within the buccal mucosa bilaterally and adjacent to the premolars, the papilla is a raised area of mucosa, which contains the punctal orifice of the parotid duct.

3. Submandibular hilum: The posterior edge of the mylohyoid muscle seen on ultrasonography separates the submandibular duct into a hilar component and a distal ductal region. Calculi posterior and inferior to the posterior edge of the mylohyoid muscle are considered hilar calculi and may be more difficult to palpate and extract.

4. Ramus of the mandible: The anterior and posterior edges of the ramus of the mandible can be seen on ultrasonography. Location of a calculus relative to the mandible will often dictate the ease and approach for sialolithotomy.[1]

Prerequisite Skills

1. Diagnostic ultrasonography

2. Sialendoscopy

Operative Risks

1. Bleeding due to fine needle trauma to a superficial vessel (self-limited): Using color flow Doppler prior to performing an aspiration, the practitioner can plan a biopsy route to avoid vasculature.

2. Duct perforation: The parotid and submandibular ducts are pliable membranous structure. Sialendoscopy involves rigid endoscopy under a hydrostatic irrigation. Vigorous blind instrumentation can lead to duct perforation and fluid extravasation. Patient real-time feedback with respect to examination comfort is an advantage of awake sialendoscopy. In addition, use of a guide wire for Seldinger advancement of the scope may also reduce trauma in the patient with a stricture. Given the narrow nature of the parotid duct, its thicker wall, and its tortuous course over the ramus of the mandible, the parotid duct is more prone to injury.

3. Duct avulsion: This is primarily an issue when a practitioner attempts to extract a calculus, which exceeds the lumen size, with wire basket retrieval using excessive force. If a calculus is snared but the calculus does not withdraw with mild tension, the practitioner should be prepared to perform a direct duct cutdown and removal.

4. Hyperinflation of the gland: Overzealous irrigation during endoscopy, particularly in long cases, can lead to significant gland swelling and discomfort, as well as disruption of the basement membrane of the acini. Low-volume irrigation is recommended. If local anesthesia is used in the irrigation during the endoscopy, the volume of local anesthetic should be limited to prevent extravasation of the local anesthetic resulting in facial weakness or intravascular absorption resulting in vasovagal reactions or tachycardia.

Surgical Technique

Ultrasound-Guided Fine Needle Aspiration

Prior to discussing ultrasound guidance for needle aspiration, a review of proper ultrasound technique is required. The linear transducer is a flat, narrow-based probe that produces the highest quality images when applied to a flat surface. The quality of the image depends on the transmission and collection of sound waves, —hence a gel buffer between the probe and skin is required to maximize sonic transmission.

As the neck is a highly contoured region, the utility of ultrasound depends on probe manipulation in an orientation that maximizes complete flat contact. Proper handling of the probe, with the operators' fingers and thumb gently and comfortably grasping the base of the probe above the transducing portion, allows for maximal control for fine motor manipulation, rotation, angulation, and steadying of the probe during biopsy.

Procedure Preparation

1. Prep the skin with alcohol.
2. Percutaneous injection of local anesthesia under ultrasound guidance
    a. Typically 0.5 to 1 mL of 1% lidocaine with 1:100,000 epinephrine loaded on a 1-mL syringe with a 27-gauge needle will suffice.
3. Map lesion with ultrasound probe lined with gel.
    a. As opposed to the traditional FNA, when performing ultrasound guided-FNA, the site of skin puncture does not typically directly overlie the mass. Instead, the probe overlies the mass and the needle is introduced into the skin tangential to either the long axis (longitudinal technique) or short axis (transverse technique) of the probe. The degree of angulation of the needle with respect to the skin and probe is dependent on the depth of the wound, and with experience, this angulation can be better predicted.

Longitudinal Technique

1. Probe and needle orientation

For novice practitioners, the longitudinal technique is preferred, as the full shaft of needle can be visualized during correct placement. In this technique, the probe is centered over the mass with the orientation notch to the patient's right, and local anesthesia is applied to the skin adjacent to the end of the probe with the notch. This ensures that the direction of the needle on screen will mirror that of the needle in the clinician's hand. This provides the clinician an opportunity to assess the trajectory necessary for the biopsy. (Fig. 87.3A and B)

2. Needle placement

It is my practice to handle the needle directly, and either perform capillary (suction free technique) action or use a suction aspiration technique where an IV extension tubing is used to connect the needle to a syringe operated by an assistant. The needle is advanced initially through the skin in line with midline longitudinal axis of the probe under ultrasound guidance toward the lesion, adjusting the trajectory as needed. To maximize visualization of the tip, the needle should be placed with the bore facing directly toward the face of the probe.

3. Biopsy technique

Once in the mass, the suction is applied, or the finger released off of the hub, in the capillary technique, and brisk stokes are made with the needle under guidance through the mass. The length of the stroke is dependent on the space of the lesion. The ability to vary needle stroke length and improve tissue acquisition with each individual mass is another benefit afforded by ultrasound guidance. Aspiration is discontinued once material enters the needle hub; the improved diagnostic yield afforded by ultrasound guidance allows clinicians to limit the sample to one to two passes.

Transverse Technique

The transverse technique is more technically challenging but is also more versatile than the longitudinal technique (see Fig. 87.3C and D). The transverse technique minimizes the distance between the skin and the lesion, mirroring more the trajectory of the traditional unguided technique. The relative disadvantage of this technique is the limited visualization of the needle, as the needle is traveling through the tissue in a plane perpendicular to the probe and therefore will appear only as a dot on the two-dimensional screen

1. Probe and needle orientation

During this technique, the probe is typically held in standard cross-sectional fashion, and the skin is anesthetized superior to the probe in the midsagittal plane of the probe. The degree of angulation of the needle with respect to the skin and the probe is dependent on the depth of the lesion. Deep lesions require a more vertical needle orientation with

respect to the skin.

2. Needle placement

In this technique, the needle is introduced into the skin and advanced with a gentle vibratory motion while the operator keenly observes the area of motion on the screen until a bright "dot" appears. Attention during this portion of the exam is important, as the needle image will never appear bigger than a dot, regardless of which portion of the needle is in view. If there is concern of the needle being "passed point," either the needle can be slowly withdrawn until the dot disappears or the probe can been manipulated along a plane parallel to the needle trajectory. Once in the specimen, aspiration can begin as noted previously.

3. Technical tips

Adjusting (lowering) the dynamic range on the control panel will help to enhance the appearance of the needle during biopsy. The activation of color flow during the biopsy allows the operator to visualize vessels but simultaneously reduces the visualization of the needle. It is recommended therefore to map the pathway on color flow Doppler first and then perform the needle biopsy on the standard B-mode.

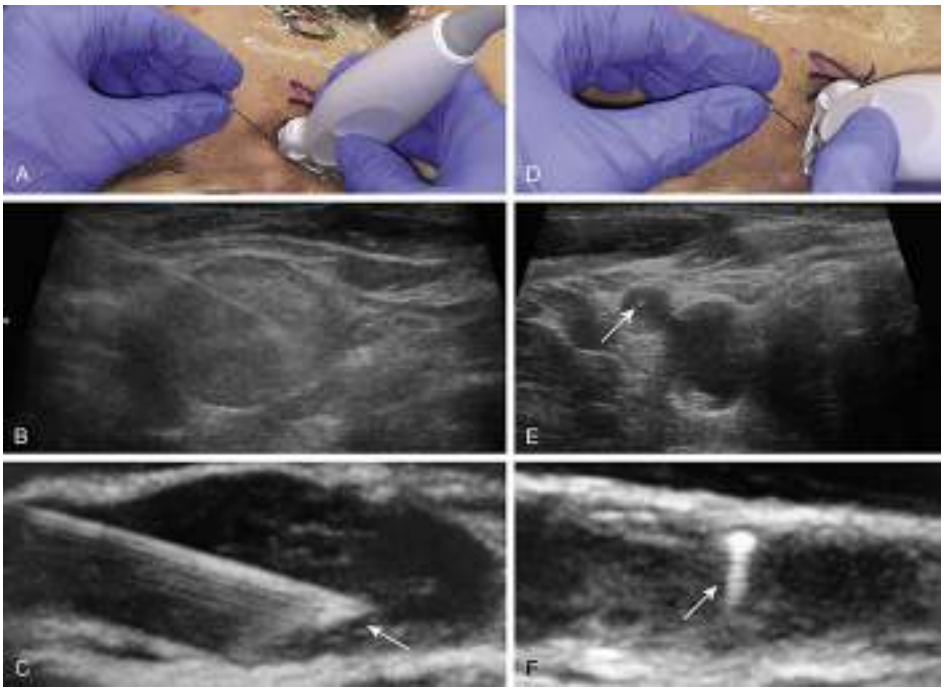

FIG. 87.3 Ultrasound fine needle aspiration techniques.

Office-Based Sialendoscopy/Sialolithotomy

Office-based salivary procedures are well tolerated in appropriately selected patients.[2] These are two-person procedures, and thus a capable assistant is required. Patients with large (>4 mm) parotid calculi will likely require a transfacial approach and hence should be excluded from an office setting. However, submandibular calculi may be removed in an office setting, provided they are either palpable and/or less than 3 mm.[2,3] Endoscopic retrieval is well tolerated, and direct floor of mouth incisions for megalith calculi (>7 mm) are very feasible in the appropriately selected patient. As a rule, the submandibular duct is more challenging to access for dilation and endoscopy but easier to navigate than the parotid duct, due to the variances in the size of the duct, the thickness of the wall, and surrounding anatomic barriers (ramus of the mandible).[2,3]

Procedure Preparation (Fig. 87.4)

The patient is placed in the upright position with suction available. The scope is white balanced and irrigation connected. Scope selection is dependent on the goal of the procedure. Diagnostic exams are best performed with the 0.8-mm sialendoscope. Stone removal requires a 0.6-mm or 0.4-mm (preferable size for parotid duct procedures) working channel scope. The default setup in the office is to have the tower behind the patient's left shoulder with the practitioner standing alongside the patient's right and facing the patient with the chair height position ergonomically adjusted for the practitioner. Dilators and probes, along with topical and injectable anesthesia, are laid out. Prior to insertion, it is

essential the practitioner have the scope oriented to the display screen. Unlike sinus endoscopy, the camera attachment is separate from the handheld portion of the scope. Therefore, the camera attachment must be stably oriented before the procedure. Such orientation will assure the practitioner of a 0-degree view when the scope is held with the irrigation port in the upright position.

Sialendoscopy

Stensen's Duct

The patient maintains mouth opening while the practitioner gently grasps the cheek at the oral commissure. The other hand gently massages the gland from the tail to the duct orifice while observing for salivary outflow. The duct orifice is identified and then gently dilated serially with lacrimal probes or tapered dilators. This step often is painless, however, if the patient reports discomfort; injectable anesthesia can be placed around the papilla. Next, the sialendoscope is introduced and a topical lidocaine infusion is used while the practitioner advances the scope under direct visualization to the hilum. The parotid duct may take a tortuous course, and manipulating the patient's degree of mouth opening may help navigate the scope over the ramus of the mandible. After the initial 5 mL of 2% lidocaine infusion with pressure titrated to patient comfort, a normal saline infusion is used. Debris is flushed from the system. Debris may indicate a calculus or inflammation of the duct. If a calculus is seen, the 0.4-mm working channel scope is then introduced. In cases where the duct is narrow/tight, a guide wire may be used to navigate the duct in Seldinger fashion and lower the risk of duct trauma/perforation. Small calculi may then be extracted via deployment of a 0.4-mm wire basket through the working channel of the scope. The basket is opened beyond the calculus and slowly withdrawn until the calculus is captured. The calculus and scope are removed together. If the calculus will not deliver from the orifice, a small controlled incision is made to widen the papilla. The scope is reinserted to check for further calculi.

FIG. 87.4 Sialendoscopy Office Procedure.

A, Mayo stand set-up with scope, tubing, dilators, saline, and local injectable anesthesia. **B,** Room set-up for procedure. **C,** Practitioner and patient in ergonomic position for procedure.

In the case of salivary stricture, the ultrasound may be used with the scope to visualize the stricture and duct trajectory. In these cases, the proximal duct is often dilated and readily visible on ultrasound, as is the metal scope. Imaged-guided dilation may be performed with the scope or balloon catheters and then a stent placed for 2 to 3 weeks.

Wharton's Duct

The patient maintains mouth opening and lift of the tongue to expose the papilla. Mild submandibular pressure allows the surgeon to visualize flow out of the papilla. Citric acid powder may also be helpful. Next, serial dilation is performed with the various probes and dilators mentioned previously. When the patient reports discomfort local anesthesia 1% lidocaine with 1:100, 000 epinephrine may be injected with a 27- to 30-gauge needle, 0.1 to 0.3 mL, with care to place the injection site away from the expected natural orifice. The use of injection may also help with a "floppy" papilla, increasing the tissue turgor and allowing

visualization of the orifice for dilation. The papilla should *not* be grasped with forceps during this step, as this results in trauma, bleeding, and potential scarring, as well as causing orifice confusion. If the orifice cannot be found, the practitioner can inject the floor of mouth proximal to the papilla with 0.5 mL of local anesthesia and perform a small cutdown and ductotomy (described later) to permit duct access and sialendoscopy.[4] Once access has been obtained, endoscopy proceeds as described previously. In cases of removal of a calculus, the larger 0.6-mm working channel scope is frequently used, as the duct is larger in caliber and has a greater capacitance.

Sialoithotomy

In cases of palpable submandibular stone more than 4 mm, endoscopic retrieval is not feasible. While laser lithotripsy has been described, its efficacy is poor and the time and safety implications with this technique obviate its use in the clinic setting. In the properly selected patient, floor of mouth cutdown may be performed at any portion of the duct, from the papilla to the hilum of the gland.

The patient maintains mouth opening while the practitioner displaces the tongue medially. In cases of posterior/hilar stones, the patient or assistant delivers superior submandibular gland pressure to displace the stone toward the floor of the mouth. Local anesthesia of 2 to 4 mL is injected into the floor of the mouth. After 5 minutes, a 3- to 4-cm incision is made in the mucosa overlying the palpable stone. Dissection is continued in the submucosa with sharp scissors. Care is taken to first identify and lateralize the lingual nerve. The stone is palpated in the duct and typically visible after identifying the nerve. A controlled linear longitudinal incision is made on the duct over the calculus, large enough to remove the calculus. The ultrasound may be useful for localizing and sizing the calculus prior to or during the procedure. After release of the calculus and secretions, the sialendoscope is then introduced through the ductotomy to evaluate the proximal system and ensure there is no further pathology. For anterior calculi, it is recommended to place a suture proximal to the calculus to prohibit retropulsion of the stone to the hilum prior to floor of mouth incision or consider endoscopic basket entrapment prior to performing the cutdown.

In the case of posterior incisions, no duct repair is necessary, and the incision is left to heal by secondary intention as the rate of stricture is low. In addition, there is often up to 1 cm of soft tissue separation between the duct and mucosa. If significant trauma to the duct occurs, as in the case of an adherent calculus, stent placement may be performed from the natural orifice. Within the anterior floor of mouth, the duct is smaller and within millimeters of the mucosal surface, and therefore a formal sialodochoplasty is performed. 5-0 to 7-0 interrupted chromic sutures (three to five sites) are used to approximate the duct to the mucosa. If there is concern for duct lumen trauma, a stent may be placed as well.

Common Errors in Technique

Ultrasound-Guided-Fine Needle Aspiration

1. Delayed visual acquisition of needle in longitudinal technique

A common error is to place the needle into the deep tissue and then search for the shaft. Often the angle and level of the needle are off target, and the practitioner will struggle to change the trajectory of the needle. Manipulation of the needle trajectory after the shaft is within the tissue is challenging, as often the thin bore shaft of the needle will bend under the pressure of the surrounding tissue. The practitioner should identify the tissue displacement created by the needle pressure at the skin level and then trace the needle shaft fully to the target in the longitudinal technique.

2. Using a large-bore needle—greater than 23 gauge

This leads to increased blood in the specimen, decreasing the diagnostic yield.

3. Pass point placement of needle in transverse technique

The tip and the shaft of the needle will look identical in this technique, so careful observation of the screen is needed to avoid a needle passed point error. Slow advancement of the needle and gentle toggling of the probe in a cranial-caudal direction ensures proper placement.

4. Overaggressive aspiration

Too much blood in the specimen will lower the diagnostic yield. Careful observation of the vascular flow on ultrasound and the needle hub during biopsy prevents excessive blood in the specimen.

5. Leaving excess gel on the neck at the puncture site

Ultrasound gel will distort the cytology smear and create an artifact if it incidentally enters the needle hub during aspiration.

Sialendoscopy/Sialolithtomy

1. Grasping the papilla with forceps or injection near the papilla

This can result in bleeding or trauma leading to delayed scarring, or distortion of the anatomy leading to false passage during dilation.

2. Improper camera orientation

This significantly hinders driving the scope and performing endoscopy.

3. Advancing the scope against resistance and/or without view of the lumen

This may lead to perforation of the duct and soft tissue trauma, which results in aborting the case.

4. Overaggressive irrigation

This leads to patient discomfort and gland swelling. If performed with local anesthesia, the patient may develop transient facial weakness, headache, or vasovagal symptoms due to extravasation of to the soft tissue and vasculature.

5. Withdrawing the calculus in a wire basket against resistance

If the calculus fails to slide forward for extraction, excessive force may lead to duct avulsion. In the case of a trapped basket, a cutdown technique is needed to complete stone removal.

6. Excessive torque on the endoscope

The scopes are rigid, but *very* fragile. The scopes will fracture very easily if bent while trying to navigate around a corner on the screen. This is a particular risk in parotid sialendoscopy when trying to maneuver

around the mandible.

Postoperative Period

Ultrasound-Guided Fine Needle Aspiration

Postoperative Management

1. Assess for bleeding at the skin level.

2. Assure the patient is not lightheaded after completion of the biopsy and in a seated position.

3. If symptomatic, the patient's vital signs should be checked.

Complications

1. Hematoma

Given the fine-gauge needles used, if a hematoma occurs, it is small and self-limiting and will respond to direct pressure.

2. Nondiagnostic yield

If a nondiagnostic sample occurs, repeat sampling versus and open biopsy may be performed.

Alternative Management Plan

1. Core needle biopsy

When lymphoma is suspected, more tissue may be necessary and a core needle may be performed. However, a prior fine needle aspirate result suspicious for lymphoma should direct whether this is necessary.

2. Incisional biopsy

When lymphoma is suspected, more tissue may be necessary and an incisional biopsy may be performed. However, a prior fine needle aspirate result suspicious for lymphoma should direct whether this is necessary.

Sialendoscopy/Sialolithotomy

Postoperative Management

1. Patients undergoing posterior floor of mouth cutdown require 3 to 5 days of a narcotic analgesic.

2. All patients are instructed to maintain hydration and massage their glands at least twice per day.

3. If stents are placed, the patient returns 2 to 3 weeks later for removal.

Complications

1. Perforation of the duct

This occurs from overaggressive blind advancement of the scope—typically in the parotid system. If this occurs, the procedure is immediately terminated.

2. Trapped basket: Basket containing a stone that cannot be removed

A cutdown procedure is needed to remove the basket and the calculus.

3. Punctal trauma and false passage

This occurs with grasping the papilla and may lead to stricture. It can be avoided with the no touch gentle technique described previously.

4. Failure to reach or removed calculus

Patient may require an operating room attempt at removal versus excision of the gland.

5. Trauma to the duct

If severe, this may lead to stricture and recurrent obstructive sialadenitis; stent placement may mitigate risk of stricture.

6. Vasovagal reaction

This may be due to patient factors or overinfusion of lidocaine solution. The case should be aborted and patient recuperated.

7. Bleeding

This is rarely an issue and usually responsive to bipolar cautery. It is seen in posterior floor of mouth cutdown procedures, typically with deep dissection.

Alternative Management Plan

1. Operating room procedure

Patients may not tolerate the procedure from a pain or vasovagal reaction standpoint. In these situations, an operating room attempt may be successful.

2. Excision of the gland

If the patient is refractory to endoscopic therapy or the stone cannot be removed, gland excision is an effective treatment option.

Discussion

Evidence-Based Medicine Question: Does Ultrasound Guidance Improve Specimen Adequacy in a Cost-Effective Manner?

Khalid et al. in 2008 performed a cost-effective analysis of ultrasound-guided FNA and traditional FNA. Ultrasound guidance improved specimen adequacy 95% versus 80% at an additional cost of $289 per correct diagnosis.[5]

Editorial Comment

The practitioner faced with patients with salivary problems has many fine tools available for office-based diagnosis and treatment. Increasingly, ultrasound has become an extension of the physical exam of head and neck patients. Salivary endoscopy is increasingly finding its way into the office as well, for the diagnosis and treatment of certain obstructive salivary pathologies.

Barry Schaitkin

Evidence-Based Medicine Question: Is Sialendoscopy Effective in the Management of Salivary Pathology?

A meta-analysis revealed weighted pooled success rates of 86% (endoscopy alone) and 93% (endoscopy with combined procedure) for patients undergoing sialendoscopy for obstructive disease.[6]

Review Questions

1. Ultrasound guided FNA can reliably diagnose the following lesions *except*

   a. Squamous cell carcinoma

   b. Lymphoma

   c. **Schwannoma**

   d. Thyroid cancer

2. All of the following factors affect specimen adequacy *except*

   a. Ultrasound gel

   b. Needle gauge

   c. Suction aspiration

   d. **Use of local anesthesia**

3. Which of the following remarks about technique is accurate?

   a. **Capillary action is preferable for a vascular thyroid nodule**

   b. Longitudinal technique is preferred for a deep lobe thyroid nodule

   c. Transverse technique involves tracking the needle throughout its course

   d. Needle track adjustments are easier once the needle is within the deep tissues

4. All of the following are true with regard to salivary stone management

except

a. Parotid stones greater than 4 mm should be addressed in the operative room

b. Follow-up endoscopy is necessary after stone removal

c. **All cutdown procedures require a sialodochoplasty**

d. Impacted calculi have a higher rate of delayed stricture

5. Which of the following techniques should be avoided?

a. Placing a suture around the duct proximal to the stone

b. Injection of the papilla with local anesthesia

c. Floor of mouth incisions for stones greater than 7 mm

d. **Grasping the papilla during dilation**

6. All of the following increase the risk of gland/duct trauma *except*

a. **Use of ultrasound for image guidance**

b. Overaggressive irrigation

c. Advancement of the scope against resistance without a clear lumen

d. Wire basket removal against resistance

7. Which of the following statements is true?

a. Sialendoscopes are easily fractured with minimally force/bend

b. Duct perforation necessitates immediate case abortion

c. Submandibular stone size does not determine candidacy for an office-based procedure

d. **All of the above**

Salivary Endoscopy

Barry Schaitkin, and Rohan R. Walvekar

Introduction

Salivary endoscopy is a minimally invasive technique for the treatment of a variety of inflammatory salivary gland pathologies. The procedure has been in practice globally since the early 1990s. The small high-resolution telescopes are in their fifth generation of development and now incorporate rinsing and instrumentation capabilities. The technique is useful for removing calculi and treating stenosis, as well as for inflammatory conditions such as Sjögren's syndrome, recurrent juvenile parotitis, and for the secondary effects of radioactive iodine on the major salivary glands.

Patients most commonly present with meal-time obstructive symptoms of swelling of the gland and discomfort with provocation. The inflammatory processes can have more constant symptoms not associated with meals.

Key Operative Learning Points

- The dilation of the papilla of the submandibular gland (SMG) and parotid gland is the initial rate-limiting step and requires delicate handling of the tissue.
- The SMG duct is difficult to access via the papilla but very easy to navigate with the salivary endoscope.
- Although the papilla of the parotid is relatively easy to dilate, the challenge is where the duct curves around the masseter muscle. Straightening the duct helps to facilitate this part of the endoscopy.
- The scopes range in size from the diagnostic scope (0.8 mm) to

therapeutic scopes (1.1 to 1.6 mm).

Preoperative Period

History

- History of present illness
  - Duration of symptoms
  - Age at onset
  - Provocation with meals
  - Previous history of calculi
  - Dry eye and/or dry mouth
- Past medical history
  - History of radioactive iodine
  - Previous surgery of the salivary gland
  - Medical illness
  - Family history
  - Medications:
    - Anticoagulants

Physical Examination

- Palpation of all major salivary glands
- Intraoral examination including examination under the operating microscope
  - Notation of size and location of the papilla particularly of SMG
  - Observation of quality and quantity of expressible saliva
  - Palpation for calculi along Wharton's duct
  - Palpation for calculi at or near the papilla of Stensen's duct
  - Evaluation of potential surgical challenges to the procedure

- Teeth
- Tori
- Piercings

Imaging

- Ultrasound (US) is the primary imaging modality outside of the United States and is becoming more popular in the United States. US is able to detect calculi as small as 2 mm and is very good at demonstrating ductal dilation associated with any form of obstruction. It is also a dynamic study and can be done with concurrent salivary stimulation with food. It is also possible to do the study with intraoral palpation to further delineate calculi. The most difficult area to image is the anterior aspect of Wharton's duct.
- Computerized tomography (CT) without contrast is very good at identifying calculi larger than 1 mm. It is not useful for most cases of stenosis unless the duct is dramatically dilated. Contrast should be used in cases where a neoplasm remains in the differential diagnosis.
- Sialography
  - Conventional sialography is invasive and very operator and interpreter dependent, but it can be useful in some difficult to understand cases of obstruction.
  - MRI sialography is available in a few centers. No contrast is required because the saliva is used as contrast. It is expensive and has all the limitations of normal MRI. It requires extra back table work and programming to acquire the images.

Indications

- Obstruction of the salivary glands by history and imaging compatible with calculi or stenosis
- Inflammatory conditions significant enough to warrant operative intervention due to frequency and severity
- Symptoms related to administration of I^{131}

Contraindications

- Salivary endoscopy during an acute infection is a relative contraindication with the possibility of worsening the infection or perforating the duct.
- Medical comorbidities should not be a contraindication because most of these procedures can be done using local anesthesia alone or with awake sedation.

Preoperative Preparation

- Preoperative antibiotics if necessary to control an acute process

Operative Period

Anesthesia

- General: Although this procedure can be done using local anesthesia or with awake sedation, general anesthesia is often preferred for patient comfort. For some hybrid procedures and bilateral cases, nasal intubation may provide better exposure in the oral cavity.
- Awake sedation is possible.
- Local anesthesia, including office salivary endoscopy, is possible in some situations.

Positioning

- Supine: The patient is positioned the same as any endoscopic sinus procedure with the head turned slightly toward the surgeon.

Perioperative Antibiotic Prophylaxis

Not all surgeons use perioperative or postoperative antibiotics for a routine type of procedure. However, if there has been recent infection or for a combined approach with some degree of opening through the

mucosa combined with an endoscopy, antibiotics are recommended.

- If combined approach through a face lift incision is used to address parotid pathology, then a first-generation cephalosporin is used.
- Clindamycin if the patient is allergic to penicillin
- Patients having transoral hybrid procedures receive amoxicillin/clavulanic acid.

Monitoring

- For combined approaches to the parotid gland and Stensen's duct, some surgeons use facial nerve monitoring. There is no evidence that it improves outcomes, and we do not use such monitoring.

Instruments and Equipment to Have Available

- Camera and light source tower for endoscopy
- Basic salivary endoscopy set with mouth props, dilators of multiple types, and delicate scissors and forceps
- Retractors including sweetheart, malleable, and self-retraining
- 20-cc syringe with saline
- Irrigations with intravenous (IV) connecting tubing
- Multiple salivary endoscopes of different dimensions (1.1, 1.3, and 1.6 mm) for different pathologies
- Disposable instruments including stone baskets, balloons, dilators, and stents
- Kenalog
- Local anesthesia if the case is not under general; local without epinephrine can be used as the irrigation fluid instead of saline to stent the duct open to perform the procedure

Key Anatomic Landmarks

- Internally the SMG papilla is located posterior to the anterior incisors, although its exact location is variable and should be noted in the office while stimulating the patient's salivary glands with food.
- The parotid papilla is adjacent to the second molar in the buccal mucosa.
- Stensen's duct is in close proximity to the buccal branch of the facial nerve.
- Calculi in the hilum of the SMG are close to the lingual nerve, which frequently has to be moved laterally for hybrid approaches to an SMG calculus.

Prerequisite Skills

- Endoscopic skills
- Basic open head and neck surgery skills
- Patience

Operative Risks

- Failure to retrieve the calculus or eliminate the pathologic process
- Perforation of the duct by penetrating the duct with the scope
- Avulsion of the duct by pulling too hard on an impacted calculus
- Blocked basket requiring an open procedure to retrieve the basket stuck on a salivary calculus
- Stenosis of the duct from instrumentation, laser thermal injury, or combined approach incisions
- Airway obstruction from irrigation
- Cranial nerve injury to the lingual or buccal branch of the facial nerve during hybrid procedures

- Bleeding from an injured vessel. No risk of these during purely endoscopic procedures
- Failure of the procedure and the need for excision of the salivary gland

Surgical Technique

- Salivary endoscopy

Submandibular Gland

- Patients are selected for local, monitored anesthesia care, or general anesthesia based on patient factors, pathology, and comorbidities.
- Visualize the papilla with magnification.
- Saliva milked from the gland is a useful landmark but is of limited quantity and must be used sparingly.
- Do not use toothed forceps or instruments that can create a dimple in the mucosa simulating an orifice.
- Atraumatic dilation technique with rigid dilation progressively or with Seldinger technique (Video 88.1)
- Choose scope size based on expected pathology and instruments that fit through each port.
- Check scope for optics, focus, and white balance, and determine the direction of up while holding the scope in your hand outside the patient so that you will know this direction during the endoscopy.
- Irrigate both ports of the scope with saline to avoid air bubbles.
- Insert the scope without force.
- Use appropriate stone (calculus) baskets for size (more wires for smaller calculi and fewer for larger stones) (Video 88.2).
- Stones larger than 4 mm in their smallest dimension that are not near the papilla will need either hybrid procedures or fractionation before retrieval.
- Floating calculi are usually retrievable.

- Most calculi require papillotomy for extraction (Video 88.3).

Parotid Gland

- Identify the papilla near the second molar. These are usually easier to locate than the submandibular papilla.
- Dilation using metal dilators
- Scope set up as previously described
- Realize that Stensen's duct is smaller

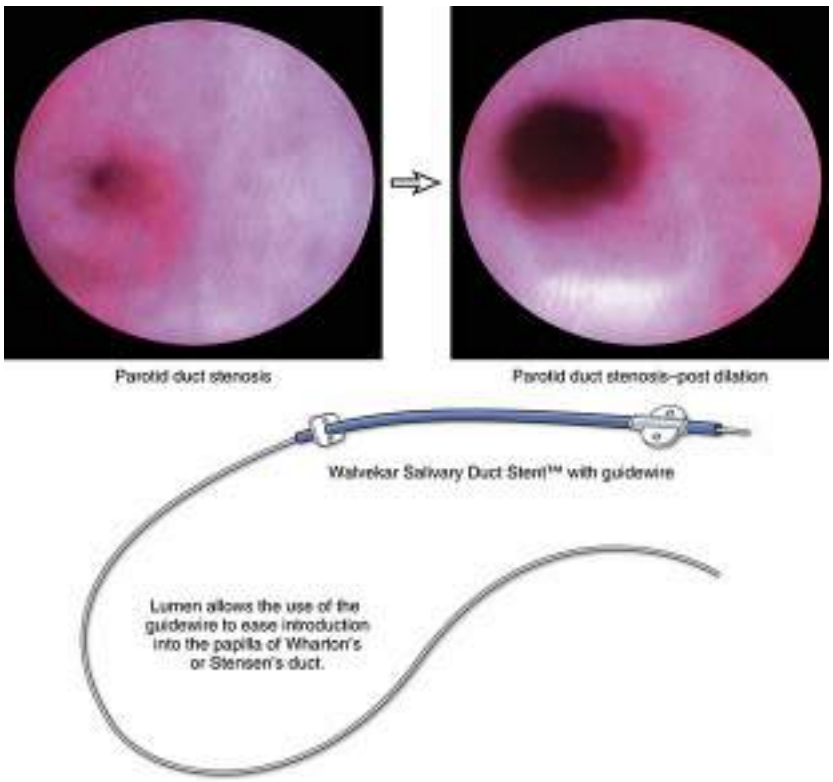

FIG. 88.1 Dilation of parotid stenosis before and post stenting. *(Hood Laboratory, Pembroke, MA.)*

- Be aware that attempted endoscopic removal of calculus in the ductal system proximal to the masseter muscle has a low success rate.[1]
- Calculi larger than 3 mm that are not floating may need fragmentation or hybrid approaches.

- Most stenosis tends to occur in the parotid ductal system.
- Stenosis cases may be single diaphragmatic ideal cases or more difficult multilevel or severe cases.
- A stenotic duct can be dilated by a balloon or scopes in sheaths (Fig. 88.1).

Hybrid Approaches

- SMG (Video 88.4)
  - Distal calculi at the papilla can be extracted as an office procedure.
  - Medium calculi in the midduct or hilum can be treated with transoral sialolithotomy or fragmented and extracted with salivary scopes.
  - Large calculi in the midduct or hilum can be removed by transoral sialolithotomy, with care taken to see and protect the lingual nerve.[2,3]
  - Postextraction endoscopy confirms no residual fragments. Fragments left behind will lead to recurrence/persistence of disease.
  - Repair of the duct is not necessary.
  - Mucosa is loosely closed over the sialolithotomy.
- Transfacial (Video 88.5)
  - Mini-face lift incision used with typical parotid exposure and protection of the greater auricular nerve
  - Calculus should either be:
    - Seen and marked with methylene blue by US
    - Easily palpable
    - Highlighted by parotid salivary scope left in place
    - Ideally trapped in a stone basket so that it can be manipulated within the duct to facilitate extraction
  - An anteriorly based U-shaped superficial muscular aponeurotic system (SMAS) flap is elevated over the calculus.

- The buccal branch of the facial nerve if visualized is dissected free of the calculus entry site.
- Scalpel sialolithotomy is enlarged with middle ear scissors as much as necessary to retrieve the calculus.
- Watertight closure of the parotid duct is necessary and is checked by placing water at low pressure via the scope and observing the closure.
- SMAS flap provides second layer closure.
- Vein grafts for stenosis not amenable to dilation have been described.[3]

- Transbuccal (Video 88.6)
  - A curvilinear incision is placed anterior to the papilla of the parotid duct.
  - The incision is developed through the buccinator muscle to expose Stensen's duct in the buccal space.
  - A variety of interventions are then possible after this access has been obtained.
    - Parotid duct stenosis or calculi distal to the anterior border of the masseter muscle can be treated by performing a sialodochotomy and calculus release in the buccal space or alternatively dilating the parotid duct stenosis under direct visualization. After the stenosis is dilated or the calculus is removed, the duct can be visualized by endoscopy via the natural ostium to go past the area of pathology into the more proximal duct, followed by placement of a guidewire and stent. Usually, if the duct has been incised, it is repaired at this time over the stent. Botox injection of the parotid parenchyma should be a consideration to prevent sialoceles.
    - The midbuccal space sialodochotomy also provides access to perform endoscopy through it and visualize and treat pathology in the parotid hilum.
    - For more distal stenosis, the curvilinear incision can be completed to create a circumferential incision around the duct opening in the buccal mucosa. The duct is dissected from the buccal space to retract it into the oral cavity (i.e., duct stretching). The distal duct

can then be excised (usually 1 to 2 cm) and the remnant proximal duct sutured to the buccal mucosa to complete the sialodochoplasty.

Common Errors in Technique

- Inability to dilate the papilla
- Making punctures with injection needles, dilators, or guidewires that look like the papilla opening
- Not staying central in the lumen and so no real view
- Pushing without visualization and perforating the duct
- Continuing to irrigate after perforating the duct
- Basketing a fixed calculus and having the basket trapped—"trapped basket syndrome"
- Breaking the salivary endoscope by excessive force or bending it over the teeth
- Too much irrigation, consequently overinflating the gland or causing ductal injury and extravasation of irrigation into the floor of the mouth or buccal space, causing swelling of the floor of the mouth or cheek, respectively

Postoperative Period

Postoperative Management

- These procedures are done in the clinic under local anesthesia or in the operating room, and then the patient is discharged.
- Antibiotics are given for patients with evidence of infection during endoscopy.

Complications

- Perforation of the duct is usually managed with antibiotics,

occasionally by stenting the duct.

- Infection can occur because of postoperative edema of the duct and papilla.
- Blocked baskets occur when the calculus is not floating and the calculus can be grasped but not released.
- Duct avulsion comes from pulling too hard on a stone basket combination. This requires removal of the gland in most cases.
- Vascular and neural complications are rare; lingual nerve paresis with combined approach techniques for submandibular calculi
- Scopes are fragile; be gentle so as not to break them.

Alternative Management Plan

The alternatives to gland-preserving approaches that involve salivary endoscopy and hybrid approaches are either observation or excision of the gland. Patients in whom salivary endoscopy has not been helpful in mitigating symptoms should consider excision of the gland. In patients with parotid sialadenitis, Botox injection with US guidance may temporize symptoms and can offer an alternative in some patients who do not wish to undergo parotidectomy with a risk of facial nerve paresis and disfigurement that may be associated with the procedure.

Discussion

Evidence-Based Medicine Question

After removal of hilar submandibular calculi by salivary endoscopy, what percentage of patients have stable or increased salivary flow as judged by scintigraphy?[4]

In general, large SMG calculi and hilar calculi are often looked upon as situations in which gland preservation is not feasible. The premise of salivary endoscopy was the ability of the procedure to permit return of flow and afford gland preservation. The authors denote that up to 66% of glands demonstrate stable or increased salivary flow as judged by

scintigraphy after removal of submandibular hilar stones. The study provides objective evidence that validates endoscopic gland-preserving techniques. Salivary flow is not the only indicator of successful intervention. The patients must be evaluated for symptom relief (i.e., relief of obstructive symptoms), pain, and recurrent stenosis or calculi formation. The latter are often responsible for salvage gland excision after successful endoscopic intervention.

Editorial Comment

Inflammatory disease of the salivary gland traditionally involved removal of the gland. Minimally invasive approaches can now be used for obstructive calculi and stenosis, as well as inflammatory conditions such as juvenile recurrent parotitis, radioactive iodine–induced sialadenitis, and Sjögren's syndrome. There is a learning curve, and the technique requires gentleness and patience. With the addition of hybrid techniques, gland retrieval can be used to rescue a small percentage of cases of inflammatory and obstructive diseases of the salivary glands.

Barry Schaitkin

Review Questions

1. Calculi may need to have hybrid approaches or fragmentation of calculi if they are

   a. In the submandibular duct and smaller than 3 mm

   b. In the parotid duct and smaller than 2 mm

   c. **In the parotid duct and larger than 4 mm**

   d. At the papilla

2. A blocked basket occurs when

   a. A calculus is irregular and does not fit well into the basket

   b. Dilating a stenosis that is tight

   c. **A calculus that is not floating is grasped and the basket cannot be released**

d. A calculus is particularly dense

3. Stenosis is most commonly

a. Found in the submandibular duct

b. **Found in Stensen's duct**

c. Found in Bartholin's duct

d. Found in Wharton's duct

Surgical Management of Ranula

Rohan R. Walvekar, and Rachel Barry

Introduction

A ranula is an extravasation mucocele that arises in the floor of mouth secondary to trauma to the sublingual gland or obstruction of the salivary ducts. The term ranula is derived from the Latin word *rana*, meaning frog, which describes the bluish floor of mouth swelling that resembles a frog's underbelly. These lesions are classified into two types: oral or simple ranulas and cervical or "plunging" ranulas. Oral cavity ranulas present only in the floor of mouth and are located above the mylohyoid sling, while the plunging ranula presents as swelling in the neck and arises from herniation of the ranula through or around the mylohyoid muscle (Figs. 89.1 and 89.2). Plunging ranulas are pseudocysts, meaning that the wall of the ranula is lined with granulation or connective tissue and lacks an epithelial lining.[1]

While surgical therapy is the recommended treatment modality for both oral and plunging ranulas, the preferred approach has evolved over the years. Various methods have been described, including marsupialization and excision of the ranula with or without excision of the sublingual gland for oral ranulas. Others have described a transcervical approach and excision of the submandibular gland in the management of a plunging ranula. More recent literature supports the excision of the sublingual gland with transoral drainage of the plunging component as the modality with the fewest complications and recurrences.[2]

Key Operative Learning Points

1. A comprehensive knowledge of anatomy of the sublingual gland is

essential to avoid injury to the lingual nerve and Wharton's duct.

2. Surgical management of plunging ranulas has shifted from combined approaches with excision of transcervical ranula, and sometimes excision of the submandibular gland, to intraoral excision of the sublingual gland with evacuation of the ranula.

3. Complete excision of the sublingual gland is associated with the fewest recurrences of ranulas.

Preoperative Period

History

1. History of present illness
   a. Painless swelling of the floor of the mouth
   b. History of recurring lesions with formation of cysts with resolution being pathognomonic of a ranula.
   c. Larger lesions can lead to difficulty with speech, swallowing, and breathing.
   d. Mass effect can cause impairment of submandibular salivary flow, leading to swelling and pain in the gland after eating.
   e. Plunging ranulas present with an enlarging, painless mass in the neck, with or without accompanying swelling of the floor of the mouth.
2. Past medical history
   a. Trauma to the floor of the mouth or neck
   b. History of surgical procedures to the floor of the mouth or salivary glands
3. Family history
   a. Bleeding disorders
4. Medical illness
   a. Medical comorbidities that may impact eligibility for or viability of surgical intervention

5. Medications

a. History of anticoagulant therapy or the use of herbal products

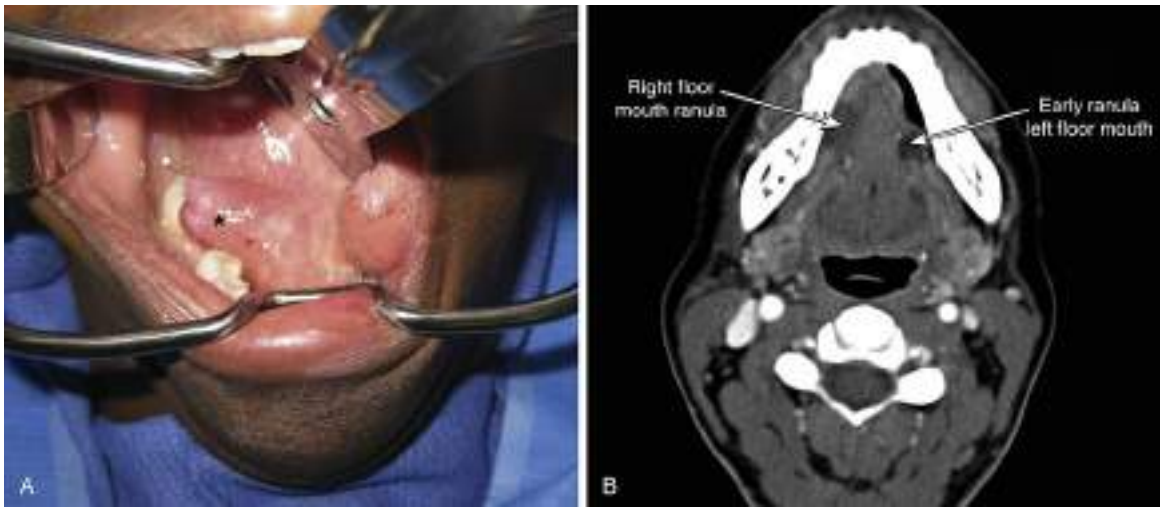

FIG. 89.1 **A,** Bilateral floor of mouth ranula; the *asterix* showing a prominent floor of mouth ranula. **B,** Computed tomography scan (axial view) showing bilateral floor mouth ranulas.

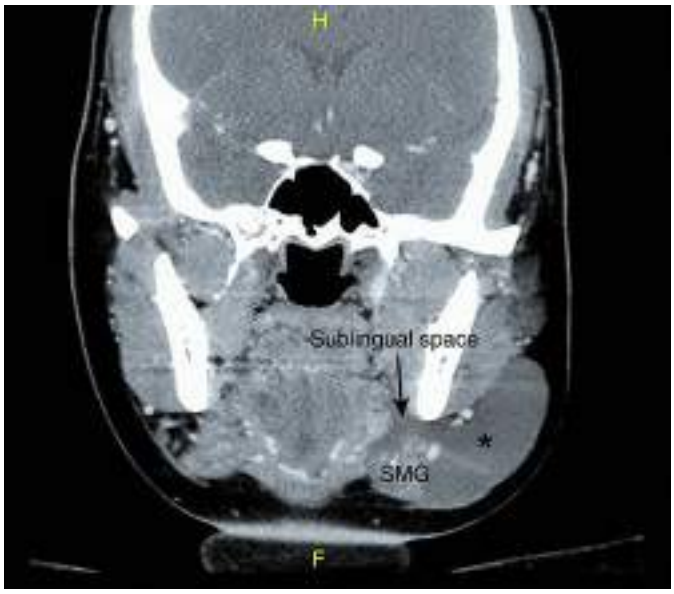

FIG. 89.2 Computed tomography scan (coronal view) showing ranula involving sublingual space and expanding beyond the mylohyoid sling into the upper

neck spaces. The arrow points to the sublingual space. SMG indicates the location of the submandibular gland being displaced by the plunging component of the ranula (indicated by asterix).

6. Allergies
   a. Antibiotics
   b. Local anesthetics

Physical Examination

1. Oral cavity
   a. Unilateral bluish mass beneath the mucosa of the anterior floor of the mouth
   b. If large, the lesion may cross the midline.
   c. Bimanual palpation of the floor of the mouth must be performed to rule out coincidental salivary calculi. In the case of a plunging ranula, external pressure on the neck mass often makes the corresponding sublingual fossa prominent.
   d. An effort must be made to identify and check the function of the submandibular duct. Location of the papilla of the submandibular duct must be recorded. These steps facilitate cannulation of the submandibular duct if placement of a stent is considered and also facilitates early decision making to perform a marsupialization of the submandibular duct if the submandibular papilla is stenotic.
   e. Patency of all four salivary ducts must be examined and documented
2. Neck
   a. Fluctuant, nontender, unilateral mass in the submandibular region
   b. Giant ranulas can extend to also involve parapharyngeal space or to the level of the clavicles.
   c. Can have neck mass without oral cavity component

Imaging

1. Computerized tomography (CT) scan of neck with contrast and without contrast, 1 mm cuts[3]
    a. Essential in cases of plunging ranula to determine cervical extent and relationships prior to operative management
    b. Appears as a nonenhancing, homogeneous, unilocular lesion in the sublingual space with extension to the submandibular and sometimes the parapharyngeal spaces in plunging ranulas (see Fig. 89.2)
    c. Sublingual gland or space may be replaced by radiolucent material suggestive of extravasated saliva, typical of ranula formation. The submandibular gland is often displaced or surrounded by the radiolucency making it difficult at times to decipher if the gland is the origin of the pathology or is being affected as a consequence of it.
2. Magnetic resonance imaging (MRI)[3]
    a. Not required, can complement or replace CT scan
    b. Hyperintense cystic lesion on T2-weighted images, low to intermediate intensity on T1-weighted images
3. Ultrasonography[4]
    a. Ultrasound has also been shown to successfully evaluate cystic lesions in the submandibular space, as well as evaluate areas of dehiscence in the mylohyoid muscle.
    b. Ultrasound can be a valuable tool intraoperatively as well as to ensure complete drainage of the plunging component of the ranula.
4. Laboratory tests
    a. Serum amylase: The diagnosis of a ranula is a clinical and radiological diagnosis; however, in cases where there is a question regarding the origin of the cyst, a raised serum amylase level in cyst aspirate can confirm salivary origin.

Indications

1. Ranulas causing airway obstruction or compromise require immediate treatment with either incision and drainage or excision.

2. Recurrent ranula with infection

3. Partial obstruction of Wharton's duct with obstructive sialadenitis

4. Interference with speech and articulation

5. Asymptomatic patients who want to avoid progression to the above

6. Cosmesis

Contraindications

1. Patient with medical comorbidities precluding administration of general anesthesia

2. Active infection is considered a relative contraindication.

Preoperative Preparation

1. Evaluation by

   a. Head and neck surgeon

   b. Anesthesiology

      1) A coordinated effort is important to plan the management of the airway for large obstructing ranulas that may distort the anatomy or make for a difficult airway.

      2) If there is a concern, an awake fiberoptic oral or nasal intubation is preferred. Use of video laryngoscopes are also advocated for better visualization.

2. Discontinue antiplatelet drugs if possible 5 to 7 day prior to surgery.

3. Preoperative imaging

Operative Period

Anesthesia

- General anesthesia
  - Oral or nasal intubation
  - Muscle relaxation is recommended for better intraoral access.
- Local anesthesia can be considered for localized floor of mouth ranula in adults where simple marsupialization is being considered.

Positioning

- Supine
- Intraoral and extraoral betadine prep may be considered. We do not routinely prep the oral cavity.
- Mouth opening is facilitated by the use of dental props or mouth retractors.

Perioperative Antibiotic Prophylaxis

- Perioperative administration of antibiotics to cover oral flora is recommended; usually clindamycin.

Monitoring

- Routine anesthesia monitoring; nerve monitoring is not indicated in these procedures

Instruments and Equipment to Have Available

- Head and neck set
- Monopolar and bipolar electrocautery
- Intraoral retractors
  - Disposable plastic cheek retractors
  - Jennings retractors, Minnesota retractors, Dental props

- Salivary duct dilators and stent for cannulation of Wharton's duct
  - Marchal or Schaitkin Dilator Systems (Karl Storz, Germany)
  - Disposable dilator systems (Cook Medical, Bloomington, IN, USA)
  - Salivary duct stents
  - Salivary endoscopy set along with salivary endoscopes to perform a diagnostic or interventional sialendoscopy, if indicated or considered by surgeon (Karl Storz, Germany)

Key Anatomic Landmarks

- A comprehensive knowledge of the sublingual gland and the surrounding anatomy is essential in the successful treatment of ranulas. The sublingual gland is the smallest of the three major salivary glands and lies in the sublingual space. This potential space is bounded anterolaterally by the medial surface of the mandible, medially by genioglossus muscle, and posteriorly by the submandibular gland. The inferior boundary is the mylohyoid muscle, and the superior boundary is the mucosa of the floor of the mouth. Wharton's duct and the lingual nerve lie medial to the gland. The submandibular duct passes adjacent to the sublingual gland and, in its distal 10 to 15 mm, lies just deep to the mucosa of the floor of the mouth. In this position, the duct is liable to be injured during resection of the sublingual gland. Consequently, some surgeons routinely stent the submandibular duct prior to excision of the sublingual gland in an effort to protect it from injury. The lingual nerve must also be identified as its terminal branches pass beneath the sublingual gland and course below the submandibular duct to innervate the tongue.
- There are no posterior fascial limitations, allowing spread of ranulas into the submandibular and parapharyngeal spaces. In contrast to the parotid and submandibular glands, the sublingual gland lacks a surrounding capsule. Drainage of the gland into the floor of the mouth occurs through 8 to 20 small ducts of Rivinus. These ducts can also join together to form one major sublingual duct called the duct of Bartholin, which joins Wharton's duct.[5]

Prerequisite Skills

- Experience with salivary gland and salivary duct surgery

Operative Risks

- Risks of general anesthesia
- Bleeding
- Infection
- Recurrence of the lesion
- Injury to the lingual nerve: sensory loss to anterior two-thirds of the tongue, tongue numbness, or metallic taste in the mouth
- Submandibular duct injury/papillary stenosis: obstructive sialadenitis or salivary leakage subsequently requiring excision of the submandibular gland if not resolved
- Need for additional procedures

Surgical Techniques

- There are varying surgical procedures described to manage ranula. The most common ones include excision of the floor of the mouth cyst and marsupialization of the cyst to the floor of the mouth. This chapter will focus on the comprehensive technique that is associated with the lowest recurrence rate, that is, excision of the sublingual gland with excision or drainage of the floor of the mouth ranula or drainage of the plunging component of the ranula.
- General anesthesia with oral or nasal intubation is induced. Bite block and oral retractors are placed for adequate intraoral exposure.
- The submandibular papilla is identified and sequentially dilated. After appropriate dilation, the duct is cannulated with a salivary duct stent to assist with identification and preservation during the procedure. If the opening of the submandibular duct is abnormal and the duct cannot be cannulated easily, this step can be deferred. If expertise and instrumentation are available, a diagnostic endoscopy of the submandibular duct to ensure that there is no coincidental submandibular duct pathology is reasonable and will also allow

identification of the duct for cannulation or repair.

- A monopolar electrocautery with a fine tip is used to make an incision along the floor of the mouth lateral to the submandibular duct. In cases where the cyst is prominent, an elliptical excision of the mucosa of the floor of the mouth can be made to include the adherent portion of the cyst wall (Fig. 89.3).
- Dissection is carried in the plane between the sublingual gland and the submandibular duct, with the inferior limit being the mylohyoid and posterior limit being the submandibular gland.
- The lateral portion of the gland is dissected away from the surrounding tissue.
- Adequate hemostasis is key to prevent incomplete excision of the gland or damage to the lingual nerve and Wharton's duct. The submandibular duct runs in an anterior-superior direction from the submandibular gland to its papilla on the floor of mouth, and it makes contact with the medial surface of the sublingual gland.
- The lingual nerve is identified in association with the posterior portion of the sublingual gland, running lateral to medial and deep to the submandibular duct.
- In cases with a plunging component, the cervical pseudocyst can be drained transorally with probing through the mylohyoid muscle or bimanual palpation. Since the plunging ranula is a pseudocyst, merely draining the cyst will allow for the resolution of the cyst as long as the source of the saliva is removed, that is, the sublingual gland.

FIG. 89.3 The incision is outlined on the floor of the mouth. The entire sublingual gland must be excised with the cyst.

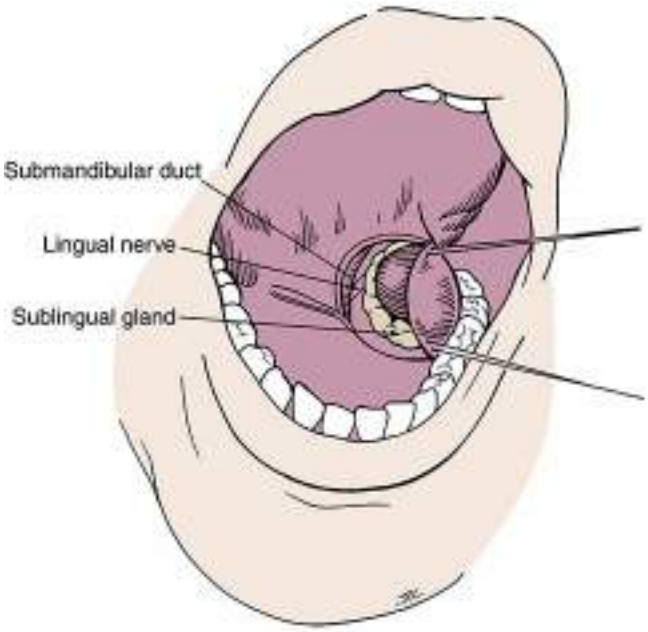

FIG. 89.4 If the submandibular duct has been interrupted, it should be marsupialized by suturing the edges of the

duct mucosa to the edges of the floor mouth mucosa or the wound, whichever is possible without adding excessive tension to the sutures. However, suturing the duct to the floor mouth mucosa is preferred.

- If the submandibular duct is damaged or interrupted, the posterior remnant of the duct is opened and marsupialized into the wound using absorbable sutures (Fig. 89.4).
- If the submandibular duct is intact, the incision in the floor of the mouth is then closed loosely with interrupted absorbable suture to allow drainage of any postoperative bleeding. The stent in the submandibular duct can be removed at the conclusion of the procedure. If there is a concern regarding the integrity of the submandibular duct, a diagnostic salivary duct endoscopy can be performed after removing the stent.

Common Errors in Technique

1. Failure to use imaging studies may lead to underestimating a plunging ranula.

2. Failure to remove the sublingual gland increases the recurrence rate.

3. Transcervical approaches may increase morbidity with little added benefit.

4. Failure to identify Wharton's duct and the lingual nerve will result in injury to these structures.

Postoperative Period

Postoperative Management

- Half-strength hydrogen peroxide or chlorhexidine rinse 15 mL tid, after meals, to keep the suture line clean
- In general, postoperative antibiotics are not necessary. However, if a salivary stent is left in place to manage a damaged submandibular duct, a course of postoperative antibiotics for 10 to 14 days is

recommended. The stent is usually left in place for 10 to 14 days and can be removed as an in-office procedure.

- In our institution, this procedure is scheduled as a same-day surgery procedure. However, overnight observation may be required if there is significant edema of the floor of the mouth with concern for airway compromise; in our experience this is a very rare occurrence.

Complications

- Recurrence
  - Rare with complete removal of the sublingual gland
  - Subsequent excisions significantly more difficult due to scarring in the floor of the mouth
- Hypoesthesia of the tongue
- Bleeding/hematoma
  - Hematoma requires evaluation and control of bleeding to avoid swelling of the floor of the mouth and potential airway compromise
- Postoperative infection
  - Incision and drainage, culture, antibiotics
- Injury to Wharton's duct
  - Marsupialization of the duct if identified intraoperatively
  - Sialocele or salivary fistula: aspiration and anticholinergics. If persistent, diagnostic salivary endoscopy and stent and/or Botox injection with ultrasound guidance. In recalcitrant cases, submandibular gland excision
  - Stricture or stenosis: sialendoscopy with dilation and stent placement, duct marsupialization, or excision of the submandibular gland

Alternative Management Plan

- Marsupialization can be performed under local anesthesia in patients unable to undergo general anesthesia; this is, however, associated with

higher recurrence rates.[2]

- Sclerotherapy with intracystic injection of OK-432 has been described as an alternative to surgery.[6]
- A case series reported three cases of simple ranula treated with injection of Botox into the ranula and sublingual gland. The proposed mechanism is denervation of parasympathetic nerve endings responsible for saliva production.[7]
- Low-dose radiation has also been described in the treatment of a case of a recurrent plunging ranula that failed initial surgical treatment.[8]

Discussion

Evidence-Based Medicine Question

Oral and plunging ranulas: What is the most effective treatment?[2]

The surgical treatment of ranulas, particularly plunging ranulas, has been controversial and has evolved over the years. Described approaches for oral ranulas include incision and drainage, marsupialization, excision, and sublingual gland excision. Others have described a transcervical excision and submandibular gland excision in the management of a plunging ranula.

More recent literature, however, has shown that even in the case of a plunging ranula, a transcervical approach to remove the ranula and submandibular gland is unwarranted and may place the marginal mandibular and hypoglossal nerves at unnecessary risk. A literature review performed by Patel et al. reported 864 patients who underwent various methods of treatment for oral and plunging ranulas, including incision and drainage, marsupialization, sclerotherapy, ranula excision, sublingual gland excision, submandibular gland excision, and transcervical ranula excision. They found that the treatment modality yielding the lowest recurrence and complication rates for both oral and plunging ranulas is removal of the ipsilateral sublingual gland with evacuation of the ranula. In cases of plunging ranula, complete removal of the pseudocyst wall is unnecessary. Transcervical excision may be required in cases where intraoral drainage was unsuccessful or if drain

placement is desired.[1]

Novel surgical and nonsurgical treatment modalities for ranula continue to be introduced. Lai et al. published a three-person case series and literature review describing carbon dioxide laser ablation for intraoral ranula. The laser in these cases was used to unroof the ranula and vaporize the walls and base of the lesion, all while maintaining excellent hemostasis and visualization. There were no documented recurrences or complications in this group.[9] Robot-assisted transoral management of ranula (oral and plunging) has also been described with favorable results.[10]

Editorial Comment

Ranulas can be very symptomatic due to recurrent infection, large size, or compressive effects. However, in most cases, they tend to be asymptomatic. Surgery must be tailored to the severity of the problem. Patients with a small asymptomatic ranula can be observed or benefit from minimally invasive intervention (aspiration, marsupialization), while patients with recurrent, symptomatic, or plunging ranula must be managed aggressively by excision of the sublingual gland. In relative terms, one could consider complications associated with ranula surgery (injury to the lingual nerve and submandibular duct) as minor since they are not life threatening. However, it must be remembered that these complications can cause significant morbidity and disturbances in quality of life for patients and should be carefully considered in surgical consent and decision making.

Review Questions

1. What CT finding is considered pathognomonic for plunging ranula?

a. Lyre sign

b. Thumb sign

c. **Tail sign**

d. Frog sign

e. Halo sign

2. Which is associated with the highest rate of recurrence of ranula?

a. Marsupialization

b. **Aspiration**

c. Sclerotherapy

d. Sublingual gland excision only

e. Ranula excision only

3. Which is not a complication of transoral ranula surgery?

a. Lingual nerve injury

b. **Hypoglossal nerve injury**

c. Recurrence

d. Submandibular duct injury

e. Hematoma

Mass in the Buccal Space

Phillip Huyett, and Eugene N. Myers

Introduction

A mass appearing within the substance of the cheek is unusual and suggests a tumor of the buccal space or the accessory lobe of the parotid gland. The buccal space, first described by Kostrubala in 1945, is a potential space between the buccinator muscle and the more superficial muscles of facial expression (Fig. 90.1).[1] There are a number of reports of buccal space masses, and many surgical approaches have been suggested in the literature.[1-9] Lesions in the buccal space are readily apparent because they are easily palpated just beneath the buccal mucosa or the skin of the cheek.

Most neoplasms in the buccal space are tumors of minor salivary gland origin. Benign tumors are most often pleomorphic adenoma, monomorphic adenoma, or Warthin tumor. Malignant tumors in the buccal space include adenocarcinoma; adenoid cystic, mucoepidermoid, acinic cell, anaplastic, and small cell carcinoma; carcinoma ex pleomorphic adenoma; polymorphous low-grade adenocarcinoma; and metastasis from other sites. Other less common primary tumors include fibroma, fibrosarcoma, lipoma, lymphoma, melanoma, nerve sheath tumor, and hemangioma. For tumors other than lipoma, biopsy is necessary because no clinical or radiographic criteria are reliable in establishing a histologic diagnosis.

Key Operative Learning Points

- Evaluate the patient with fine-needle aspiration biopsy and imaging before surgery to enhance planning for the surgical procedure and patient counseling.

- Evaluate the patient's needs regarding cosmetic appearance. The modified parotid incision leaves an unobtrusive but visible scar, so for a female patient, a rhytidectomy approach may be a better option, whereas the incision in a male patient is usually hidden in the beard line and is acceptable.
- Undermining in the plane between the subcutaneous tissue and the superficial musculoaponeurotic system (SMAS) protects the facial nerve.
- Identify the buccal and zygomatic branches of the facial nerve and dissect them off the mass.
- Retract the branches of the nerve away from the mass so that it may be excised without injury to the nerve.
- Closing the SMAS either primarily or with a flap will prevent an unsightly depression in the face.

Preoperative Period

History

History of Present Illness

- The typical history encountered in patients with a mass in the buccal space is that of a slowly growing, painless mass in the cheek (Fig. 90.2).
- If the mass is more deeply seated, it tends to lie more medial and the patient may be able to feel the intraoral mass with the tongue (Fig. 90.3).
- When the mass is located in the oral cavity, patients are often seen initially by their dentist or an oral maxillofacial surgeon.
- Constitutional symptoms suggest infection, an inflammatory condition, or lymphoid neoplasm.

Past Medical History

- History of previous salivary gland or other neoplasms
- Recent dental work or cervicofacial infections

- Recent injection of facial fillers for cosmetic purposes
- Serious comorbidities
- Social History
  - Use of alcohol and tobacco
- Medications
  - Many medications may increase the likelihood of sialolithiasis.
  - Use of anticoagulants

Physical Examination

- A complete examination of the head and neck is warranted, as with all masses in the head and neck.
- Particular attention should be given to examination of the skin for primary cutaneous malignancies and palpation for cervical metastases.

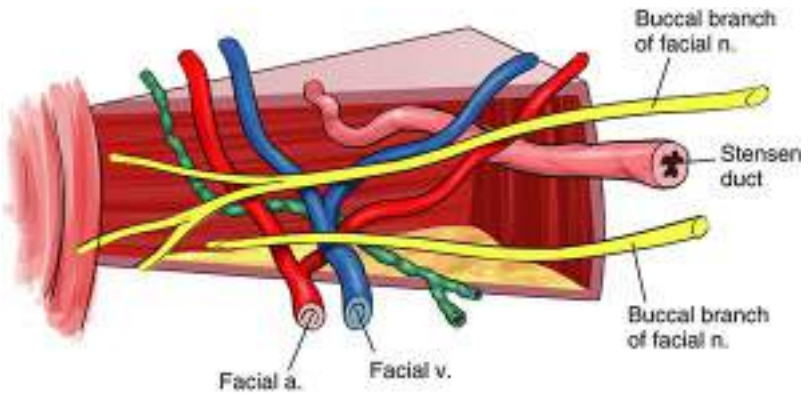

FIG. 90.1 The left buccal space and its contents.

- Inspection and bimanual examination usually reveals a mobile mass within the substance of the cheek that can be seen in the oral cavity (see Fig. 90.3).
- Although facial nerve deficits are uncommon given the rich distal cross-innervation, attention to the facial nerve function is mandatory.
- Basic determination of the patency of Stensen duct can be achieved by visualizing the duct orifice while milking or massaging the parotid

gland from posterior to anterior.

FIG. 90.2 Preoperative frontal view illustrating a mass in the cheek.

Imaging/Diagnostics

- Kurabayashi et al. evaluated the computed tomography (CT) features of masses in the buccal space in 53 patients (33 benign tumors, 11 malignancies, 9 non-neoplastic lesions) and concluded that CT was useful in demonstrating the presence and location of masses in the buccal space.[7] CT can sometimes assist in the differential diagnosis but the value of CT in differentiating benign from malignant lesions in the buccal space is limited.
- Tumors of the buccal space were found adjacent to the outer surface of the buccinator muscle in contrast to epidermoid cysts and tumors of the accessory lobe of the parotid gland, which were completely separate from it.
- Tumors of the accessory lobe of the parotid gland, epidermoid cysts,

lipomas, and lymphoma could be differentiated from other lesions.

- Hemangiomas were characterized by multiple masses and the presence of phleboliths.
- Kurabayashi et al. also studied 30 patients with benign and malignant lesions in the buccal space with magnetic resonance imaging (MRI).[6] MRI was useful in demonstrating the extent of lesions in the buccal space, but similar to CT its diagnostic value in predicting malignancy was very limited (Fig. 90.4). This was especially true for malignant tumors of minor salivary gland origin, which were typically seen as well-defined masses without infiltration into surrounding structures on MRI.
- Ultrasound may be helpful in characterizing the lesion (size, echogenicity, flow, calcifications) or in assisting fine-needle aspiration biopsy.
- Fine-needle aspiration biopsy is most helpful in determining the need for surgery rather than providing a definitive diagnosis.
- Definitive diagnosis of a mass in the buccal space is made by excision of the mass and histopathologic evaluation.
- Incisional biopsy is never appropriate, as the risks of facial nerve injury and tumor spillage are increased and postbiopsy changes may make the definitive surgery more complex.
- The differential diagnosis of a mass in the buccal space includes lesions originating from each of the tissue components in the space. Table 90.1 lists the lesions that have been found in the buccal space.

FIG. 90.3 **(A)** External view of a right buccal space mass. **(B)** Internal view. Note the intraoral bulge produced by the mass.

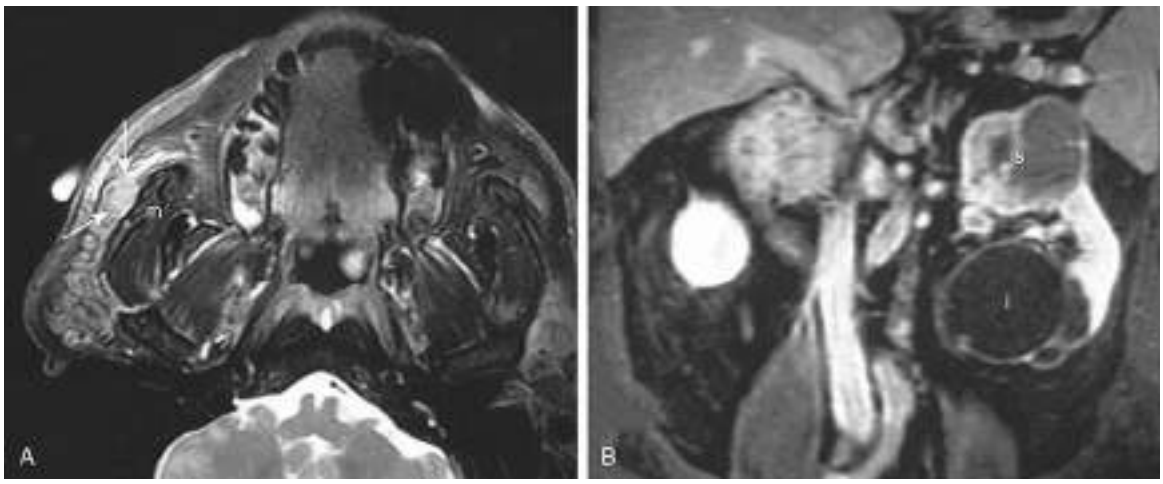

FIG. 90.4 **(A)** T2-weighted axial MRI through the parotid gland demonstrating a round 10-mm mass *(arrows)* overlying the masseter muscle *(m)*. The mass has a signal intensity slightly higher than the adjacent gland but not high enough to be definitive for pleomorphic adenoma. It proved to be renal cell carcinoma metastatic to the accessory lobe. **(B)** Sagittal post-contrast-enhanced spoiled-gradient MRI of the abdomen with T1

weighting shows two distinct masses in the left kidney. The superior mass *(s)* has cystic and solid components. The inferior mass *(i)* is predominantly cystic and has extensive septations. This renal cell carcinoma was the primary tumor.

TABLE 90.1

Reported Lesions in the Buccal Space

Connective

Angioleiomyoma

Extraskeletal mesenchymal chondrosarcoma

Fibroma, fibrosarcoma, solitary fibrous tumor

Fibromatosis

Lipoma, liposarcoma

Nodular fasciitis

Rhabdomyosarcoma

Spindle cell lipoma

Glandular

Accessory parotid or aberrant salivary gland tumors

Acinic cell carcinoma

Adenoid cystic carcinoma[6]

Carcinoma ex pleomorphic adenoma

Chronic sialadenitis

Minor salivary gland calculus

Mucoepidermoid carcinoma (low and high grades)

Oncocytoma

Papillary cystadenoma lymphomatosum

Parotid duct tumor or calculus

Pleomorphic adenoma

Polymorphous low-grade adenocarcinoma

Sebaceous adenoma

Tuberculous granuloma and adenoid cystic carcinoma manifested as a single buccal space mass

Inflammatory

Abscess formation

Aspergilloma

Sarcoidosis

Lymphatic

Benign reactive lymph node

Calcified lymph node

Lymphangioma

Lymphoma

Lymphosarcoma

Metastasis to lymph node

Muscular

Masseteric hypertrophy

Myositis ossificans

Neural

Neurofibroma

Neuroma

Other

Facial fillers and injectables

Lymphoepithelial cyst

Metastatic carcinoma (skin, sinus, renal cell, lung, buccal mucosa)

Migrated molar

Vascular

False aneurysm

Hemangioendothelioma

Hemangioma

Hemangiopericytoma

Hyalinized thrombus

Indications

- Excisional biopsy is indicated in patients whose preoperative examination suggests a neoplastic condition.
- Undesired cosmetic appearance of the mass

Contraindications

- Patients who are not healthy enough to tolerate or benefit from excision of the mass

Preoperative Preparation

- Several surgical approaches to the buccal space have been described.
- The approach used most commonly is a direct transmucosal intraoral incision with dissection and removal of the mass. This approach is appealing, because the bulging of the mass into the intraoral area lends itself to easy excision and eliminates a skin incision with its inevitable scar (see Fig. 90.3).

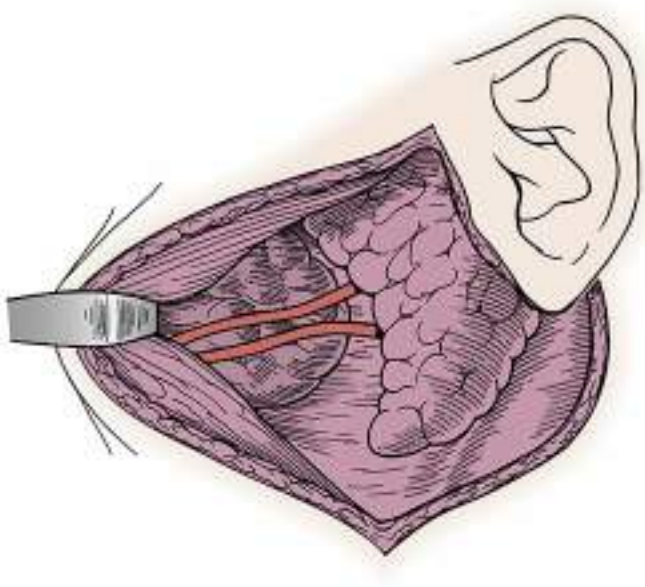

FIG. 90.5 Surgical exposure of a mass in the buccal space demonstrating the branches of the facial nerve adherent to the lateral aspect of the mass.

- Despite this apparent advantage, the intraoral approach may not provide adequate exposure. While removing these masses through the external approach, we have observed that the buccal branches of the facial nerve are always closely associated with or actually incorporated into the capsule on the *lateral* aspect of the mass, which cannot be well visualized through the intraoral approach (Fig. 90.5). Stensen duct is also closely associated with these tumors. Without proper exposure, these vital structures are at risk for injury, which could produce facial paralysis and sialocele.
- The direct transcutaneous approach is appealing because of the advantage of requiring less time and dissection and no need to raise skin flaps, thereby avoiding the possibility of flap necrosis. We do not recommend this approach because of the highly visible scar and the risk to branches of the facial nerve and Stensen duct. This approach also makes it difficult to use local tissue to fill in the depressed area left after removal of the mass.
- An extended parotid-submandibular incision (Fig. 90.6) for removal of a mass in the buccal space is used in our department because it provides excellent exposure and minimizes the risk of complications such as injury to Stensen duct or the facial nerve during excision of

these tumors.[4,5] This technique also provides an excellent cosmetic result.

- The rhytidectomy approach that Madorsky and Allison described can be used for removal of a mass in the buccal space and offers a superior cosmetic result.[8]

Operative Period

Anesthesia

- General anesthesia
- Oral intubation with the endotracheal tube secured to the contralateral side
- FiO_2 less than 30% if electrocautery is to be used in order to avoid an airway fire

Positioning

- For rhytidectomy and extended parotid-submandibular approach, a shoulder roll with the head rotated contralaterally will facilitate better exposure.

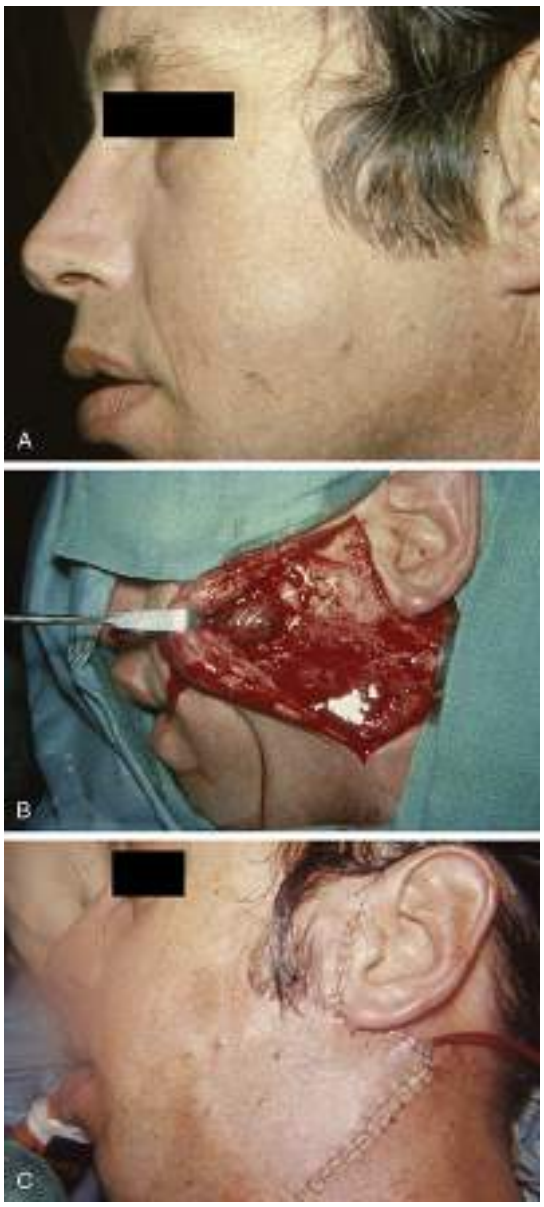

FIG. 90.6 **(A)** Lateral view of a mass in the buccal space. **(B)** Surgical exposure of the mass. **(C)** Surgical closure over suction drains.

- The hemi-face should be prepped and draped in the field for observation of facial nerve stimulation.

Perioperative Antibiotic Prophylaxis

- Not required with external approaches

Monitoring

- No routine monitoring is required, and facial nerve monitoring is optional.

Instruments and Equipment

- Standard head and neck set
- Handheld nerve stimulator, vessel loops

Key Anatomic Landmarks

- Understanding the three-dimensional anatomy of the buccal space is necessary for proper management.[4,5]
- Medial wall: Buccinator muscle and its overlying fascia, which extends from the mandibular body inferiorly to the maxilla superiorly, orbicularis oris anteriorly, and pterygomandibular raphe posteriorly (see Fig. 90.1)
- Lateral wall: Muscles of facial expression (risorius, zygomaticus major, and levator labii superioris) and their fascia. More superficial to these muscles lie the superficial fascia and skin.
- Anterior border: The orbicularis oris muscle
- Posterior border: Anterior border of the masseter muscle and parotid gland
- Superior and inferior limits: Fascial attachments of the muscles of facial expression to the zygomatic arch and mandibular periosteum
- Anatomic structures found in the buccal space include Stensen duct, the facial artery and vein, lymphatic channels, minor salivary glands, accessory parotid lobules, and most laterally, the buccal branches of the facial nerve (see Figs. 90.1 and 90.5). These nerve branches enter the medial surface of the muscles of facial expression, except the buccinator, which is innervated from its lateral aspect.
- The majority of the buccal space is filled with adipose tissue, referred to as the buccal fat pad, and lymph nodes.
- The accessory lobe of the parotid gland is an island of salivary gland

tissue found anterior to and separate from the main parotid gland. It is present in approximately 21% to 56% of the population.

- The accessory lobe is generally 0.5 to 2.5 cm in size and is separated from the main parotid gland by an average of 6 mm. This is in contradistinction to the anterior facial process of the parotid gland, which is an anterior extension of the main gland.
- The accessory lobe of the parotid gland is usually located along Stensen duct, and the lobe drains through one or more ducts into Stensen duct. This position makes it intimately related to the buccal and zygomatic branches of the facial nerve.
- Neoplasms of the accessory lobe of the parotid gland are more often malignant than the parotid gland proper (50%) and are predominantly of salivary gland origin with few case reports of metastatic cancers to this area. One to seven percent of all parotid neoplasms arise within the accessory lobe of the parotid gland, depending on inclusion criteria.

Prerequisite Skills

- Parotidectomy (Chapter 115) and rhytidectomy techniques (Chapter 168)

Operative Risks

- Patients are counseled that the buccal branch of the facial nerve will be dissected and elevated off the tumor and is therefore vulnerable to intraoperative injury and postoperative weakness as a result of dissection and stretching of the nerve. Permanent facial nerve paralysis is possible but unlikely.
- Other risks include facial paresthesias, injury to the parotid duct, undesirable scars, hematoma, and infection.

Surgical Technique

Extended Parotid-Submandibular Incision

- The incision is a modification of the standard parotidectomy incision (see Fig. 90.6). Extension of the preauricular incision somewhat superiorly and extension of the cervical incision into a submandibular space skin crease allows for wide undermining of the flap, which is necessary to gain exposure anterior to the parotid gland for visualization of the mass.
- It is not necessary to carry out a formal parotidectomy or to identify the facial nerve at the stylomastoid foramen, because the mass is anterior to the anterior border of the parotid gland and therefore only the buccal branches of the nerve are anatomically associated with these masses.
- The skin flap is elevated anterior to the anterior border of the parotid gland where the mass will be encountered. Further elevation of the flap provides exposure of the entire mass. The SMAS is divided over the mass.
- Care must be taken when undermining the superior aspect of the flap because the zygomatic branch of the upper division of the facial nerve is superficial in this area and the branch could be injured with resultant facial nerve paralysis.
- The buccal branches of the facial nerve and Stenson duct are easily identified, usually during blunt dissection of the mass, and confirmed using a facial nerve stimulator (Figs. 90.5 and 90.6).
- Dissection of the branches of the nerves somewhat anterior and posterior to the mass itself will allow undermining and mobilization of the nerve. A small nerve retractor is then used to retract the branches of the nerve away from the mass. Once dissected, the nerves may be marked with arterial loops.
- The mass itself is then removed by sharp and blunt dissection. After the mass is removed, the nerves are returned to their normal anatomic position.
- Removal of the mass leaves a noticeable defect in the facial contour that is eliminated by approximating the SMAS.
- Hemostasis is obtained, the wound is irrigated, and a Hemovac drain is inserted under the skin flap and brought out through a separate stab wound posterior to the incision.

- The skin incision is closed with subcutaneous 4-0 Vicryl or equivalent and then a running closure with 5-0 or 6-0 fast-absorbing plain gut suture.
- Steri-Strips and a pressure dressing are applied.

Rhytidectomy Approach

- In 1976, Mitz and Peyronie described the rhytidectomy approach and how this technique allows reconstruction of the contour defect associated with tumor extirpation by SMAS interposition.[9] They used this technique in five patients: two tumors of the accessory lobe of the parotid gland, one cyst in the parotid gland, one case of nodular fasciitis of the anterior masseter muscle, and one lymphoma.
- The incision begins at the temple and continues in a preauricular crease and then post-tragal. The incision is carried inferior to the earlobe, up to the level of the posterior auricular muscle posteriorly, and posteriorly into the hairline.
- The skin is undermined anterior to the mass, mobilized, and retracted away from the mass. The mass is then excised as described earlier.
- After removal of the mass, the SMAS is closed directly to give sufficient support to the cheek to avoid deformity.
- Rotation of a flap of SMAS has been recommended for defects that are too large for direct closure or advancement closure. This technique distributes the volume defect over a wider area and converts the depression to a gradual transition that is less noticeable.
- Madorsky and Allison relied on their extensive experience with the rhytidectomy approach in managing 126 patients who had a tumor of the parotid gland and adjacent structures.[8] They described the relationship of the SMAS as being superficial to the facial nerve. If too much tension is placed by direct SMAS closure, the SMAS is mobilized by dissecting the facial nerve branches underlying it and advancing it for closure.
- Closure and wound care are implemented as described previously.

Common Errors in Technique

- Failure to select the proper incision based on the patient's perceived needs can leave undesired visible scars.
- Failure to identify and preserve the important structures contained in the buccal space, especially the facial nerve and Stensen duct, can lead to complications.
- Failure to close the SMAS properly will result in an unsightly depression in the cheek.

Postoperative Period

Postoperative Management

- The patient is allowed to recover from anesthesia and is admitted overnight if a drain is left in place.
- Within 24 hours, the drainage has usually stopped, the pressure dressing and drain are removed, and the patient is discharged.

Complications

- Complications are minimized with the extended parotidectomy-submandibular and rhytidectomy approaches because of the superior exposure.
- The need to identify the branches of the facial nerve is the fundamental advantage over the transcutaneous approach.
- The general principles of surgery are never better demonstrated than in this procedure, which includes (1) adequate exposure, (2) potential to extend the surgery if necessary, (3) complete excision of the mass, and (4) an acceptable cosmetic result.

Alternative Management Plan

- Antibiotics and observation for infectious processes

- Observation if the patient declines surgery

Editorial Comment

The experience of caring for a patient who had a mass previously removed through an incision in the buccal mucosa during which an injury to the facial nerve was sustained and a sialocele developed in the buccal space because of inadvertent injury to Stensens duct provided the incentive to design the extended parotid-submandibular incision.

The outcomes of using this technique are invariably positive. Using these techniques that provide excellent exposure enables complete removal of the mass. Complications are rare and the prognosis is good since most of these masses are benign.

Excision of the Submandibular Gland

Rebecca E. Fraioli

Introduction

The submandibular gland is one of three paired major salivary glands that drains into the oral cavity. It is midway in size and location between the largest, the parotid gland, and the smallest, the sublingual gland. Histologically, it consists of both serous and mucinous acini, which collectively drain into an excretory duct that carries the secreted saliva into the oral cavity.

The gland is located within the submandibular triangle, superior and lateral to the hyoid bone and digastric sling, and inferior to the mandible. Its excretory duct, known as Wharton's duct, passes deep to the mylohyoid muscle, paralleling the course of the lingual nerve. The duct and nerve lie immediately adjacent to the sublingual gland, just deep to the mucosa of the floor of the mouth. The duct opens through the sublingual papilla adjacent to the lingual frenulum (Fig. 91.1). The narrowest point in the duct is at its orifice; therefore calculi that form in the gland may become impacted at the orifice and be visible or palpable in the floor of the mouth. Eighty percent of all salivary calculi are found in the Wharton's duct. This is likely due to both the horizontal path of and the higher concentration of mucin in the Wharton's duct. Impacted calculi that obstruct salivary outflow will result in enlargement of the gland, stasis of secretions, and ultimately inflammation of the gland (sialadenitis).

With age, the submandibular glands tend to become ptotic and assume a more inferior position, often even prolapsing lateral to the greater cornu of the hyoid bone. In this ptotic position, the gland may be mistaken for a neoplastic mass and lead to referral for further evaluation.

Key Operative Learning Points

- The marginal mandibular branch of the facial nerve lies within the operative field and must be either identified or avoided, depending on the situation.
- It is important to recognize that when a shoulder roll is placed and the patient's head is rotated to the contralateral side, the marginal mandibular nerve is found more inferiorly and may lie directly over the gland.

FIG. 91.1 The opening of the Wharton's duct *(arrow)* adjacent to the frenulum of the tongue.

- When excision of the gland is being performed for benign disease, identification of the nerve may not be necessary. In such cases the nerve may be protected by ligation and elevation of the facial vein (Hayes-Martin maneuver; Fig. 91.2).
- When the gland is removed for malignancy or in conjunction with a neck dissection, the marginal mandibular nerve must be identified to allow the removal of the prevascular and postvascular nodes. Identification of the nerve will help to avoid injury of the nerve posterior to the gland, where the nerve may often be located a significant distance inferior to the level of the mandible.
- In cases in which there is extensive inflammation and scar tissue, a handheld nerve stimulator may be useful to help to locate and

preserve the marginal mandibular nerve.

- The proximal stump of the facial artery should be double-ligated and the wound examined for bleeding vessels before closure.
- Care must be taken in patients who have had significant infection and scarring to ensure identification of the lingual nerve before sectioning Wharton's duct.
- Care should be taken after the gland is freed posteriorly to visualize the hypoglossal nerve as it courses deep to the vessels, parallel to the submandibular duct. If inflammation hinders identification of the nerve, it is advisable to find the nerve inferior to the posterior belly of the digastric muscle and follow it in a posterior-to-anterior direction through the submandibular triangle to avoid injury.

Preoperative Period

History

- History of present illness
  - Patients with sialadenitis often present with unilateral erythema, edema, and pain in the submental region that worsens with eating. Patients may also report foul-tasting (purulent) saliva, particularly when pressure is applied to the affected gland.

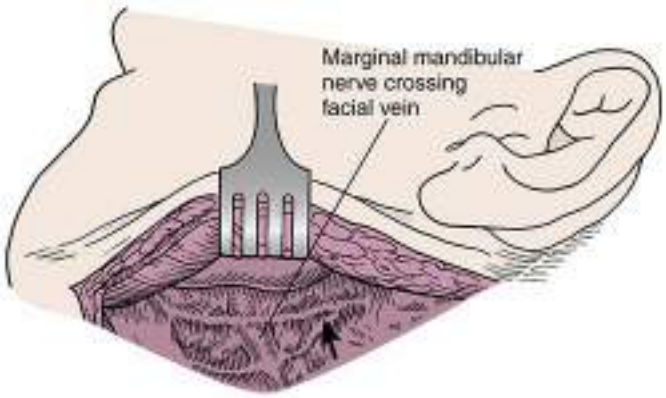

FIG. 91.2 Exposure of the submandibular gland by elevating the platysmal muscle with the skin flap. Note the position of the

marginal mandibular nerve *(arrow)*.

- Patients may present with a mass in the submandibular area.
- Neoplasms of the submandibular gland are not common and are more likely to be benign than malignant, but the finding of a mass in the submandibular gland merits further investigation to rule out malignancy.
- Signs or symptoms of nerve invasion, such as weakness of the tongue or lower lip or numbness of the tongue, suggest malignancy.
- Patients presenting for excision of the submandibular gland for chronic sialorrhea must be evaluated for duration and severity of the drooling, as well as for the underlying cause of the sialorrhea and its likelihood of improvement.

- Past medical history
  - Medical history
    - Collagen vascular disease such as Sjögren's syndrome (or its symptoms)
    - Prior radiation to the neck or treatment with I^{131} increases the risk of sialadenitis and of salivary neoplasm.
  - Surgical history
    - Prior attempts at drainage, biopsy, or surgical removal of salivary calculi
    - History of other neck surgery
  - Social history
    - Occupational exposure to silica dust or nitrosamines is linked to an increased risk of cancer of the salivary glands.
    - Use of tobacco and alcohol
- Medications
    - Antiplatelet drugs and anticoagulants
    - Use of supplements that may predispose to bleeding

Physical Examination

- Complete examination of the head and neck should be performed. Lymphadenopathy in the neck must trigger a full evaluation for suspected malignancy. Approximately one-quarter of cancers of the submandibular gland will have regional neck metastases.[1]
- Visual examination and palpation of the floor of mouth may reveal a calculus in the distal Wharton's duct.
- Bimanual palpation of the submandibular gland allows for evaluation of the size of the gland, presence of a discrete mass or calculus, tenderness of the gland to palpation, and degree of fixation of the gland to surrounding structures.
- The quality of the expressed saliva on each side should be evaluated and compared. Cloudy or purulent saliva suggests sialadenitis. The absence of salivary flow in the presence of an enlarged gland suggests obstruction of the outflow tract.
- A careful neurologic examination of the head and neck must be performed. Weakness of the tongue ipsilateral to the involved gland may be a sign of tumor or perineural invasion along the hypoglossal nerve. Likewise, numbness of the ipsilateral tongue may represent involvement of the lingual nerve. Facial weakness involving the ipsilateral lower lip is worrisome for malignant invasion of the marginal mandibular branch of the facial nerve.

Imaging/Diagnostics

- Ultrasound is useful for visualization of salivary calculi and for localization of a mass within the submandibular gland for fine-needle aspiration (FNA). Ultrasound can also show a dilated ductal system in cases of chronic sialadenitis.
- Computed tomography (CT) is most sensitive for identifying a calcified salivary duct calculus and should be ordered for patients presenting with acute or recurrent swelling of the gland with postprandial pain.
- Contrast is not indicated for sialolithiasis but should be used if neoplasm or severe infection with abscess is in the differential diagnosis.
- CT with intravenous (IV) contrast is the most useful modality in a

known or suspected malignancy if there is suspicion of bone involvement or destruction.

- Magnetic resonance imaging (MRI) with IV gadolinium contrast is the imaging modality of choice for a suspected neoplasm of the submandibular gland. MRI is able to clearly delineate the neoplasm from the surrounding gland and can demonstrate invasion into nearby structures. In addition, MRI is the best modality for identifying evidence of perineural spread of tumor, which is especially important if adenoid cystic carcinoma is suspected.
- Sialography may reveal narrowing of the duct from scarring with secondary ductal ectasia within the hilum and the gland itself. However, sialography is contraindicated in an acutely infected gland, and MRI sialography has now essentially replaced this procedure.
- FNA is an important element in the diagnostic evaluation for suspected neoplasms of the salivary gland. However, a negative FNA is not definitive, and excision of the gland should still be performed for definitive diagnosis.

Indications

- Neoplasm or suspected neoplasm is an indication for excision of the submandibular gland. If FNA is nondiagnostic and the mass is confined to the gland, excision of the gland can be performed for diagnosis. For a known malignancy, more extensive excision including lymph node dissection is indicated.
- Sialolithiasis with subsequent duct obstruction and sialadenitis was formerly a common indication for excision of the submandibular gland. With the advent of sialoendoscopy, excision of the gland for this indication is now rare.
- In patients with dilated ectatic ducts and chronic infection, excision of the gland may still be necessary for chronic sialadenitis.
- Chronic sialorrhea in patients with neuromuscular swallowing disorders may be treated with submandibular gland excision. In such cases, this procedure is performed bilaterally and in combination with ligation of Stensen's duct.

Contraindications

- Excision of the submandibular gland should be avoided in cases of acute infection due to loss of tissue planes and subsequent difficulty in identifying key structures. In fulminant cases in which abscess and elevation of the floor of mouth occur, incision and drainage, possibly even requiring tracheotomy, may be necessary; however, definitive gland excision can often be delayed until the acute inflammation has passed.
- Although not a contraindication, obstruction of the duct due to calculus, chronic sialadenitis, prior radiation, or Sjögren's syndrome can sometimes be managed with sialoendoscopy. Minimally invasive procedures should be considered prior to proceeding with excision of the gland.

Preoperative Preparation

- FNA results and imaging should be reviewed preoperatively in patients with a mass in the submandibular gland.
- Anticoagulant/antiplatelet medications should be discontinued if possible.
- Several approaches to excision of the submandibular gland have been described, and the choice of approach should be made before surgery.
- The lateral transcervical approach is the traditional approach to excision of the submandibular gland and remains the most commonly used approach despite the description of newer approaches in recent years.[2]
- The intraoral approach is designed to avoid visible scarring from the cervical incision and injury to the marginal mandibular nerve, which is the most frequently injured nerve in the traditional transcervical approach. Branches of the facial nerve are not at risk with the intraoral approach and are not identified during this dissection.[3,4]
- Pitfalls of the intraoral approach stem from significant retraction of the floor of the mouth, including the lingual nerve and mylohyoid muscle. In one study, temporary injury to the lingual nerve was observed in

81% of patients, and 68% reported a temporary decrease in tongue mobility that resolved within 2 weeks of surgery and was attributed to edema of the floor of the mouth rather than injury to the hypoglossal nerve.[3]

Operative Period

Anesthesia

- General anesthesia is preferred; however, excision of the submandibular gland may be performed under local anesthesia in patients who are poor candidates for general anesthesia as long as the gland does not have findings suspicious for malignancy.[5]
- Paralysis should be avoided to aid in identification of the marginal mandibular and hypoglossal nerves, especially in cases with suspected malignancy or a history of recurrent infection.

Positioning

- For the transcervical approach, placement of a shoulder roll is used to extend the neck and provide better exposure of the submandibular triangle. The patient is then positioned with the head elevated slightly and rotated toward the opposite side.
- Orotracheal intubation is performed for the transcervical approach, and the tube is taped to the side contralateral to the surgical site.
- Nasotracheal intubation is necessary for the intraoral approach.

Perioperative Antibiotic Prophylaxis

- Antibiotic prophylaxis is not required when using the transcervical approach because this is a clean procedure according to the Centers for Disease Control and Prevention (CDC) surgical site infection guidelines.
- Transoral excision is a clean-contaminated procedure, and a 24-hour course of prophylactic antibiotics covering oral flora is recommended.

Monitoring

- Nerve monitoring is not routinely performed during excision of the submandibular gland.
- Handheld nerve monitoring without the use of IV paralytics may be useful in cases of suspected malignancy or severe chronic infection where surgical planes may be lost.

Instruments and Equipment to Have Available

- Head and neck surgical set
- Bipolar electrocautery
- Handheld nerve monitor

Key Anatomic Landmarks

- The facial vein will be identified on the lateral surface of the submandibular gland. Ligation and elevation of this vein will help to preserve the marginal mandibular nerve (Hayes-Martin maneuver) (see Fig. 91.2) in cases in which the adjacent prevascular and postvascular nodes do not require dissection.
- The anterior belly of the digastric muscle should be identified and reflected posteriorly to expose the mylohyoid muscle.
- The mylohyoid muscle is an important landmark in that the lingual nerve and Wharton's duct, as well as the sublingual gland and the anterior portion of the submandibular gland, lie immediately deep to it.
- The posterior belly of the digastric muscle may be used to help identify the hypoglossal nerve in cases in which inflammation makes identification of the nerve difficult. The hypoglossal nerve may be found inferior to the posterior belly of the digastric muscle and then can be followed in a posterior-to-anterior direction through the submandibular triangle.

Prerequisite Skills

General surgical skills and an intimate knowledge of the anatomy of the head and neck

Operative Risks

- Injury to the marginal mandibular nerve
- Injury to the hypoglossal nerve
- Injury to the lingual nerve
- Retained calculus with possible obstruction and infection
- Hemorrhage from the facial artery with possible hematoma and elevation of the floor of mouth
- Wound infection
- Fistula formation
- Unsightly scar
- Xerostomia

Surgical Technique

Transcervical Approach

- The incision is made at the inferior margin of the submandibular gland in a natural skin crease, usually slightly above the level of the hyoid bone.
- Localization of a smaller submandibular gland can be simplified by placing a gloved finger in the mouth and depressing the floor of the mouth on the affected side.
- The incision is carried through skin, subcutaneous tissue, and platysma muscle. Once through the platysma muscle, the nerve is at risk, and dissection should first be directed toward the inferior portion of the submandibular gland.

- After exposure of the submandibular gland, the fascia overlying the gland is incised and the superior flap of fascia is elevated from the lateral surface of the gland. As this is performed, the facial vein is encountered. Ligation and elevation of this vein will help preserve the marginal mandibular nerve (see Fig. 91.2).
- If the gland is excised as a part of a neck dissection or if the gland is being excised for possible malignancy, the nerve must be dissected free of the underlying vein and adjacent prevascular and postvascular nodes (Fig. 91.3), which should be removed.
- When the superior aspect of the gland has been encountered, blunt dissection is used to free it from the surrounding soft tissue. The marginal mandibular nerve will be preserved if dissection is maintained directly on the gland and deep to the fascia.

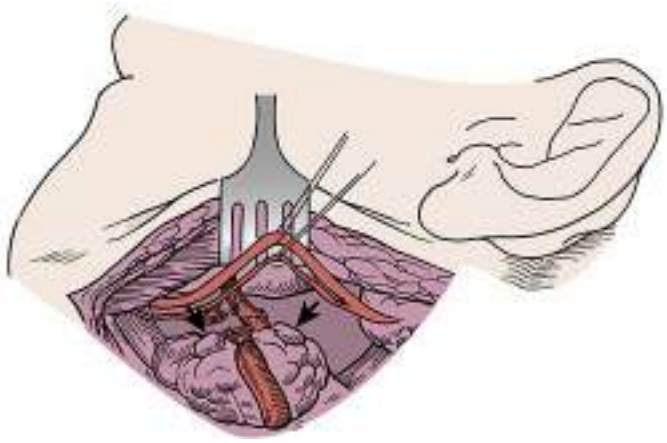

FIG. 91.3 Elevation of the marginal mandibular nerve can be done by dividing the facial vein low on the gland and elevating the nerve along with the vein. Note the prevascular and postvascular lymph nodes *(arrows)*.

- If the gland has been chronically inflamed and is adherent to surrounding soft tissue, it is often necessary to identify the nerve. Magnification and a handheld facial nerve monitor may be helpful.
- After the entire flap has been elevated off the lateral aspect of the gland, the anterior portion of the gland is freed from soft tissue at the level of the anterior belly of the digastric muscle. This is best done by incising the fascia over the anterior belly of the digastric muscle and

reflecting it posteriorly.

- As this reflection occurs, the mylohyoid muscle is encountered. The muscle can be identified by the direction of its fibers extending from posterosuperior to anteroinferior (at a significantly different angle from that of the anterior belly of the digastric muscle).
- The dissection is carried posterior to the edge of the mylohyoid muscle. The mylohyoid muscle is occasionally difficult to identify, especially with chronically infected glands adherent to the muscle. This muscle may also be dehiscent in areas and lead to difficulty identifying its posterior aspect.
- Several perforating vessels, as well as its motor nerve, enter the mylohyoid muscle. The vessels are usually sacrificed to free the overlying portion of the submandibular gland.
- A small right-angled retractor can be used to retract the muscle anteriorly off of the deep portion of the gland (Fig. 91.4).
- The anterior portion of the gland, the duct with the closely adherent sublingual gland, and the lingual nerve will be encountered immediately deep to the mylohyoid muscle. The lingual nerve can be seen superiorly as a broad band extending from deep to the mandible posteriorly and looping close to the anterior portion of the gland, where it gives rise to nerve roots extending into the submandibular ganglion.
- The lingual nerve ascends superiorly as it extends anteriorly to innervate the anterior aspect of the tongue and floor of the mouth. This nerve must be carefully dissected free and the rootlets incised.
- Every effort should be made to identify and preserve the lingual nerve because injury will result in loss of sensation of the lateral aspect of the oral tongue.
- After the nerve has been identified and the rootlets incised, the duct can usually be identified in the fascia superficial to the floor of the submandibular triangle. A large vein generally accompanies the duct and should be ligated separately.
- The hypoglossal nerve can then be identified extending along the floor of the triangle, where it emerges from deep to the posterior belly of the

digastric muscle. Care must be taken to avoid injury to the hypoglossal nerve. Injury is unusual unless previous inflammation has made it difficult to identify the plane deep to the gland.

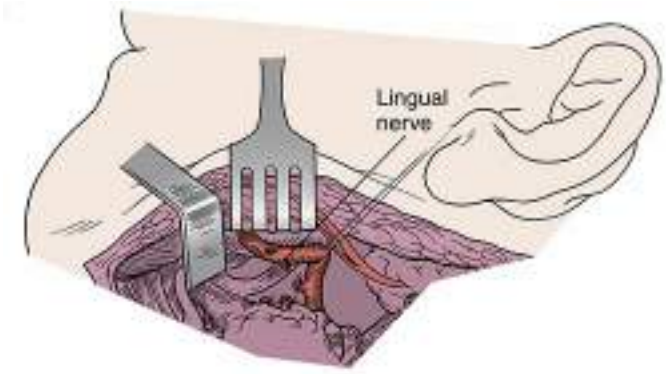

FIG. 91.4 The posterior edge of the mylohyoid muscle is exposed and then retracted anteriorly to expose the Wharton's duct and the lingual nerve.

- After the hypoglossal nerve has been identified, the duct can be divided (Fig. 91.5). Care must be taken to include dissection of the duct up to the mucosa of the floor of the mouth; otherwise, calculi can be retained in the duct and result in postoperative chronic inflammatory disease of the duct remnant. Bimanual palpation at this stage often helps prevent retained calculi in the duct.
- A salivary scope can be placed into the duct through the neck in a retrograde fashion if there is concern regarding retained calculi.
- When the anterior portion of the gland has been freed from the lingual nerve and submandibular duct, the remainder of the gland is easily detached from the underlying fascial planes over the floor of the submandibular triangle. The gland can then be retracted inferiorly with countertraction placed on the soft tissue superior to the gland, and the superior aspect of the gland is dissected free from the soft tissue just inferior to the mandible.
- Care must be taken to avoid injury to the marginal mandibular nerve where it courses just lateral and superior to the gland. Injury is avoided by either identifying the nerve or by maintaining dissection within a plane immediately adjacent to the substance of the gland. The

latter technique may be difficult in a severely inflamed gland.

- As the gland is reflected inferiorly, the facial artery can be seen indenting the posterosuperior surface of the gland. It is usually divided as it leaves the gland superiorly and then again as it enters the gland, although it can be preserved in noninflamed cases by dissecting the artery free of the gland and individually identifying, dividing, and ligating the feeding vessels extending into the substance of the gland.
- When the gland has been freed from the artery, the gland is removed.
- The submandibular triangle should be examined for vessels that require ligation. Particular care should be taken to examine the anterior portion of the triangle deep to the mylohyoid muscle.
- The wound is irrigated, a suction drain is inserted, and the wound is closed. The platysma muscle, subcutaneous layer, and skin should each be closed separately.

Intraoral Approach

- Following nasotracheal intubation, lidocaine with epinephrine (1:100,000) is injected into the mucosa for hemostasis.

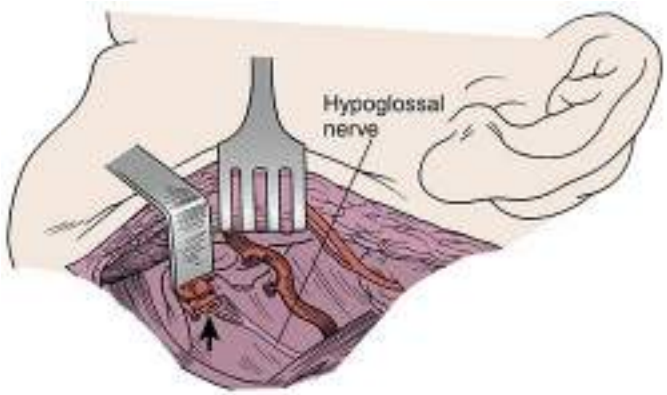

FIG. 91.5 The branches of the lingual nerve passing to the submandibular ganglion are divided to free the nerve from the specimen. The Wharton's duct is divided *(arrow)*, and the specimen is removed. Care must be taken to ensure that there are no calculi distal in the duct, or postoperative infection in the duct remnant may

result.

- A probe is inserted into Wharton's papilla, and an intraoral incision is made through the mucosa of the floor of the mouth from the duct orifice posteriorly to the lingual aspect of the retromolar region.[3]
- Dissection and removal of the sublingual gland will facilitate exposure of the duct.
- Careful dissection along the course of the Wharton's duct will reveal its close relationship to the lingual nerve. Retraction of the tongue and floor of the mouth, including the lingual nerve, allows visualization of the mylohyoid muscle.[3]
- Anterior retraction of the posterior margin of the mylohyoid muscle allows visualization of the superficial portion of the submandibular gland. Blunt dissection is used to free the submandibular gland from surrounding structures.
- Transcervical pressure on the gland will elevate the gland in the floor of mouth and aid in visualization.
- The facial artery and vein and their branches are identified and may be either avoided or ligated.
- The gland is then carefully removed, and hemostasis is achieved. A drain may be inserted through the incision site, and the mucosa is re-approximated with absorbable suture.

Endoscopic Approach

There are case reports of endoscopic excision of the submandibular gland via either a transoral or small neck or hairline incision. Techniques are endoscopically assisted but otherwise are similar to those described above.

Robotic Approach

- The robotic approach, although not yet commonly performed, shows promise in reducing operative times over straight endoscopic techniques.[6]

- A retroauricular incision can be used[7,8] or else three small incisions (14, 10, and 10 mm) are made in the neck to allow trocar placement.[6] In the latter case, the gland is removed through the 14-mm incision.
- If trocars rather than the retroauricular approach are used, a surgical pocket is created with inflation of a hernia balloon.[6]
- The gland is approached in the subplatysmal plane, and dissection proceeds from inferior to superior in the subcapsular plane to avoid injury to the marginal mandibular nerve.
- The Wharton's duct and facial artery and vein are ligated with surgical clips.

Common Errors in Technique

- Failure to protect the marginal mandibular nerve
- Failure to address calculi in the hilum or distally at the time of gland resection for calculi
- Failure to achieve adequate homeostasis before closure

Postoperative Period

Postoperative Management

- Postoperative management is minimal and includes elevation of the head of the bed and removal of the drain after drain output decreases.
- Excessive persistent drainage will require re-exploration because uncontrolled hematoma in this area may result in airway difficulty secondary to displacement of the tongue musculature.
- Patients undergoing excision of the submandibular gland are customarily observed for 24 hours postoperatively, primarily to avoid the risk of airway compromise due to unanticipated postoperative edema.

Complications

- The marginal mandibular nerve can be injured and result in paralysis of the lower lip, especially in patients with chronic inflammation of the gland where the anatomic planes of dissection are obliterated by inflammation and scarring.
- Failure to dissect Wharton's duct all the way to the mucosa of the floor of the mouth during excision of the submandibular gland can result in retained calculi with infection later on.
- Postoperative hemorrhage can lead to significant airway obstruction as a result of edema of the tongue musculature.
- The lingual nerve can be injured by injudicious sectioning of the duct without first identifying and freeing the nerve where it lies directly superior to the duct.
- The hypoglossal nerve may be adherent to the medial aspect of the gland and inadvertently resected or transected.

Alternative Management Plan

- Sialoendoscopy has changed the paradigm for patients with calculus, obstruction, and chronic sialadenitis, and the excision of the gland can often be avoided in such patients.[9]
- Excision of the gland is necessary for the diagnosis and treatment of a mass in the submandibular gland. Patients refusing surgery should, at a minimum, be followed as an outpatient.

Discussion

Evidence-Based Medicine Question

How do rates of marginal mandibular nerve injury with the newer approaches to submandibular gland excision compare with rates with the traditional transcervical approach?

The intraoral approach to submandibular gland excision accesses the submandibular gland from its deep surface, thereby avoiding the marginal mandibular nerve. Although authors have been successful in

avoiding marginal nerve injury, overall neurologic injury may be higher with this approach, with one study showing 81% of patients developing transient partial anesthesia of the tongue and 68% developing mild temporary limitation of movement of the tongue, although this was attributed more to edema than to nerve injury.[3] A subsequent study by Weber et al. found no changes in mobility of the tongue and a lower (43%) incidence of temporary alteration in sensation of the tongue sensation.[4] However, the study by Weber and colleagues consisted of only seven patients, and it is not clear that these results can be generalized to a wider population.

The submental approach has been studied by Roh[10] in a prospective randomized fashion, with no increased incidence of injury to the facial nerve found with the submental approach. Roh has also studied the retroauricular approach and had no instances of marginal nerve injury with this approach, although he had two such incidents in the same study while using the traditional transcervical approach.[7] Endoscopic and robotic approaches are being developed that may be able to further improve visualization and limit neurologic trauma.

A limitation of all of the above studies is small sample size. It is important to recognize that even with the traditional transcervical approach reports of transient injury to the marginal mandibular nerve have varied significantly, from 7.7% to 36%.[2] The indication for gland excision (e.g., benign disease vs. malignant disease versus inflammatory disease) may, to some degree, explain this variability. However, given this wide variability, we must be cautious in extrapolating the findings of the current small studies to a wider population of surgeons and patients. Nevertheless, the findings of these early studies are promising, and alternative approaches to submandibular gland excision are reasonable to consider in the properly selected patient.

Editorial Comment

Inflammatory disease of the submandibular gland is increasingly managed with minimally invasive techniques. This is better for the patient and allows the surgeon to avoid open surgery in an inflamed or infected difficult surgical field. Open procedures are still indicated for nonendoscopic candidates, for surgical failures, and for neoplasms. The

chapter highlights the important anatomy and suggests techniques for avoiding the neurologic complications that are functionally very important.

Review Questions

1. What is the most commonly injured nerve in the transcervical approach?

   a. Lingual nerve

   b. Hypoglossal nerve

   c. **Marginal mandibular branch of the facial nerve**

   d. Alveolar nerve

2. What is the least commonly injured nerve in the transoral approach?

   a. Lingual nerve

   b. Hypoglossal nerve

   c. **Marginal mandibular branch of the facial nerve**

   d. Alveolar nerve

3. Injury to the lingual nerve causes which of the following deficits?

   a. **Numbness to ipsilateral anterior 2⁄3 of tongue**

   b. Numbness to ipsilateral posterior 1⁄3 of tongue

   c. Weakness of the ipsilateral tongue

   d. Weakness of the contralateral tongue

4. Injury to the hypoglossal nerve causes which of the following deficits?

   a. Numbness to ipsilateral anterior 2⁄3 of tongue

   b. Numbness to ipsilateral posterior 1⁄3 of tongue

   c. **Weakness of the ipsilateral tongue**

d. Weakness of the contralateral tongue

5. The lingual nerve is identified deep to the:

a. Facial vein

b. Facial artery

c. Anterior belly of digastric muscle

d. Posterior belly of digastric muscle

e. **Mylohyoid muscle**

Superficial Parotidectomy

Lisa Galati

Introduction

Tumor resection is the most common indication for superficial parotidectomy. Approximately 85% of parotid neoplasms are benign. Malignant tumors vary greatly in behavior, from the indolent (acinic cell carcinoma) to the highly lethal (carcinosarcoma). A recent surveillance epidemiology and end results (SEER) data base review of more than 22,000 cases showed that mucoepidermoid carcinoma continues to be the most common salivary gland malignancy (31%).[1] Some high-grade malignancies may be managed with superficial parotidectomy but require neck dissection as well. Metastatic lymphadenopathy from primary skin malignancies is also a common indication for parotidectomy. Lymphoma poses a particular challenge to the parotid surgeon—accurate diagnosis may be available only after open biopsy. Therefore it is important to keep lymphoma in the differential to avoid extirpative surgery for this medically-managed disease. Chronic parotitis is a less common indication for superficial parotidectomy and is recommended for patients who are refractory to medical management or minimally invasive techniques.

Key Operative Learning Points

- Superficial parotidectomy allows resection of either part or all of the gland lateral to the facial nerve.
- The facial nerve has arbitrarily been set as the divider of the parotid, actually a single structure, into superficial (lateral) and deep lobes.
- Systematic dissection—dividing the parotidomasseteric fascia;

identifying the "pointer" of the cartilaginous external auditory meatus, mastoid tip, and tympanomastoid suture line; and delicate handling of the tissues to avoid undue bleeding—allows for consistent identification of the main trunk of the facial nerve at the outset of this procedure.

Preoperative Period

History of Present Illness

- Pain, gradual onset of facial paralysis, rapid growth, and fixation are suggestive of a malignant tumor.[2]
- A history of radiation exposure increases the risk of mucoepidermoid carcinoma; a prior history of lymphoma or Sjögren disease should place lymphoma higher in the differential diagnoses.
- A history of skin cancer or nonhealing skin lesions
- Family history is not usually contributory, but there are case reports of familial parotid malignancies in the literature.[3]
- Social history of smoking in a patient with a cystic parotid mass makes a Warthin tumor a likely possibility.
- A long history of a parotid mass may pose a higher risk of malignancy. Malignant degeneration occurs in 5% to 10% of pleomorphic adenomas; although the risks are not well defined, a long-term history or recurrence of pleomorphic adenomas may point to an increased prevalence of carcinoma ex pleomorphic adenoma.
- History of previous parotid surgery.
- Medications—use of nonsteroidal anti-inflammatory drugs (NSAIDs) and/or vitamin/herbal supplements or aspirin may contribute to prolonged bleeding and should be stopped 1 week prior to surgery.

Physical Examination

- A mobile mass is suggestive of a benign tumor. Fixation is worrisome but may occur in benign tumors that extend through the

stylomandibular tunnel into the prestyloid parapharyngeal space or that are inflamed.

- Cervical lymphadenopathy is concerning for malignancy but occasionally may result from an inflammatory process.
- Paralysis of one or more branches of the facial nerve is a hallmark of malignancy.
- There may be evidence of previous surgery in the parotid area.

Imaging

- Computed tomography (CT) or magnetic resonance imaging (MRI) with contrast is indicated to evaluate the anatomy, tumor extension and characteristics, presence of lymphadenopathy, and sialoliths.
- MRI is particularly useful in the evaluation of parotid neoplasms.
  - Lesions with irregular borders, infiltration into soft tissue, and low signal intensity on T2-weighted images should raise suspicion of malignancy.
  - Recent studies have demonstrated the usefulness of MRI in identifying malignant tumors because they enhance earlier and have less "washout" at longer relaxation times.[4]
  - Pleomorphic adenomas may be heterogeneous and have sharp scalloped borders.
  - Warthin tumors are cystic and have high signal intensity on T2 imaging.
- Positron emission tomography (PET) is indicated for staging a known malignancy.
- Ultrasound is useful for identifying enlarged intraparotid lymph nodes. If normal architecture is preserved, surgery may be avoided.

Indications

- Neoplasms of the superficial lobe
- Chronic parotitis refractory to medical management

Contraindications

- Patient is a poor surgical candidate owing to medical history
- Involvement of the deep lobe
- Malignant tumor extending into the parapharyngeal space, mandible, skin, or ear canal or the presence of distant metastases

Preoperative Preparation

Biopsy

- Fine-needle biopsy (FNA) is indicated in the case of any suspicious tumor.
- The false-positive rate of FNA is about 10%.
- Frozen section analysis has lower false-positive results (5%)[5] and is used to confirm the diagnosis and evaluate margins.
- FNA results are useful in managing salivary gland tumors in patients who are elderly and/or have significant medical contraindications to surgery.
- Open biopsy should be used with caution owing to risk to the nerve or seeding of tumor. However, with a large mass in the tail of the parotid extending beyond 1 cm posterior to the ascending ramus, a small incision can be made parallel to the ramus, 1 cm posterior to it, to obtain tissue for flow cytometry and pathology. This technique is very useful in elderly patients with lymphoma and can be performed in the office.

Operative Period

Anesthesia

- General anesthesia
- Avoidance of long-acting paralytic agents

Positioning

- The entire side of the face and ear is prepped and draped into the field after the neck is gently extended.

Perioperative Antibiotic Prophylaxis

- Prophylactic use of antibiotics in patients undergoing parotidectomy for tumor removal is not indicated.[6]
- Suction drains are not an indication for antibiotics.
- Antibiotics are indicated in surgeries performed for chronic parotitis.

Monitoring

- Facial nerve monitoring is not considered the standard of care but is often used, especially in revision cases or chronic parotitis.

Instruments and Equipment to Have Available

- Head and neck set
- Facial plastics set
- Blunt-tipped dissecting scissors
- Right-angle retractors

Key Anatomic Landmarks

- Cartilaginous "pointer" external auditory meatus
- Mastoid tip
- Posterior belly of the digastric muscle

Prerequisite skills

- Nerve dissection

Operative Risks

- Numbness of the ear and/or skin of the face and neck
- Gustatory sweating (Frey syndrome); drainage from the wound and sialocele formation
- Facial nerve injury
    a. The risk of injury to the facial nerve and its significance must be discussed with all patients.
    b. Patients who have malignant tumors must be informed of the plan regarding nerve sacrifice and reconstruction.

Surgical Technique

Incision

- The modified Blair incision is most commonly used (Fig. 92.1A). For tumors at or above the level of the lobule, the incision need not extend onto the neck.
- The skin is elevated off of the SMAS. If it is not involved by tumor, the superficial musculoaponeurotic system (SMAS) may be elevated as a flap for later use to fill the defect.

Identification of the Facial Nerve

- The superior aspect of the sternocleidomastoid muscle is skeletonized.
- The greater auricular nerve is divided in most cases.
- Dissection is carried along the cartilaginous external auditory meatus, the pointer is identified, and the parotid gland is retracted anteriorly. *From here it is helpful to continue dissection in a plane parallel to the floor*; a more perpendicular course will lead to the styloid, deep to the facial nerve (see Fig. 92.1B).
- The parotidomasseteric fascia is incised. This exposes parotid tissue

and allows access to the plane in which the nerve courses.

- Palpation of the tympanomastoid suture line, which is located between the pointer and mastoid tip, helps to identify the spot at which the nerve will enter the gland parenchyma (large tumors may displace the main trunk in a more vertical direction, paralleling the course of the sternocleidomastoid (SCM)). Staying over the suture line and carefully dividing small pieces of fascia and parotid are very reliable methods of exposing the facial nerve (see Fig. 92.1B and C).
- Identification of the digastric muscle is also helpful, as the stylomastoid foramen lies just medial to its attachment to the mastoid (see Fig. 92.1D).
- Retrograde dissection of the marginal mandibular nerve is a seldom used but reliable technique used to identify the main trunk of the nerve when the standard approach is not possible.

Parotid Dissection

- Once the nerve has been identified, dissection continues along the main trunk and branches.
- The parotid lateral to the visible portion of the nerve is divided.
- Overstimulation of the nerve is to be avoided. Overuse of the facial nerve stimulator can cause praxis of the nerve, as can improper dissecting technique. The tissues over the nerve should be spread apart in a plane parallel to the nerve fibers; any angulation away from this plane may cause undue trauma to the nerve.
- Superficial parotidectomy is the current standard procedure for parotitis[7]; removal of the entire superficial lobe with or without duct ligation produces cure rates approaching 100%.[8]
- Endoscope-assisted accessory parotid lobe excision aids in safe facial nerve dissection without the large or facial incisions that would be necessary to reach this anterior position.[9]

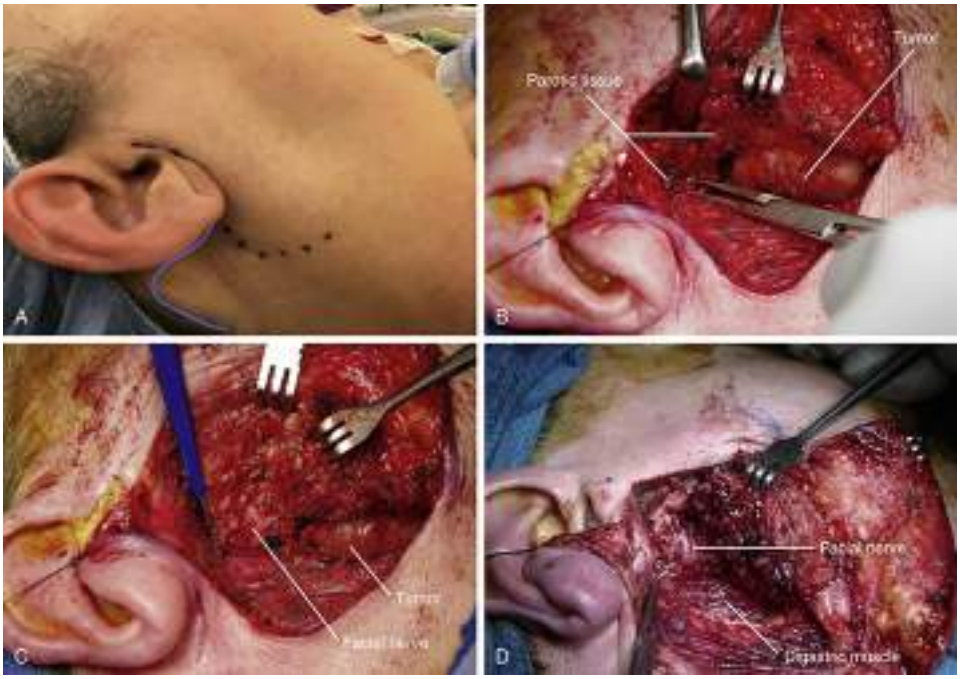

FIG. 92.1 **A,** The classic modified Blair incision is marked in the preauricular crease at the level of the meatus, behind the lobule and down into a neck crease. The solid line depicts the "face lift" modification, to hide the posterior limb near the hairline. **B,** The McCabe dissector allows dissection of the delicate tissues lateral to the facial nerve. Here the dissection is carried out near the tympanomastoid suture line in a plane moving toward the parotid, not down toward the bony ear canal. The nerve lies deep to this tissue. **C,** The facial nerve is exposed and dissection continues along its branches until reaching soft tissue anterior to the mass. **D,** The digastric muscle inserts onto the mastoid process and lies lateral to the nerve as it exits the stylomastoid foramen.

- Extracapsular dissection descended from the technique of intracapsular enucleation, which was performed up to the 1960s. It was intended to decrease injuries to the facial nerve but resulted in recurrence rates of over 40% due to incomplete resection of the capsule.
- Use of a microscope is required during division of salivary tissue around the tumor capsule; minimal amounts of normal salivary gland are removed and the facial nerve is not dissected.[10]

Margins

- Benign parotid neoplasms require excision of a fairly small cuff of normal gland.
- However, the deep portion of the dissection of the facial nerve often yields no margin of tissue other than the tumor capsule itself. Careful dissection of the tumor away from the nerve is necessary to avoid injury to the facial nerve and complete excision of the capsule. Once the tumor has been dissected off the facial nerve beyond the anterior limit of the lesion, the parotid is divided and the specimen is removed.
- In cases of malignancy, particularly low-grade tumors, the extent of parotidectomy may be similar to that involved in the resection of benign tumors.
- After superficial parotidectomy for a tumor with negative margins that is found to be malignant on final pathology, reoperation is not required.

Hemostasis

- Suture ligation of small vessels or bipolar cautery is used to avoid injury to the nerve.
- A harmonic scalpel appropriate for head and neck procedures was introduced in 2008. It coagulates and divides tissue and has been shown to significantly decrease operative time.

Closure

- The main trunk of the facial nerve is stimulated prior to closing to evaluate its integrity.
- Insertion of a suction drain is useful after the wound is irrigated.
- Defects resulting in obvious contour hollowing can be repaired by
    1. Approximating the SMAS to the SCM or creating a small rotation flap by dividing some of the superior fibers of the SCM and suturing them anteriorly. Care must be exercised to avoid injury to the spinal accessory nerve.

2. Use of allogenic dermal grafts. These have been reported to be safe, but this avascular foreign body has also been found to promote infection and salivary fistula.
3. Insertion of adipose tissue grafts, which are limited by reabsorption and a separate donor site

- Subcutaneous layer approximated with interrupted 3-0 absorbable suture, skin edges with either 6-0 absorbable suture or histacryl glue
- Steri-Strips are applied, followed by a sterile parotid dressing.

Common Errors in Technique

- Excessive traction on the facial nerve during dissection
- Difficulty identifying the facial nerve
- Traumatic dissection of the facial nerve or its branches

Postoperative Management

Facial Nerve Function

- If function is weak but the nerve was found to be intact intraoperatively, a full recovery of function is expected.
- Steroids are not indicated as they do not improve outcome.
- Reoperation is indicated only if the nerve was not identified during the dissection. In this case attempts to find and repair the nerve should be made.

Drains and Dressing

- Drains are left to bulb suction to avoid inadvertent stress to the nerve.
- The drain is removed if total output is less than 20 mL in 24 hours. After that point, the drain is removed if there is less than 5 mL of drainage over the next 8 hours.
- The harmonic scalpel does not decrease the amount of postoperative

drainage.

- The dressing is left on for 24 hours after discharge.
- Exertional activities are restricted for 2 weeks and driving is restricted for 1 week.

Complications

Hematoma

- Sudden facial swelling or rapid filling of the drain should be treated by exploration of the wound in the operating room.
- Evacuation of the hematoma is important in order to avoid wound infection and necrosis of the flap.

Frey Syndrome

- Occurs in up to 60% of parotidectomy patients but only about 10% consider it to have a negative impact on quality of life
- Antiperspirant application or botulinum toxin injections are temporary management options.
- Long-term control involves placement of vascularized tissue between the parotid bed and the skin.
- Intraoperatively, a flap can be created by lifting the SMAS off of the gland, leaving it pedicled anteriorly, and then placing in the defect before closure.
- Revision surgery for Frey syndrome should be carefully considered because of the increased risk of facial nerve injury due to scarring.

Injury to the Facial Nerve

- Mild neuropraxia resolves in 4 to 6 weeks.
- More severe traction injuries resulting in axonal death will take much longer to recover (6 months); imperfect recovery leads to permanent weakness and synkinesis.

- Transected nerve fibers should be repaired if possible.
- Nerve ends should be examined and freshened by excising a small amount of nerve to create a blunt edge.
- Epineurium is reapproximated using 8- or 9-0 monofilament suture; a neural tube can be placed to support the repaired nerve.
- If a nerve graft is required, the greater auricular is readily available.
- When the nerve is repaired in a second stage, the sural nerve or medial branchial cutaneous nerve is a good graft choice.
- If the nerve was normal preoperatively and a microscopic repair is performed immediately, the best result possible is a House-Brackmann grade III. Recovery takes about 6 to 12 months.

Infection

- Occurs in less than 5% of cases

Sialocele Formation and Seroma

- A very uncommon (approximately 5%) but persistent complication of superficial parotidectomy
- Use of allogenic dermal grafts or Surgicel and anterior location of the tumor have been implicated as risk factors.
- Ballotable swelling noted at the postoperative check should be aspirated in the office. The skin is prepped to avoid the introduction of bacteria, and a large-bore (16–20 French) needle is used to aspirate the collection. Pressure dressings at this point confer little advantage. Repeat aspiration may be necessary, especially in cases of seroma formation.
- We instituted the use of Botox after extrapolating from early reports its use for Frey syndrome and have had success with this nonoperative approach.
- Expectant management is also reasonable, and most of these conditions resolve without treatment in 4 to 6 weeks.

Flap Necrosis and Hypertrophic Scars

- Flap necrosis is avoidable if the skin is elevated with the subcutaneous adipose tissue.
- Smoking increases the risk of flap necrosis.
- Keloid formation may be seen early in the postoperative period and is best treated when first noted. Injection of triamcinolone directly into the scar is effective. Local anesthesia with lidocaine prior to injection or mixed with triamcinolone is important, as hypertrophic scar injection is often painful.

Recurrent Tumor or Infection

- Occurs in 2% of cases
- Is often multifocal
- Incomplete capsule removal and, less commonly, tumor spillage are causative.
- If capsule rupture occurs, the wound is irrigated with copious amounts of saline and carefully inspected to remove all tumor fragments.
- Imaging and FNA are required.
- The goal of revision surgery is resection of all tumor deposits, which may not be possible without sacrificing a portion of facial nerve.
- Radiation is used in cases of widespread recurrence or multiple surgeries.

Alternative Management Plan

If surgery for a benign tumor is contraindicated owing to the patient's medical condition, the tumor may be observed; evaluation for radiation therapy may be considered in patients with malignant parotid neoplasms.

Discussion

Evidence-Based Medicine Question

What factors influence decisions to sacrifice the facial nerve during superficial parotidectomy for malignant neoplasms?

A decision to resect the nerve is most easily made if preoperative paralysis is present. The decision is much more difficult if nerve function is normal. Given its low sensitivity (52%) in the case of suspicious and malignant lesions, FNA should not be used to determine the fate of a normally functioning facial nerve. Most reports support the concept that all efforts should be made to preserve the nerve. The exceptions—*of which the patient should be informed*—are encasement of the nerve by tumor, frozen section evidence of infiltration, or incomplete resection of gross tumor. Microscopically positive margins at the level of the nerve have been successfully eradicated with radiation therapy.

Editorial Comment

The concept of surgical excision of a parotid tumor is attributed to Bertrandi in 1802. The initial application of this surgery caused serious disfigurement and disability. John C. Warren was the first surgeon to resect a parotid tumor under ether anesthesia (Massachusetts General Hospital, 1846).

Codreanu, a Romanian surgeon, did the first total parotidectomy with facial nerve dissection in 1892. McWharten in 1917 described the surgical anatomy of the parotid gland as a bilobed structure, the interspace allowing for passage of the facial nerve.

W. E. Sistrunk of the Mayo Clinic wrote in 1921 that "surgery is the only means of curing a parotid tumor" and described a technique in which the facial nerve was identified and preserved. With the use of this technique only, permanent facial paralysis resulted in one of six patients. In 1934, Jones developed a surgical-anatomic technique for dissection and advocated isolation of the main trunk of the facial nerve with dissection carried forward so that that there would be less risk of injury to the peripheral branches of the facial nerve.

It was not until 1975 that the surgeons from the Mayo Clinic reported their results, comparing two series of cases that included 1360 primary

parotid tumors. Local resection was used in the first 15-year period (1940–1954). In the second series (1955–1969) a superficial or total parotidectomy with identification and preservation of the facial nerve was carried out. The latter technique became the standard of care owing to the decreased incidence of both recurrence and facial nerve injury.

Parotidectomy is the quintessential head and neck operation requiring a mastery of the anatomy, traction and countertraction, use of surgical planes, meticulous hemostasis, and microneurosurgical techniques. Careful preoperative planning with imaging and, where appropriate, histology allow for the best surgical planning. In the event of nerve injury, the most skilled person should repair the nerve to allow for the best possible recovery.

Review Questions

1. Which structure lies medial to the facial nerve?

   a. Cartilaginous ear canal

   b. Mastoid tip

   c. **Styloid process**

   d. Posterior belly digastric

2. Which finding is most worrisome for a malignant parotid neoplasm?

   a. Fixation

   b. Pain

   c. Size greater than 4 cm

   d. **Weakness of the temporal branch of the facial nerve**

3. FNA indicates pleomorphic adenoma preoperatively. The patient undergoes successful superficial parotidectomy without complication but final pathology is carcinoma ex pleomorphic adenoma with close but negative margins. Which is NOT an appropriate course of action?

   a. **Do revision surgery with resection of the normally functioning**

facial nerve.

b. Perform a metastatic workup.

c. Recommend close observation after multidisciplinary conference and review of all pathology and imaging results indicate no other disease.

d. Perform neck dissection after abnormal PET scan and indeterminate lymph node FNA results.

Deep Lobe Parotidectomy

Andrew Tassler, and Seungwon Kim

Introduction

The most common indication for surgery of the parotid gland is the presence of a mass or tumor. The majority of distinct parotid masses are neoplasms with benign tumors predominating. Pleomorphic adenoma (mixed tumor) and Warthin tumor (papillary cystadenoma lymphomatosum) account for the majority of benign lesions with adenomas and oncocytomas being encountered regularly.

Malignant tumors of the parotid gland represent a heterogeneous group of different pathologies with varying clinicopathologic characteristics.[1] Mucoepidermoid carcinoma is the most common malignancy found in the parotid gland with adenoid cystic carcinoma being encountered nearly as often. Other malignant tumors include acinic cell carcinoma, adenocarcinoma, salivary duct carcinoma, primary squamous cell carcinoma of the parotid gland, and carcinoma ex-pleomorphic adenoma. Nodal metastasis to intraparotid lymph nodes from skin cancers of the face and scalp are also seen with reasonable frequency; more rare are metastases from malignancies originating outside the head and neck with spread to the parotid.

Lymphoma can also present in the parotid gland and is more commonly seen in patients with chronic inflammatory disease of the parotid(s) such as Sjogren's syndrome.[2] The majority of parotid lymph nodes lie within the superficial lobe of the gland and thus are somewhat less germane to a discussion of deep lobe parotid lesions and surgery. However, in the management of a malignant tumor originating within the deep lobe, metastasis can occur that requires removal of the superficial gland as a means of lymphadenectomy.

Although it is decreasing in frequency, parotidectomy is also

sometimes undertaken for chronic parotiditis. In instances of parotidectomy for chronic parotitis, the goal of the surgery is typically removal of all remaining parotid tissue, including the glandular tissue of the deep lobe. Other causes of swelling and possible masses of the parotid include congenital lesions such as first branchial cleft cysts and inflammatory conditions such as Sjogren's syndrome and sarcoidosis.

Any condition that can affect the superficial lobe of the parotid may affect the deep lobe as well, and despite modern imaging techniques and examination characteristics, the discovery of the relationship of a mass to the facial nerve often cannot be made until the time of surgery. Parotidectomy is a procedure that has standardized steps and a variable component that must be personalized at each operation while considering the pathology, location of the lesion, and patient-specific factors.

Key Operative Learning Points

- Deep lobe parotidectomy is a procedure with both standardized steps and variable portions that should be tailored to the patient and his or her pathology.
- Preoperative imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) is recommended for all suspected deep lobe parotid lesions, as it can provide useful information regarding the tumor and its relationship to critical structures.
- Facial nerve dissection and mobilization are likely to be necessary unless the tumor is purely parapharyngeal.
- Preoperative tissue sampling is recommended, as deep lobe malignancy often requires additional exposure with a mandibulotomy.
- The surgeon should have a low threshold for removal or division of structures such as the great auricular nerve, posterior belly of digastric muscle, or stylomandibular ligament to improve access and exposure.

Patient Selection/Preoperative Period

Masses originating in the deep lobe of the parotid are typically either

discovered by the presence of the mass on examination or found incidentally on cross-sectional imaging such as CT or MRI. Most benign tumors will present with minimal symptomatology related to the lesion except for the presence of the mass itself and possibly some mild discomfort. Significant or worsening pain, trismus, immobility of the lesion, skin change overlying the mass, and facial nerve weakness are all clinical signs that should raise the suspicion for malignancy. Given their anatomic location, however, benign tumors that arise in the deep lobe of the parotid may have decreased mobility on physical examination as compared to a mass in the superficial lobe or may not be readily palpable at all.

Palpable masses can be evaluated in similar fashion to a superficial parotid mass and are often first investigated with fine-needle aspiration (FNA) biopsy. Masses that are found incidentally are often not readily palpable, and FNA of the mass often needs to be done with image guidance such as ultrasound or CT. The necessity of obtaining FNA biopsy of parotid lesions prior to surgery is debatable and goes beyond the scope of this chapter focused on surgical planning and technique. We feel that the complication rate of FNA is so low and the potential information gathered from the FNA is often quite accurate in terms of differentiating between benign and malignant lesions that we favor performing this preoperatively whenever feasible. The information obtained from FNA can often allow more informed preoperative discussion with the patient and may also allow observation of likely benign lesions such as Warthin tumors in patients who are poor operative candidates.[3]

FNA of suspected deep lobe parotid masses can be more difficult than for superficial lesions and may require image guidance. Given the anatomic location of a deep lobe parotid tumor, however, information regarding potential malignancy may be of even greater value. Complete discussion regarding possible need for mandibulotomy, nerve manipulation or even nerve resection allows for informed consent prior to removal of a deep lobe mass worrisome for malignancy. Similar to with a superficial parotid tumor, we recommend wiating for either frozen section or final pathologic confirmation of parotid malignancy prior to resecting vital structures such as the facial nerve.

Preoperative Period

1. History of present illness
   a. Presence of the mass—how discovered, how long present, growth
   b. Associated symptoms—pain, trismus, facial twitching, facial paralysis, or weakness
   c. Other head and neck symptoms—dysphagia, otalgia, aural fullness, decreased hearing, epistaxis, visual change, and voice change
   d. Constitutional/general symptoms—weight loss, fevers, chills, night sweats, and malaise
2. Past head and neck specific history
   a. Prior salivary gland surgery or infection
   b. Prior tobacco exposure (Warthin tumor)
   c. Prior head and neck cancer, prior radiation treatment including radioactive iodine
   d. Prior skin cancer of the head and neck region, primarily squamous cell carcinoma or melanoma
3. General medical history
   a. Comorbid conditions including autoimmune issues and sarcoidosis
   b. Cardiovascular health—prior pacemarker of automated implantable cardioverter defibrillator (AICD) - able to have MRI
   c. Medications/allergies—anticoagulants

Physical Examination

1. General appearance
   a. Obvious parotid/neck mass or asymmetry
   b. Facial weakness
   c. Voice change, that is, muffled
   d. Secretion management, airway obstruction

2. Complete examination of the head and neck with attention to areas noted below

3. Skin

   a. Worrisome or suspicious lesions of the facial skin or scalp—infiltration, ulceration, erythema, asymmetry, and melanotic lesions

4. Otologic

   a. Worrisome skin lesions of auricle or ear canal

   b. Middle ear effusion, possible parapharyngeal extension

5. Oral cavity/oropharynx

   a. Trismus

   b. Dentition/height of mandible if mandibulotomy possible

   c. Pharyngeal asymmetry, soft palate, tonsillar fossa, and lateral pharyngeal wall

6. Salivary glands/neck

   a. Palpable mass

   b. Size, mobility, and tenderness/firmness

   c. Borders of mass if palpable, apparent depth of extension, and relationship to angle of mandible

   d. Facial nerve function, upper and lower divisions, and weakness/twitching/paralysis

   e. Cervical adenopathy

Imaging

Cross-sectional imaging is recommended for tumors with possible deep lobe location. Imaging of a parotid mass provides information regarding both the possible location (superficial or deep lobe) and nature of the pathology (benign or malignant). Imaging landmarks that offer clues to the location of the facial nerve include the styloid and mastoid processes, the posterior belly of the digastric muscle, and the retromandibular vein. The vein is typically a superior extension of the external jugular vein (or occasionally the common facial vein) and can be identified by following

the vein in an inferior to superior fashion in the axial plane. In a normal anatomic situation, the facial nerve and its branches will lie just superficial to the vein within the substance of the parotid gland; thus, the relationship of a parotid mass to the vein can be used to infer the relationship between the nerve and a mass. Given this, a deep lobe tumor will often displace the retromandibular vein laterally and superficially.

1. MRI with contrast
    a. Superior assessment of tumor, soft tissues, and possible perineural invasion
2. CT with contrast
    a. Best assessment of bone anatomy, mandible, mastoid, and styloid processes
3. Positron emission tomography (PET)/CT
    a. Fluorodeoxyglucose (FDG) avidity of salivary gland tumors can be unreliable. Positron emission tomography (PET)/CT is rarely needed but can be considered in cases of possible high-grade malignancy or other known malignancy where a parotid lesion may represent a metastasis or to be aware of lung metastasis as part of preoperative evaluation.

Indications

1. The treatment for parotid neoplasms is surgical excision.

2. The treatment of inflammatory conditions of the parotid is first management of the underlying inflammatory condition, but surgery may eventually be indicated for refractory cases.

3. Subtotal resection or biopsy of parotid lesions may be indicated if the likely diagnosis is a condition that is typically not treated surgically such as lymphoma or sarcoidosis.

Contraindications

1. Medical comorbidities that place the patient at high risk for general anesthesia particularly if imaging and FNA suggests a benign tumor

Preoperative Preparation

1. For tumors where the relationship to the facial nerve is not obvious from preoperative workup, surgical planning is similar to that for superficial parotidectomy.

2. Prepare for extended exposure/resection if necessary.

Operative Period

1. The procedure is almost universally performed under general anesthesia.

2. Long-term paralytic agents should be avoided.

3. Use of Electromyography (EMG) nerve monitoring in primary surgery is somewhat controversial and has not been shown to decrease the incidence of facial nerve weakness or injury.

4. The use of active monitoring in revision cases is more common and often aids in the identification of nerve branches in a previously operated field.

Monitoring

- Routine anesthesia monitoring
- Patient should not be given long-term paralytic to facilitate identification and preservation of the facial nerve and its branches

Instruments and Equipment to Have Available

- Monopolar and bipolar cautery; ultrasonic tissue device if desired
- Nerve stimulator
- Topical epinephrine on pledgets
- Standard for head and neck surgery set

- Consider McCabe type dissector for fine nerve dissection.

- Saw and maxillofacial plating system if mandibulotomy considered
- Loupes or operating microscopes can be helpful.

Key Anatomic Landmarks

1. The parotid gland is located anterior and inferior to the ear lobule on either side of the face and is the largest of the major salivary glands in the body.

2. The superficial layer of the deep cervical fascia splits around the parotid gland and invests it in a fascial layer that anteriorly becomes continuous with the superficial musculoaponeurotic system (SMAS).

3. Posterior and inferior margins are the anterior border of the superior aspect of the sternocleidomastoid muscle.

4. The deep surface of the gland contacts multiple anatomic landmarks.

   a. The mastoid process of the temporal bone

   b. The external auditory canal

   c. The ascending ramus of the mandible and more inferiorly

   d. The posterior belly of the digastric and stylohyoid muscles

5. The facial nerve runs through the parotid gland with the majority of the glandular tissue (70% to 80%) lying superficial to the nerve.

6. The nerve exits the skull through the stylomastoid foramen and typically gives off small branches to the postauricular muscles and the posterior belly of the digastric prior to the more significant division into upper (temporofacial) and lower (cervicofacial) divisions at the pes anserinus.

7. The glandular tissue of the parotid gland is referred to as having both superficial and deep lobes, but there is no distinct anatomic, fascial, or compartmental delineation between the two lobes. Rather, the distinction between the two refers to relationship of the glandular tissue to the facial nerve and its branches.

8. The deep lobe of the parotid has three anatomic areas.

a. The largest portion occupies the space deep to the facial nerve and between the mastoid process posterolaterally and the ramus of the mandible anteromedially. Tumors arising from this tissue typically displace the facial nerve and its branches in a lateral or superficial direction.

b. Small portions of deep lobe parotid tissue also exist anteriorly between the distal facial nerve branches and the masseter muscle with deep lobe tumors in this location often clinically appearing more superficial than their true anatomic position.

c. There is also a small amount of parotid tissue in the posterior inferior aspect of the deep lobe where the gland is connected to the parapharyngeal space via the stylomandibular tunnel. Tumors in this location may extend medially via the tunnel into the prestyloid parapharyngeal space.

Prerequisite Skills

- Superficial parotidectomy
- Parapharyngeal space surgery
- Neck dissection

Operative Risks

1. Facial weakness—more common following the often significant manipulation required for deep-lobe tumors

2. Hematoma—most hematomas can be monitored expectantly, but operative intervention is required for expanding hematoma with airway compromise

3. Seroma/sialocele—seromas and salivary leaks will almost universally resolve with either conservative management, serial aspiration, or a combination of the two

4. First bite syndrome—can be seen after dissection into the parapharyngeal space or with mobilization of the deep lobe of the parotid gland[4]

Surgical Technique

1. The patient should be prepped in a sterile fashion such that the entire face is visible for observation.

2. The entire ipsilateral neck should be prepped as well and if a wider exposure such as mandibulotomy is felt to be possible then the exposure should extend anteriorly across the midline.

3. A modified Blair type incision is typically designed, which begins anterior and superior to the tragal cartilage and extends inferiorly around the ear lobe.

4. Incisions

   a. For lesions located more posteriorly or superiorly, the inferior limb of the incision can be extended posteriorly from the ear lobe in a postauricular location.

   b. For more anteriorly located lesions and for the majority of most possible deep lobe masses the inferior aspect of the incision anteriorly into a transverse cervical component in a natural skin crease

   c. Small hash marks can be made perpendicular to the incision to aid in approximation of the skin at the conclusion of the case.

5. An anterior skin flap over the parotid fascia is developed.

6. The anterior border of the sternocleidomastoid muscle is then identified and fascial attachments are divided.

7. The great auricular nerve

   a. Typically the nerve divides into an anterior and posterior branch.

   b. The nerve and its branches can be preserved as felt to be feasible without compromising exposure.

   c. If the nerve is divided

      1) Divide the nerve in a sharp fashion using the cold knife technique.

      2) Bury the proximal end in the muscle to prevent formation of a potentially painful neuroma postoperatively.

d. The external jugular vein typically lies approximately 1 cm anterior to the great auricular nerve and can often be preserved (but should be ligated if felt to be limiting exposure anteriorly).

8. With lateral retraction of the sternocleidomastoid muscle the posterior belly of the digastric muscle is then identified.

9. The pre-tragal tissues and the avascular plane between the parotid and tragal cartilage are developed and opened to the level of the pointer.

10. Bipolar electrocautery is used to divide the tail of the parotid using the tragal pointer and digastric levels as references.

11. Anatomic references for the facial nerve

a. The tragal "pointer"

b. The tympanomastoid suture line

c. The posterior belly of the digastric muscle

12. For tumors felt to be in the deep lobe and in the region of the stylomastoid foramen itself the surgeon must be aware of the possibility of a laterally/superficially displaced main trunk of the facial nerve.

13. Hemostasis near the facial nerve

a. Pressure

b. Topical hemostatic agents (i.e., epinephrine)

c. Well-placed surgical clips

d. Judicious bipolar cautery

14. Facial nerve dissection

a. Proceed along the facial nerve to expose the necessary branches for safe removal of the tumor or tissue in question.

b. The branches in proximity to the tumor will often need to be fully dissected and released from the underlying tissues to allow mobilization of the tumor (Fig. 93.1). Normal parotid tissue overlying the nerve branches can be divided with bipolar cautery, ultrasonic device, or even cold knife technique (Fig. 93.2).

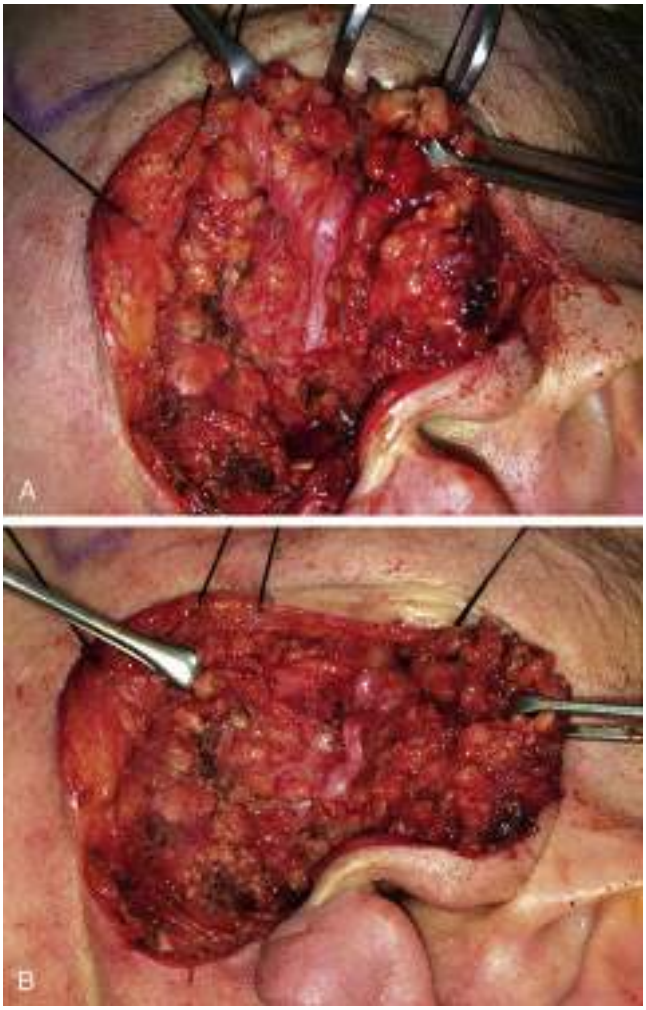

FIG. 93.1 Small left parotid tumor found incidentally on brain imaging. **A,** The tumor was found to be just deep to a main branch of the upper division of the facial nerve. **B,** The nerve was dissected free from the underlying tumor, and the tumor was removed. Pathology revealed a basal cell adenoma.

c. The use of monopolar cautery to divide tissues over facial nerve branches is discouraged as this can transmit unwanted current to the nerve.

d. The superficial lobe tissue can often be released in a posterior to anterior fashion while remaining pedicled anteriorly.

15. Closure

If the mobilized superficial lobe has been preserved it can then be replaced providing an excellent cosmetic A suction drain is placed along

the posterior digastric to avoid contact with the facial nerve and its branches.

Surgical Technique for Deep Lobe Tumor With Parapharyngeal Extension

As mentioned in the surgical anatomy section, tumors that arise from the posterior and inferior aspects of the deep lobe are positioned to extend medially into the parapharyngeal space and create so-called "dumbbell" tumors with the narrow portion being created by the limited space of the stylomandibular tunnel (Fig. 93.3—MRI of large dumbbell pleomorphic adenoma). While a purely parapharyngeal space tumor is most commonly approached via a transcervical approach without need for a transparotid component of the dissection, tumors involving both the deep lobe of the parotid and the parapharyngeal space usually require both parotid and cervical exposure and dissection.

FIG. 93.2 Large pleomorphic adenoma found to be located in the deep lobe of the right parotid gland at the time of surgery. The main trunk of the facial nerve is just deep to the arm of the retractor with the tumor located deep to the lower division of the facial nerve. Note the superiorly and inferiorly based portions of the superficial lobe that are reapproximated after the procedure.

FIG. 93.3 Magnetic resonance image (contrast enhanced, axial T1 fat suppression) of dumbbell-shaped tumor of the deep parotid gland with parapharyngeal extension.

FIG. 93.4 Large epithelial/myoepithelial carcinoma of the deep lobe parotid and parapharyngeal space. The larger portion of the tumor (superior aspect of picture) was located in the parapharyngeal space with the imprint of the stylomandibular ligament showing the demarcation between the deep lobe and parapharyngeal components.

1. Similar initial approach to deep lobe tumor without parapharyngeal extension as above

2. Design incision with more anterior/cervical extension

3. Once the main trunk of the facial nerve is identified, palpation or visual inspection can often identify the deep lobe component of the tumor, and this should be gently freed as previously described.

4. The parapharyngeal component is then approached transcervically—skeletonize the posterior belly of the digastric muscle.

5. The submandibular gland can be left in situ or lateral vasculature (facial artery and vein) divided to allow medial displacement.

6. Inferior retraction on digastric reveals deep parotid and parapharyngeal space.

7. Maneuvers that aid in mobilization of the medial portion of the tumor

   a. Division of the posterior belly of the digastric muscle

      1) If division of the digastric is performed, this should be done at the medial ligamentous portion if reapproximation is to be considered as the divided muscle fibers will not be able to be approximated.

   b. Division of the stylomandibular ligament

   c. Application of medial to lateral pressure from the oropharynx (Fig. 93.4—deep lobe tumor with imprint of the stylomandibular ligament)

Malignant Tumors of the Deep Lobe

A complete review of the varying malignant salivary pathologies is beyond the scope of this chapter. A malignant tumor of the deep lobe parotid is managed in similar fashion to one of the superficial lobe; however, the anatomic location in the deep lobe often places the tumor in even closer proximity to the facial nerve and makes it more difficult to obtain a significant margin of normal surrounding tissue.

We routinely use frozen section of a resected tumor that can reliably differentiate between high-grade malignancy and tumors that are either

benign or represent low-grade malignancy. If intraoperative findings are suggestive of a malignant tumor and facial nerve involvement is found, pathologic confirmation of malignancy is strongly suggested prior to nerve resection even if this requires waiting for final pathology. Even with confirmation of malignancy in patients with an intact functioning facial nerve preoperatively, every effort should be made to try to preserve continuity of the facial nerve.

Postoperative radiation therapy is indicated for parotid malignancy with high-grade features, positive margins, high T stage, and nodal involvement. Even with negative margin resection, pathologies such as adenoid cystic carcinoma benefit from postoperative radiation in achieving improved local control given their propensity for perineural invasion and local recurrence.

Common Errors in Technique

1. Poor patient selection in terms of adequacy of preoperative evaluation of pathologic extent on imaging and metastatic workup

2. Operating in the face of malignancy with perineural spread on multiple nerves not preoperatively assessed or not surgically resected

3. Failure to have clinical experience with a sufficient volume of surgical cases to comfortably approach deep lobe tumors

4. Resecting a facial nerve that could be preserved

Postoperative Period

Postoperative Care

The wound and the drain are monitored overnight, and the drain is typically removed on the first postoperative day unless the output is unexpectedly high (>100 cc total or >50 cc for the prior nursing shift).

Patients use topical antibiotic ointment such as bacitracin over the sutures for the first 3 to 5 days. Some patients will have an inflammatory reaction to common topical antibiotic ointments, and this should be considered if patients develop erythema of the surgical site

postoperatively.

In a healthy, nonradiated patient, sutures can typically be removed approximately 1 week postoperatively. Patients are encouraged to massage the surgical site and the incision starting at 2 weeks postoperatively to soften the area and more rapidly disperse edema and lessen scar formation.

Outcomes, Prognosis

Long-term outcomes are related to the pathology being addressed surgically. For benign tumors of the deep lobe, complete excision is curative. Multiple case series regarding the excision of parotid pleomorphic adenomas demonstrate the long-term control of this tumor with close but negative margins. For malignant tumors of the deep lobe, outcome and prognosis are closely related to the specific pathology, grade of the tumor, and margin status.

Evidence-Based Medicine Question

Does greater auricular nerve preservation improve sensation?

Periauricular numbness is a common, sometimes the most common, complaint after parotidectomy. In studies that investigate the preservation of the posterior branch of the nerve, short-term improvement of sensation was better in the preservation group. In addition, there is long-term improvement in sensation, but the deficit is always greater than the normal unoperated side, and long-term quality of life data do not support preservation.

Editorial Comment

Deep lobe parotid tumors are decidedly uncommon related to superficial pathologies. Similar to many operations, complications are related to clinical volume. Deep lobe tumors should be managed, as discussed in this chapter, by high-volume salivary gland surgeons. When this is performed, even difficult but appropriate inflammatory and malignant lesions can be safely managed.

Review Questions

1. Deep lobe parotid tumors do which of the following?

   a. Usually present as a facial paralysis

   b. Usually turn out to be malignant

   c. **Frequently are discovered incidentally on imaging for other indications**

   d. Are never palpable

2. Surgery on the deep lobe tumor can sometimes be enabled by all of the following, except

   a. Division of the digastric muscle

   b. Division of the stylomandibular ligament

   c. Medial to lateral pressure applied intraorally

   d. **Mastoidectomy**

Office-Based Diagnosis of Sinonasal Disorders

*Berrylin J. Ferguson**

Introduction

Nasal endoscopy is integral to the physical examination of patients with sinonasal symptoms seeking management from the otolaryngologist. With proper local decongestion and anesthesia, it is possible to obtain excellent visualization of the nasal mucosal lining, middle meatus, inferior meatus, sphenoethmoid recess, olfactory cleft, turbinates, septum, and nasopharynx with minimal discomfort to the patient.

Anesthesia is accomplished with a variety of techniques, including atomizers using disposable nasal tips with the topical anesthetics 4% lidocaine or 2% tetracaine. Frequently a topical decongestant, such as oxymetazoline 0.05%, is added. These agents may also be used on cotton pledgets that are placed in the nose for 5 to 10 minutes until decongestion and anesthesia are achieved.

The examination is facilitated if there is access to small-caliber endoscopes, such as the 2.9-mm rigid Hopkins telescope (Fig. 94.1). A 30-degree endoscope is typically most useful for office-based diagnosis of sinonasal disease. For patients who have had sinus surgery, a 70-degree endoscope can be helpful to visualize the frontal and maxillary sinuses. A video camera and high-definition monitors are a critical part of visualizing the examination. Video documentation with archiving can be helpful in monitoring the patient's progress over time.

The following discussions (and accompanying videos) highlight some of the common disorders encountered in endoscopic diagnosis of the nose and sinuses.

Key Operative Learning Points

1. Nasal endoscopy should be performed in a standardized manner and include examination of the nasal mucosal lining, middle meatus, inferior meatus, sphenoethmoid recess, olfactory cleft, turbinates, septum, and nasopharynx.

2. Failure to inspect the nasopharynx will lead to inability to diagnose common disorders that mimic sinusitis (i.e., Thornwaldt cysts, hypertrophic adenoid tissue or tumors).

3. In addition to anatomic description, the diagnostic examination evaluates the presence of mucopurulent drainage, presence of polyps, masses, and characteristics of the sinonasal mucosal lining.

4. Vasculitic diseases should be considered if the mucosa is abraded or bleeding (i.e., granulomatosis with polyangiitis [GPA], formerly known as Wegener granulomatosis), as well as cocaine or intranasal opioid abuse.

5. Sarcoidosis can present with cobblestone appearance of the mucosa with inflammation and edema refractory to decongestion.

6. If the mucus is tenacious and appears to contain eosinophil by-products, send it for fungal cultures and stains to evaluate for possible allergic fungal sinusitis.

7. Endoscopically obtained cultures can help to direct antibiotic therapy.

History

1. History of present illness

   a. Determine symptoms that are most troublesome to the patient in order to best direct therapeutic recommendations.

   b. Patients with suspected chronic rhinosinusitis (CRS) should be questioned regarding symptoms of nasal obstruction, discolored drainage, facial pain/pressure, and loss of the sense of smell.

      1) Antibiotic and steroid treatment

      2) Imaging, if available

3) Allergic rhinitis symptoms and, if positive, history of allergy testing and treatment

4) Past surgical procedures, specifically endoscopic sinus surgery (ESS)

2. Past medical history

3. Social history

a. Patients with allergic rhinitis should be asked about environmental exposures at work and home

b. Occupation

c. Tobacco history

4. Family history

a. Allergic rhinitis

b. Asthma

c. Nasal polyposis or cystic fibrosis

Physical Examination

1. Proper topical decongestion and anesthetic should be administered before nasal endoscopy.

2. A 30-degree Hopkins endoscope can be used to visualize all key landmarks in patients who have not had ESS. A 70-degree endoscope is helpful to visualize the frontal sinus osteum and the maxillary sinus in patients who have had ESS.

a. First pass along the middle meatus with the endoscope angled at the 4-o'clock position. The light source can then be angled superiorly to visualize the olfactory cleft.

b. Second pass visualizing the inferior meatus with the endoscope angled at 6-o'clock position and then toward the nasopharynx, passing the scope medial to the inferior turbinate. The light source can then be angled superiorly to visualize the sphenoethmoid recess superiorly.

3. Examination of the cranial nerves can help to evaluate patients

suspected of a sinonasal malignancy or a granulomatous process.

FIG. 94.1 A 2.9-mm 30-degree Hopkins telescope can be useful in performing a complete nasal endoscopy with minimal discomfort to the patient, especially in patients who have not had sinus surgery.

Imaging

Maxillofacial computed tomography (CT) scan is indicated in patients suspected of having the following:

1. CRS
2. Nasal polyposis
3. Unilateral sinusitis
4. Concern for malignancy
5. Cerebrospinal fluid (CSF) rhinorrhea and associated skull base defect

Indications

Diagnostic nasal endoscopy is indicated in patients suspected of the following:

1. Symptoms suggestive of CRS with or without polyposis

2. Acute bacterial rhinosinusitis

3. Unilateral symptoms

4. Concern for malignancy

Contraindications

1. Patients unable to tolerate rigid endoscopy; rare if adequate topical decongestion and anesthetic is used

2. Patients with hereditary hemorrhagic telangiectasia (HHT) require caution when performing endoscopy and if actively bleeding or with packing in place; endoscopy and control of epistaxis is best done in the operating room.

Preoperative Preparation

1. Topical anesthesia and decongestion should be administered before endoscopy (see section on Anesthesia).

2. Patients should be positioned appropriately for endoscopy (see section on Positioning).

3. Maxillofacial CT scan should be performed for patients with CRS, nasal polyposis, unilateral disease, CSF rhinorrhea/skull base defect, or any patient with concern for malignancy.

4. It is helpful to turn off the overhead lights for optimal visualization of the monitor during the procedure.

Anesthesia

1. Topical anesthesia can be accomplished with 4% lidocaine either via atomization into the nasal cavities or on pledgets.

2. Use of 2% tetracaine can be helpful in patients who require in-office procedure, débridement, or inadequate anesthesia with topical lidocaine.

3. Oxymetazoline is commonly added to the topical anesthetic to provide concomitant mucosal decongestion.

Positioning

Seated and reclined if possible with the patient head turned facing the physician. The patient, the screen, and the physician should be coaxial.

Perioperative Antibiotic Prophylaxis

None necessary

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Hopkins telescopes: 0-, 30-, 70-degree endoscopes. The 30-degree endoscope is the most popular scope, and, if available, a 2.9-mm scope allows for improved visualization of the sphenoethmoid recess and nasopharynx with minimal discomfort to the patient.

2. Flexible endoscope for patients who cannot tolerate rigid endoscopy or when the floor or anterior wall of the maxillary sinus cannot be fully examined with a rigid endoscope.

3. Topical decongestant and anesthetic. We prefer 4% lidocaine with oxymetazoline either on pledgets or via an atomizer. For patients who require débridement, biopsy, or in-office procedures, 2% tetracaine is preferred. The window of toxicity with tetracaine should be considered, with the use of doses not to exceed 100 mg.[1]

Key Anatomic Landmarks

1. Middle meatus

2. Sphenoethmoid recess

3. Nasopharynx

4. Inferior meatus

5. For patients who have had functional ESS (FESS), visualization of all sinus cavities should be performed.

Prerequisite Skills

1. Appropriate use of the rigid nasal endoscope to visualize key anatomic landmarks

2. Flexible laryngoscopy

Operative Risks

1. Epistaxis

2. Vasovagal episode

Surgical Technique

Allergic Rhinitis (Video 94.1)

1. After administration of topical decongestion and anesthetic, a 30-degree endoscope is used to examine the patient's nasal cavities.

2. The middle meatus is examined bilaterally to demonstrate the absence of polyps or mucopurulence. The nasopharynx appears clear.

3. Polypoid middle turbinates can be an indication of allergic rhinitis.

4. History should direct whether patients should undergo allergy testing. In this example, a 33-year-old male presented with bilateral nasal congestion with seasonal exacerbation in the spring and summer. Skin testing was positive for dust mite, cat, dog, Bermuda grass, Timothy grass, oak tree, and maple tree.

5. Typically in allergic rhinitis, turbinates have a pale edematous appearance. Erythematous mucosa suggests other etiologies, such as exposure to tobacco smoke, irritants, rhinitis medicamentosa, or food allergy.

Rhinitis Medicamentosa (Video 94.2)

1. This patient had been using oxymetazoline 2 or 3 times a day for several months.

2. Note the upregulation of seromucinous glands characterized as "cobblestoning" along the septum and the inferior turbinate.

3. The mucosa is typically erythematous and friable. Septal perforations can also be seen in patients with chronic use of a topical decongestant spray.

Acute Bacterial Rhinosinusitis With Endoscopically Directed Middle Meatal Culture (Video 94.3)

1. Patients presenting with mucopurulent drainage benefit from having an endoscopically directed culture obtained to facilitate decision making for antibiotic therapy.

2. Maxillary sinus taps (MSTs) have largely fallen out of favor as a preferred method for obtaining culture data.

3. A Calgi swab is bent at a 30-degree angle at the tip and followed to the middle meatus with a 30-degree endoscope. A 0-degree endoscope can be used if visualization is adequate.

4. The culture swab is inserted carefully so as not to contaminate it with bacteria from the nasal vestibule.

5. Typically, aerobic cultures only are necessary. For suspected odontogenic infections, anaerobic cultures are indicated.

Maxillary Sinus Tap in Acute Bacterial Sinusitis (Video 94.4)

1. This procedure is rarely needed due to endoscopic approaches that can be performed in the operating room or with balloon dilation techniques in the office for patients who cannot tolerate general anesthesia. Unilateral maxillary sinusitis should also raise the concern for an odontogenic source or obstructive mass. Imaging should be conducted

prior to instrumentation of the sinus. In this case of acute bacterial sinusitis, the nasal cavity is first anesthetized for an MST.

2. A cotton pledget with 4% Xylocaine and a few drops of epinephrine 1:1000 is placed into the nasal cavity.

3. After a few minutes, when the mucosa is partially decongested and anesthetized, this pledget is removed and a second pledget is placed under the inferior turbinate into the inferior meatus.

4. An ear curette is useful in positioning the pledget under the inferior turbinate. After this pledget has been in place for approximately 5 to 10 minutes, it is removed and 0.5 to 1 mL of 1% Xylocaine with 1:100,000 epinephrine is injected into the mucosa of the inferior meatus using a 1.5-inch long 25-gauge needle. This is usually painless after the topical anesthetic has been in place for 5 to 10 minutes.

5. Anesthetizing the inferior turbinate allows one to painlessly medialize the inferior turbinate, if needed, in the placement of either a 16- to 18-gauge spinal needle or a commercial antral tap trocar.

6. The antral tap trocar or needle is introduced through the thin bone in the lateral inferior meatus into the maxillary sinus. The bone is usually thin and easiest to penetrate in the superior lateral aspects of the inferior meatus.

7. Occasionally, very thick bone or nasal anatomy precludes inferior meatal antral tap. After the needle or trocar is introduced through the bone into the sinus, the trocar is removed and the purulent exudate is aspirated from the maxillary sinus with a syringe.

8. The aspirated specimen obtained is sent for Gram stain and aerobic and anaerobic cultures. Depending on the circumstances, such as in an immunocompromised patient or fungal sinusitis, fungal cultures should be obtained.

9. After the culture specimen is obtained, the sinus can be irrigated. If the sinus tap is free of secretions, then a small amount of sterile saline is introduced into the maxillary sinus and re-aspirated.

10. To irrigate the sinus, the patient is given a basin and asked to lean forward while the sinus is gently irrigated with 10 to 50 mL of sterile saline. If the procedure is uncomfortable to the patient, it should be

stopped because sometimes the outflow tract of the sinus is obstructed with edema, preventing fluid egress.

11. MST and irrigation can be not only diagnostic but also therapeutic. At the end of the irrigation, air is usually introduced into the sinus cavity. Topical antibiotics can also be introduced, if desired.

Chronic Bacterial Sinusitis With Biofilm (Video 94.5)

1. Occasionally, patients' sinus infections are refractory to both surgical and medical intervention.

2. The biofilm is readily apparent in this patient by rigid endoscopy with a 30-degree endoscope.

3. Patients with stenotic sinuses or purulence along the floor or anterior aspect of the sinus may require flexible fiberoptic examination for visualization and diagnosis.

4. Cultures of the purulent exudate can be obtained, and irrigation can be performed.

5. A 3-mm curved suction facilitates aspiration and irrigation of the sinus.

Complete Internal and External Nasal Valve Collapse With Inspiration (Video 94.6)

1. This patient demonstrates collapse of the nasal valve with inspiration, due to lack of support from the lower lateral cartilages.

2. Surgery of the septum and the inferior turbinates would not successfully resolve this situation.

3. The condition was treated with cartilage battens added to the lower lateral cartilages to strengthen them to prevent closure with inspiration.

4. The more rapidly a patient inspires, the more vigorous the closure of the nasal valve. This is due to the Bernoulli effect of a vacuum produced by increased velocity of the inspired air.

5. Patients who complain of nasal obstruction and in whom no site of obstruction is detected on physical examination with the nasal speculum

should be evaluated for nasal valve collapse.

Anterior Epistaxis (Video 94.7)

1. Epistaxis commonly occurs from the anterior nasal septum, often called Little area or Kiesselbach plexus.

2. In such a patient, the nasal cavity should be decongested and anesthetized with topical tetracaine 2% and oxymetazoline.

3. If the nose is actively bleeding, the source should be identified if possible and selectively cauterized with silver nitrate.

4. Opposing areas of the septum should not be cauterized, due to the risk of septal perforation.

5. Telangiectasias can also be a source of significant bleeding, often only visible as a 1- to 3-mm domelike lesion.

6. If gently touched with the silver nitrate stick, brisk bleeding will often then occur, identifying this as the source of epistaxis. Usually this is successfully treated with cauterization.

Septal Perforation With Placement of Nasal Septal Button (Video 94.8)

1. Symptomatic perforation bleeding and crusting can often be controlled with the placement of a Silastic septal button.

2. Septal buttons are commercially available through several manufacturers and are available in different sizes.

3. The septal perforation should first be measured, and then the button should be fashioned to fit the defect. Most perforations are not perfectly round but oval shaped, and therefore care should be taken to trim the button to the appropriate shape.

4. The nasal cavity is first anesthetized, and then, using the endoscope or a headlight for visualization, the button is introduced into the nose on one side.

5. The flange is extracted through the contralateral side, and then the button is positioned to optimally span the perforation.

6. Placement of a water-soluble antibiotic ointment to the nasal cavity daily may delay the formation of a bacterial biofilm.

7. However, crusting along the button may require removal. At this point the perforation may be sufficiently mucosalized, so there is no further bleeding or crusting.

Atrophic Rhinitis (Video 94.9)

1. Atrophic rhinitis is commonly caused by *Klebsiella ozaenae,* but other bacteria may be responsible.

2. *Citrobacter koseri* was cultured from this 80-year-old Cambodian woman with a 1-year history of a foul smell from her nose.

3. The nasal cavities can be débrided using Tobey forceps and using a 0- or 30-degree endoscope.

4. After extensive débridement of her nasal cavity, initiation of topical antibiotics directed toward the pathogen (gentamicin 80 mg per 500 mL of saline with 20-mL irrigations twice a day), and after several months of an oral fluoroquinolone, the patient's foul-smelling crusting resolved.

Eosinophilic Mucin Rhinosinusitis (Video 94.10)

1. Patients with refractory CRS with polyposis often present with eosinophilic mucin, as shown in this video.

2. This patient's evaluation via culture and pathology did not exhibit a bacterial or fungal etiology. Note the tenacity of the mucous secretions, which often show copious eosinophils and Charcot-Leyden crystals on pathology.

3. If the mucin is filling the sinus, local irrigation can help with removal of the tenacious secretions.

4. The mucin should be sent for histopathologic evaluation for the presence of fungi. Hyphae present in eosinophilic mucin in conjunction with elevated immunoglobulin E (IgE) to the cultured fungus are diagnostic of allergic fungal rhinosinusitis.

5. An attempt should be made to remove all eosinophilic mucin, if

possible, to help to remove the source of inflammation and allow for effective topical therapy.

Chronic Rhinosinusitis With Polyposis and In-Office Polypectomy (Video 94.11)

1. Patients with CRS have symptoms at least 12 weeks or longer of nasal obstruction, discolored drainage, facial pain/pressure, and diminished sense of smell.

2. Nasal endoscopy helps to confirm the diagnosis by determining whether the patient has polyps in the nasal cavity or the middle meatus or purulent mucous/edema in the middle meatus or anterior ethmoid area. Radiographic imaging showing inflammation can also confirm the diagnosis of CRS when endoscopy is normal and patients present with the symptoms described.

3. This patient's endoscopy (see Video 94.11) demonstrates polyps completely filling the nasal cavities. Unilateral polyps are concerning for tumor or possible encephalocele.

4. Polyps can be debulked in the office for appropriately selected patients who have nasal obstruction, are not appropriate candidates for general anesthesia, or who do not wish to undergo sinus surgery. Appropriate preparation as followed for FESS is applicable, including discontinuation of anticoagulation and pretreatment and posttreatment with oral steroids.

Sarcoidosis

1. A disorder of exclusion and of unclear etiology but assumed to be a reaction to a variety of antigens that induce noncaseating granulomas in the nose, skin, and lungs particularly but also other organ systems

2. This patient presented with cutaneous manifestations, as well as significant nasal crusting and inflammation as shown in this video.

3. *Staphylococcus aureus* is commonly cultured from these patients, and, with appropriate immunomodulatory therapy, topical steroids, and culture-directed antibiotics, patients can have improvement in their symptoms, as shown in the second endoscopic examination.

4. Sarcoidosis may be localized to the nose and have a remitting or active course. Systemic involvement without adequate diagnosis and treatment can be fatal.

5. On endoscopic examination of the nasal cavity, sarcoidosis should be suspected when the septal mucosa appears cobblestoned, reflecting very small collections of lymphocytes and submucosal granulomas. Crusting and mucopurulent secretions can also be seen.

6. Biopsy of the affected nasal lining can facilitate the diagnosis.

Granulomatosis With Polyangiitis, Formerly Referred to as Wegener Granulomatosis

1. A systemic disorder that is a form of vasculitis characterized by both granulomas and polyangiitis and if untreated has a high mortality rate secondary to pulmonary and renal damage

2. Patients often present with serous otitis media, as demonstrated in this video, as well as significant nasal inflammation with a friable lining and mucopurulent exudate present on nasal endoscopy.

3. After being appropriately treated with immunomodulator therapy, topical steroids, and culture-directed antibiotics, the patient can have reasonable control of disease, as shown in the subsequent nasal endoscopies.

4. The course is often one of remission and relapse. Early relapse can be suspected by return of nasal bleeding and excoriations, as well as evaluation of anti-neutrophil cytoplasmic antibody serology.

5. Biopsy of the affected nasal lining can facilitate the diagnosis.

Inverted Papilloma

1. The most common benign tumor of the nasal cavity, inverted papilloma, should be suspected with unilateral polypoid lesions and unilateral sinusitis.

2. Biopsy can be performed in the office, but a maxillofacial CT scan should be performed to rule out skull base dehiscence or other pathology.

3. The site of suspected inverted papilloma is first injected with 1% lidocaine with epinephrine 1:100,000, and the cup biopsy forceps are used to obtain the biopsy.

4. Localized bleeding can be controlled with oxymetazoline on pledgets.

Cicatricial Pemphigoid

1. In this patient with cicatricial pemphigoid, complete restenosis of the right side of her nose is seen and well over 50% restenosis of the left side despite several prior surgical procedures.

2. The left side of her nose is kept patent only with the insertion of a stent, which is only removed for cleaning and then is reinserted.

Common Errors in Technique

1. Inadequate decongestion and anesthesia leading to incomplete endoscopic examination

2. Improper positioning

3. Instrumentation and endoscope should move in tandem, and typically the instrument should be below the endoscope to allow for proper visualization.

Postoperative Management

1. Patients who undergo procedures in the office are advised to avoid nose blowing or strenuous activity.

2. Appropriate use of topical analgesics should eliminate the need for opioid medications.

Complications

1. Epistaxis can occur in patients with inadvertent abrasions to the mucosa during nasal endoscopy or in-office procedures.

2. Vasovagal episodes

Alternative Management Plan

1. Flexible endoscopy may be necessary in patients who cannot tolerate rigid endoscopy.

2. Management in the operating room for patients who require extensive débridement, extensive polypectomy, biopsy, control of epistaxis, or other procedures that would be difficult to accomplish in the office due to patient discomfort and equipment needs

Discussion

A large number of disorders can present with sinonasal manifestations, and therefore a careful history and a comprehensive physical examination, often including nasal endoscopy, are necessary. Patients often describe such symptoms as nasal congestion, facial pressure, and postnasal drainage that are quite common but may not correlate with objective findings.[2]

Nasal endoscopy is an important skill in the armamentarium of the otolaryngologist to accurately diagnose and treat patients with sinonasal disorders. Diagnostic nasal endoscopy can be facilitated by using adequate decongestion and topical anesthetic. We prefer to use 4% lidocaine with oxymetazoline on cotton pledgets and 2% tetracaine as an alternative to lidocaine in patients who require procedures including débridement post FESS.

A 2.9-mm endoscope is useful in patients who have not had prior surgery in order to obtain a comprehensive examination with minimal discomfort to the patient. Typically, a 30-degree endoscope is most useful for diagnostic nasal endoscopy and angled telescopes, such as the 45- and 70-degree endoscopes, to examine the maxillary and frontal sinuses in patients who have had prior surgery.

The most common procedures performed in-office include biopsies, control of epistaxis, endoscopically directed cultures, and, in appropriately selected patients, polypectomy, placement of septal buttons, and inferior turbinate reduction. With appropriate decongestion and topical anesthesia, these procedures can be successfully performed. However, patient selection is key in determining their tolerance for an in-

office procedure, and expectations should be fully discussed with the patient. Balloon dilation has recently emerged as an in-office procedure, but indications and patient selection need further clarification (see Chapter 10).

Maxillofacial CT scan is also a useful adjunct in patients in which CRS or recurrent acute rhinosinusitis is suspected but nasal endoscopy is negative. Patients with suspected tumors or unilateral disease also merit undergoing maxillofacial CT.[2] Odontogenic sinusitis is commonly missed, and careful attention to the dentition on imaging is important in making an accurate diagnosis.

Office-based diagnosis of sinonasal disorders is facilitated by a comprehensive history in conjunction with a complete physical examination, often including diagnostic nasal endoscopy. Validated symptom surveys can be a useful tool to assess and follow patients over time, as well as determine outcome from interventions. Often patients with sinonasal symptoms present with a disorder that impacts their quality of life, and as a result it is paramount to tailor interventions that are balanced with the severity of patient symptomatology, as well as provide a thoughtful dialogue on the role of medical management in chronic conditions.

Evidence-Based Medicine Question

Is MST comparable to endoscopically directed cultures to obtain an accurate result to diagnose and treat rhinosinusitis?

Endoscopically directed middle meatal (EDDM) culture has shown to be highly sensitive and accurate. A meta-analysis comparing MST to EDDM culture showed that EDMM had a sensitivity of 80.9%, specificity of 90.5%, positive predictive value of 82.6%, a negative predictive value of 89.4%, and an overall accuracy of 87.0%.[3] The authors concluded that EDMM may be a more sensitive culture method for diagnosis of pathogenic bacteria in acute bacterial rhinosinusitis and therefore preferred over MST.

Editorial Comment

This chapter provides an updated approach to in-office diagnosis of

patients presenting with sinonasal symptoms, the etiologies of which can range from common allergic rhinitis to rare but critical to diagnose disorders, such as sarcoidosis and GPA. BJ Ferguson was a thought leader in the field of rhinology and contributed important insights and practical guidance in the management of patients with these chronic disorders. She passed away during the writing of this chapter, and an attempt was made to best capture her insights in the completion of this work. Most important is the tailored management approach to patients and continuation of the conversation with patients regarding sinonasal disorders, which are often chronic and require thoughtful ongoing medical management.

Review Questions

1. A 42-year-old woman presents with uveitis, cough, and chronic nasal obstruction with crusting. Endoscopic evaluation reveals a cobblestone appearance and thickening of the nasal mucosal lining. What is the most likely diagnosis?

   a. Granulomatosis with polyangiitis

   b. Allergic fungal rhinosinusitis

   c. **Sarcoidosis**

   d. Allergic rhinitis

2. Patients with allergic rhinitis have characteristic findings of which of the following on endoscopy?

   a. Mucopurulence

   b. **Polypoid middle turbinate**

   c. Erythematous friable lining

   d. Telangiectasias

3. A 33-year-old man with cough, frequent epistaxis, and friable lining on endoscopy with enlarged blood vessels should be suspected of having which of the following disorders?

a. Allergic fungal rhinosinusitis

b. Nasal polyposis

c. **Granulomatosis with polyangiitis**

d. Cicatricial pemphigoid

4. Frequent and long-term use of oxymetazoline may lead to which of the following endoscopic findings?

a. Nasal polyposis

b. **Erythematous nasal mucosal lining with inflammation**

c. Pale boggy inferior turbinates

d. Telangiectasias

5. Allergic fungal rhinosinusitis is usually associated with which of the following endoscopic findings?

a. Thin, watery drainage

b. **Tenacious thick eosinophilic mucin**

c. Telangiectasias

d. Cobblestoning of the septum

Septoplasty—Classic and Endoscopic

Grant S. Gillman, and Stella E. Lee

Introduction

The most common structural cause of persistent nasal obstruction unresponsive to nasal decongestants or medical therapy is a deformity of the nasal septum.

Septal deformities may be cartilaginous, bony, or both, with tilts to the septum, curves, spurs, twists, angulations, telescoping segments, or any combination thereof. A septal deviation can be observed within a nasal framework that is straight externally, crooked, twisted, or collapsed and with compromise at the internal nasal valve, the external nasal valve, both, or neither. One must realize, therefore, that there is no single operation that will remedy all septal deviations and that some may in fact require application of more complex functional rhinoplasty techniques. In all cases, astute evaluation and flexibility in technique are the essential foundation for improved outcomes.

In this chapter we endeavor to provide guidance for the more basic or routine deformities and correction via classic (endonasal) and endoscopic approaches. The techniques of endoscopic septoplasty can be useful in addition to classical endonasal techniques, especially in patients who also require concomitant endoscopic sinus surgery. Endoscopic septoplasty can provide excellent visualization of the anatomy and can be successfully incorporated into the existing armamentarium of the endoscopic sinus surgeon. This chapter also provides recommendations on how to identify deformities that warrant more advanced surgical intervention to minimize failure and maximize success rates.

Key Operative Learning Points

1. Elevation of the mucosal flaps in the correct plane is crucial for performing the procedure with the classical endonasal or endoscopic technique.

2. Careful dissection through grooves and around angles or spurs will minimize the risk of mucosal tears and possible septal perforation. To whatever extent is possible, mucosal tears should be repaired when quilting the septal flaps at the end of the procedure.

3. Preoperatively and intraoperatively, attention should be focused specifically at the common sites of failure: curvatures within the dorsal septal strut and caudal septal deviations. Deviations within these areas can be subtle but nonetheless have a significant impact on airflow secondary to high resistance in these areas (the internal and external nasal valves).

4. With the endoscopic approach:

   a. Once the flap is elevated appropriately, it is helpful to keep an instrument or scope in the plane of dissection to facilitate visualization and limit manipulation of the flap.

   b. The axilla of the middle turbinate should be visualized bilaterally once the deviation has been corrected to allow for appropriate access, especially if frontal sinus surgery is necessary.

Preoperative Period

History

1. History of present illness

   a. Most troublesome symptoms: This helps in direct counseling and expectations of what surgery can and cannot achieve.

   b. Duration of obstruction

   c. Laterality, if any: Most often, symptoms will be worse on one side, but S-shaped septal deflections can compromise both sides of the nasal airway.

   d. Specific symptoms: Nasal obstruction, hyposmia, epistaxis, facial pressure/pain, nasal discharge/postnasal drip

e. Use of any topical medications (e.g., nasal steroid sprays) and response

f. Trial and effect of nasal dilating strips

g. History of environmental allergy

2. Past medical history

a. Prior nasal surgery, cosmetic or functional, increases the index of suspicion for loss of volume or support of upper or lower lateral cartilages and implies greater scarring between previously elevated mucosal flaps and therefore higher risk of mucosal tears.

b. Prior nasal trauma: Depending on physical findings, prior trauma may require application of functional septorhinoplasty techniques for optimal correction of the nasal airway.

c. Medical illnesses

d. Medications:

1) Antiplatelet drugs

2) Herbal products

3) Alcohol

4) Smoking cigarettes

Physical Examination

1. Observation: Breathing at rest and with moderately forceful inspiration to assess stability of nasal sidewall for static or dynamic collapse

2. Anterior rhinoscopy to enable description of the septal deflection (tilt, curves, angulation, spurs, grooves, location). This should include critical evaluation of the position of the caudal septum and patency/obstruction of the angle of the internal valve.

3. Palpation of caudal septum to clarify position, orientation with respect to dorsal strut, strength, and angulation if any

4. Nasal endoscopy to evaluate for other sources of obstruction (e.g., sinonasal mass, polyposis, adenoid hypertrophy) and document pre-existing septal perforation if present. An endoscopic evaluation involves

three “passes” of the endoscope:

a. Along the floor of the nose to inspect the inferior turbinate, inferior meatus, nasolacrimal duct, and nasopharynx (fossa of Rosenmuller and Eustachian tube orifice)

b. Toward the middle turbinate, examining the middle meatus, ethmoid bulla, uncinate and lateral nasal wall, sphenoethmoidal recess, superior turbinate, and sphenoid os

c. Superiorly toward the olfactory cleft (often with a 30-degree endoscope)

Overall, the physical examination should enable the surgeon to describe the cartilaginous and bony septal deformity in detail, with particular note made of deviations of the dorsal or caudal septum, obstruction impacting the internal or external nasal valve, and/or instability of the nasal sidewall.

Upon completion of the physical examination, the surgeon should be able to recognize the more complex septal deformity for which “routine” septoplasty might prove to be inadequate. This is an essential part of minimizing failure or revision rates. Circumstances that present a higher risk for surgical failure, for which a more involved operation (functional septorhinoplasty) might be more appropriate, are more readily identifiable at the completion of the examination by routinely asking the following questions:

- Is there a nasal valve problem?
- Is there a dorsal septal deviation?
- Is there a caudal septal deviation?
- Are there complex deformities in regions that provide critical support to the nasal dorsum or tip that cannot be treated with conventional excisional techniques and require reconstruction or reimplantation of cartilage?

Imaging

Imaging is not routinely required in the evaluation of the deviated septum unless one is concerned about alternative sources of nasal

obstruction or evaluating for concomitant sinus disease, in which case a dedicated maxillofacial computed tomography (CT) scan would be warranted.

Indications

1. Symptomatic nasal airway obstruction with a deviated nasal septum
2. Access to paranasal sinuses for endoscopic sinus surgery
3. Sphenoid sinus/pituitary access
4. Management of epistaxis posterior to a septal deflection

Contraindications

1. Unfit for general anesthesia (medical comorbidities)
2. Uncorrectable coagulopathy or use of anticoagulants that cannot be held through the perioperative period

Preoperative Preparation

1. Discontinue antiplatelet drugs.
2. Coagulation profile if there is a history of excessive bleeding
3. Medical clearance if necessary
4. Preoperative counseling regarding the procedure, risks, and complications

Operative Period

Anesthesia

Although septoplasty can be done with good topical and local anesthesia, general anesthesia maximizes patient comfort and optimizes airway protection, which is particularly important in the setting of anticipated intraoperative bleeding. An oral RAE tube is preferred for intubation

because the preformed contour allows it to rest tension-free in the midline.

Positioning

Supine

With the endoscopic approach:

1. The surgeon, the patient, and the screens from which the surgeon is operating (image guidance and endoscopic view) should be in a common axis for optimal visualization and instrumentation.
2. The head of the bed is elevated to 20 to 30 degrees to assist with venous congestion and tilted 15 degrees to the surgeon's side.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Clindamycin or gentamicin if the patient is allergic to penicillin

Monitoring

Hemodynamic monitoring (anesthesiology). Although exceptions may be made due to cardiovascular status and medical history, maintaining a heart rate at 60 beats/minute and mean arterial pressure of 60 mm Hg is felt to be safe and effective at reducing bleeding.

Instruments and Equipment to Have Available

1. Basic septorhinoplasty set

2. Tower, camera, and 0- and 30-degree telescopes (endoscopic technique)

Key Anatomic Landmarks

1. Submucoperichondrial plane when elevating flap

2. Bony-cartilaginous junction

3. Perpendicular plate of the ethmoid bone, vomer, and maxillary crest

4. Internal nasal valve, external nasal valve (nasal vestibule)

Prerequisite Skills

1. Familiarity and comfort with septal anatomy

2. Functional septorhinoplasty experience for more complex septal reconstruction

3. Basic endoscopic skills

Operative Risks

1. Disarticulation of quadrangular cartilage from the perpendicular plate of the ethmoid bone (separation carried too far anteriorly) with loss of dorsal height (supratip depression)

2. Mucosal tears

3. Loss of dorsal/tip support (overly aggressive resection of cartilaginous struts)

Surgical Technique: Classic Septoplasty

1. Anterior rhinoscopy: Following the induction of general anesthesia, the nose should be reexamined (rhinoscopy) and the caudal septum palpated (to establish strength, position, and shape) to confirm prior clinical findings.

2. Injection: Inject the septum bilaterally with 1% lidocaine with 1:100,000 epinephrine (typically 5 to 10 mL), then decongest the nose with oxymetazoline-soaked pledgets. The cottonoids are left in place for 10 to 15 minutes to maximize vasoconstriction.

3. Incision: Once the table is turned and the patient is draped, a small speculum is used to expose the caudal end of the septum and a

hemitransfixion incision is made along the free caudal edge using a number 15 blade (Fig. 95.1). Typically a left-sided access incision is preferred, although this can vary with surgical preference. If the caudal septum is extremely deviated into the right nares and therefore relatively inaccessible from the left, then a right-sided hemitransfixion is used. The incision is carried through the perichondrium to expose the ice-blue color of the septal cartilage.

4. Flap elevation: Submucoperichondrial and submucoperiosteal flaps are elevated bilaterally using Woodson and Cottle elevators (Fig. 95.2). The dissection pocket is visualized directly with the benefit of a smaller speculum lower in the nose, transitioning to a medium-length Killian speculum further back in the nose. The flap elevation is begun using a Woodson elevator and transitions to a Cottle elevator when working farther posterior in the nose where it is easier to see over the flatter profile of the Cottle elevator. In the proper plane, the dissection is fairly quick and relatively bloodless. Bilateral flap elevation is felt to be advantageous for several reasons: optimizing exposure, maximizing release of deforming mucosal tension, and enhancing surgical access for more complicated correction or reconstruction of complex septal deformities. Flap elevation must be done cautiously to minimize the risk of inadvertent mucosal tears.

FIG. 95.1 Site of a left hemitransfixion incision along the caudal edge of the septum.

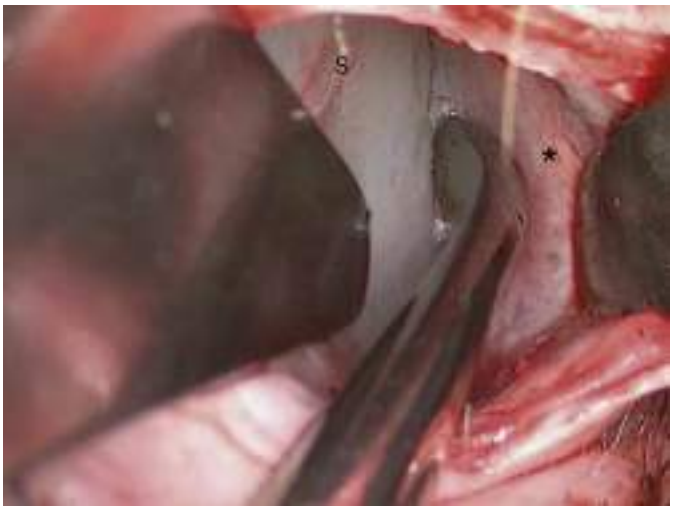

FIG. 95.2 Speculum in place showing elevation of the left submucoperichondrial flap. Septal cartilage *(S)* is seen to the left of the Woodson elevator and the mucosal flap *(asterisk)* to the right.

5. Reassess: At this point, another intraoperative assessment of the septum is carried out to get a better sense of the nature of the septal deformity and which deforming forces must be overcome to correct the septal alignment.

6. Correcting the septum: Working sequentially from the posterior nasal airway toward the caudal septum is preferred. Because alterations or manipulation of the caudal septum is potentially more disruptive to tip support, it is better to address those last and reconstruct that area as needed without the need to do more work farther back in the nose, which might destabilize a reconstructed caudal septum at that point.

7. Intraoperative checklist: In every case, the same system is consistently applied to analyze the nasal airway as the surgery proceeds. Having a system in place will focus attention in a deliberate way and reduce the chance of leaving a persistent deflection unattended or overlooked. Specifically, as the surgery proceeds from back to front, the author evaluates the following:

a. Is the nasal airway open at the back (typically bony septal deviations)?

b. Is the nose open anteriorly (dorsally) through the nasal valve? If the root of the middle turbinate can be easily visualized without having

to pass a speculum too far into the nasal cavity or without opening the nasal speculum too forcibly, then one can be reassured that airflow will move easily through the internal nasal valve. This is a common site of failure, and even modest deviations in the valve region should be addressed.

c. Is the nose open along the floor (typically spurs of maxillary crest or displacements of quadrangular cartilage over crest)?

d. Is the caudal septum straight and maintaining a tension-free position in the midline?

8. Separate the quadrangular cartilage from the bony septum: Applying steady pressure with the Cottle elevator, the quadrangular cartilage will separate from the bony septum (perpendicular plate of the ethmoid) posteriorly. The separation is carried to within 1 to 1.5 cm of the nasal dorsum (Fig. 95.3). Care is exercised not to completely disarticulate the two.

9. Removal of the deflected perpendicular plate of ethmoid and vomer: If the bone is at all off-center, the rigid nature of the bone will overpower the softer more pliable nature of the attached cartilage, tethering it into a sustained nonmidline position. Bone removal must therefore be as complete as deemed necessary rather than overly conservative. Whenever possible, superior cuts in the bone should be made sharply to avoid the very rare complication of fracturing the cribriform plate and creating a cerebrospinal fluid fistula. Using double-action scissors, cuts are made high (dorsally) and low (over the maxillary crest), and the intervening deflected segment is removed using a double-action rongeur (see Fig. 95.3). Reassessment of the nasal airway bilaterally follows.

10. Cartilage removal: If there is a persistent deviation of the quadrangular cartilage, incisions are made and cartilage removal proceeds as necessary. Under direct vision and using a number 15 blade, one incision is made in the cartilage paralleling the nasal dorsum and another incision is made paralleling the caudal septal edge/columella, outlining the segment of cartilage to be removed. Remove as little cartilage as is needed to improve the nasal airway. At a minimum, cartilage removal should preserve at least a 1-cm dorsal septal strut and a 1-cm caudal septal strut. This is critical to maintain adequate support to the nasal tip and dorsum to minimize the risk of postoperative settling of

the supratip dorsum (saddle deformity). If a determination is made preoperatively that a clinically significant curvature or angulation exists within the dorsal 1 cm of the quadrangular cartilage, then the surgeon should consider correcting the nasal airway through an external functional septorhinoplasty approach or referring this patient to a surgeon who is capable of such. An external rhinoplasty approach gives the surgeon maximal exposure to correct, divide, excise, and/or reconstruct the dorsal septal strut as needed. Removed cartilage segments that are reasonably straight (but were off the midline and hence excised) can be replaced between the septal flaps for added septal support prior to quilting the mucosal flaps. In such cases the returned segment should be positioned above the caudal strut and behind the dorsal strut to minimize inadvertent obstruction that might arise from an overlap.

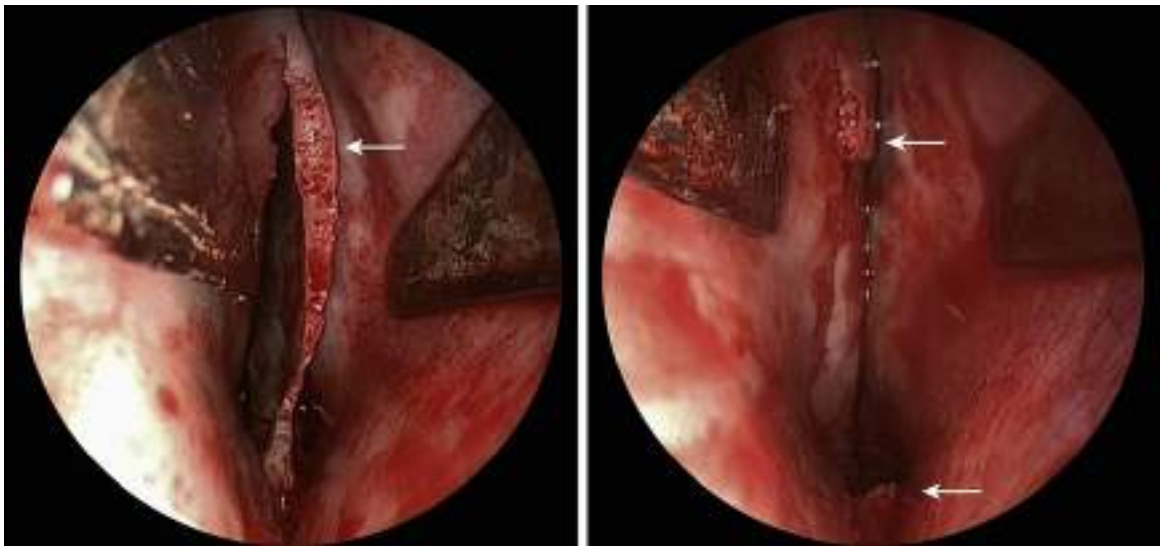

FIG. 95.3 Left image: separation of quadrangular cartilage (being displaced to the left of the speculum) from the perpendicular plate of ethmoid bone (edge indicated by *arrow*). Right image: high and low bone cuts *(arrows)* with removal of intervening bony segment.

11. Removal of inferior bony septal spurs (maxillary crest): The surgeon must decide whether a spur or localized deviation of the maxillary crest is of a magnitude that might contribute to airway compromise. Smaller deviations toward the floor of the nose are often asymptomatic, unlike

smaller deviations dorsally toward the internal nasal valve. Larger spurs, spurs that contact the inferior turbinate, or crest deviations that create a secondary deviation of the overlying quadrangular cartilage should be removed. Bilateral elevation of the mucoperiosteum over the lateral aspect of the crest can be tedious and must be done carefully because the mucosa tends to be thinner and more adherent to the bone as compared to cartilage. The deviated crest can then be removed with a double-action rongeur or a 4- to 6-mm chisel or osteotome.

12. Correction of caudal septal deformities: Severe angulation or rotation of the caudal strut off the midline sagittal plane should be readily identifiable at the preoperative consultation. Routine palpation of the caudal septum provides valuable insight over and above anterior rhinoscopy and will distinguish those deformities that would not be correctable with "traditional" excisional surgery or submucous resection. An external functional septorhinoplasty approach should be considered for more extreme caudal septal deformities to minimize the likelihood of surgical failure, patient dissatisfaction, and the need for more difficult revision surgery in the future. The caudal septum that is tilted or displaced off the anterior nasal spine or gently bowed or curved is very amenable to an endonasal correction. Likewise, if there is a mild to moderate angulation (as opposed to curvature) in the midportion of the caudal septum, where the caudal edge of the septum is still directed inferiorly and the apex of the fracture is directed laterally, this can be addressed endonasally. On the other hand, if the fracture/angulation extends along an anteroposterior vector through the junction of the caudal and dorsal septum, the caudal septal segment may be completely rotated off the axis of the dorsal septum. In this circumstance the caudal edge of the septum will not be directed inferiorly but will be oriented laterally toward the nasal sidewall and inferior turbinate instead. This type of caudal septal deviation can always be identified preoperatively with a thoughtful and thorough examination. A more radical caudal septal deviation such as this may require complete transection (explanting) of the caudal septum from the dorsal septum with reorientation and restabilization of the native segment or replacement of that segment with a separate free cartilage replacement graft and then restabilization. This can be done endonasally (but it is very challenging and requires significant experience to execute) or through an external rhinoplasty approach. Such cases can jeopardize dorsal and tip support

and as such are best attended to by surgeons experienced in reconstructive nasal airway surgery and comfortable with external approach reconstructive rhinoplasty. This will not be covered in this chapter. Caudal septal deformities are better appreciated and more readily corrected with the benefit of bilateral mucosal flap elevation.For the caudal septum that is merely tilted off the anterior nasal spine or gently bowed to one side, conservatively removing a small wedge of cartilage over the anterior nasal spine and thus shortening the posterior end of the caudal strut—nominally and conservatively—will enable movement to a midline position over the anterior nasal spine (Figs. 95.4 and 95.5). This resection is typically no more than 2 to 3 mm. The goal is to allow the caudal strut to sit tension-free right over (in contact with) the anterior nasal spine but not to hang well above it. This reduces the chance of posterior settling of the supratip dorsum and a visible dorsal depression. If the reduction is inadequate, however, the tilt or curve may persist, or the patient may complain that there is movement and "clicking" in that region as the posterior septal edge contacts or moves across the spine.For the caudal septum that is angulated (as one might see with a prior fracture), removing a small wedge above the anterior nasal spine and crest as described previously does nothing to remove the angulation and will therefore prove to be inadequate. In such cases the surgeon must transect the caudal strut along a cephalocaudal vector, through the apex of the fracture line. The caudal septum thus becomes two segments, one anterior (contiguous with the dorsal strut) and one posterior (attached at the nasal spine). The excess length will allow the two segments to be overlapped and suture secured to one another to strengthen the caudal strut. Typically one will have to try the two overlap options (posterior segment to the left of anterior segment and vice versa) to establish which arrangement is most favorable to airway patency. An alternative to overlapping is to excise the excess cartilage so that the two segments rest end to end. That junction is stabilized by using harvested septal cartilage to fashion a reinforcement batten graft, which is then sutured in place on one side or the other to bridge the two segments (Fig. 95.6).

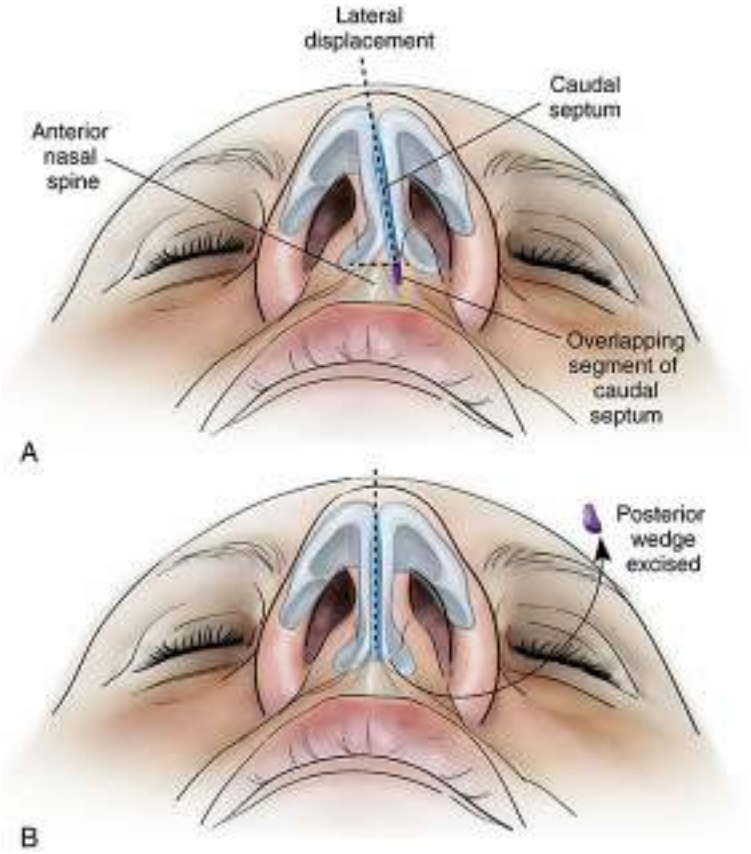

FIG. 95.4 When the caudal septum is tilted/displaced over the anterior nasal spine (A), excising a small wedge of cartilage—incrementally and conservatively—will allow the caudal strut to move into a midline position immediately atop the nasal spine (B). Adapted with permission from Kennedy DW, Myers EN(eds): Master Techniques in Otolaryngology Head and Neck Surgery: Rhinology. 1st ed. Wolters Kluwer; 2016.

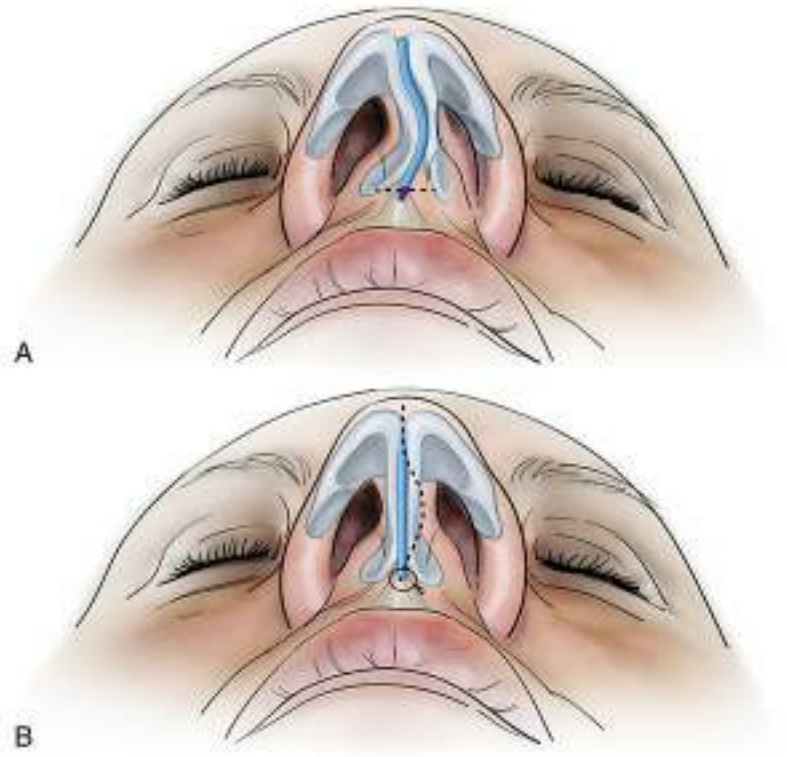

FIG. 95.5 Conservatively shortening the gently curved or bowed caudal septum above the anterior nasal spine (A) will allow the bowed segment to release, straighten, and assume a midline position (B). Adapted with permission from Kennedy DW, Myers EN(eds): Master Techniques in Otolaryngology Head and Neck Surgery: Rhinology. 1st ed. Wolters Kluwer; 2016.

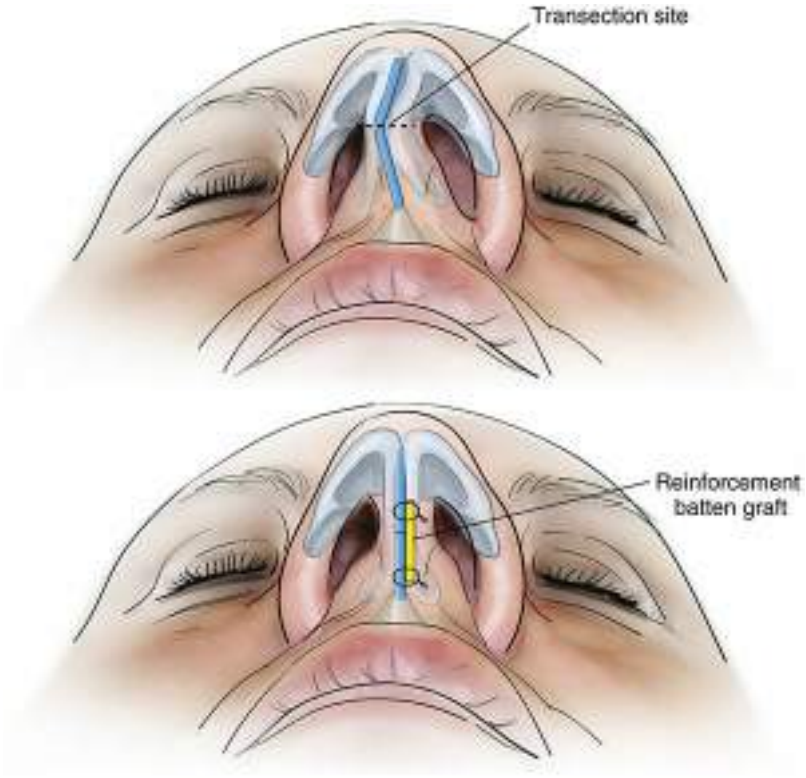

FIG. 95.6 The angulated caudal septum is divided through the apex of the angulation (A). The anterior and posterior segments can then be overlapped and suture-secured to one another. Alternatively, the overlap can be excised and the two segments aligned end to end and stabilized with a sutured-in-place batten (reinforcement) graft (B). Adapted with permission from Kennedy DW, Myers EN(eds): Master Techniques in Otolaryngology Head and Neck Surgery: Rhinology. 1st ed. Wolters Kluwer; 2016.

13. Septal flaps: The septal flaps from either side are quilted to one another with a running through-and-through 4-0 plain gut suture. The hemitransfixion incision is closed with simple interrupted 5-0 plain gut, through-and-through 4-0 plain gut septocolumellar sutures, or a combination thereof.

14. Placement of Doyle splints: Doyle splints are placed on either side of the septum and stabilized with a through-and-through 3-0 Prolene suture.

Surgical Technique: Endoscopic Septoplasty

1. Once the submucoperichondrial plane is elevated anteriorly to create a pocket large enough to allow for introduction of the endoscope (approximately 2 to 3 cm; see Fig. 5.1), the dissection at this point transitions to the endoscopic technique (Fig. 95.7).

2. A Cottle elevator is used to elevate the flaps bilaterally (Fig. 95.8). If the caudal septum is not affected by the septal deformity (e.g., superior deviation of the perpendicular plate of the ethmoid limiting the view for a frontal sinus dissection or a posterior bony spur), the flap is only raised caudally on one side, and the cartilaginous septum is traversed to the opposite side more posteriorly without disruption of the mucoperichondrial attachments of the caudal septum.

3. The location of the traversing incision is measured with an intranasal view from the nasal columella to the site just anterior to the deviation using the Cottle elevator.

FIG. 95.7 The endoscopic views are demonstrated with a 0-degree Hopkins telescope. (Mucosal flap to the *right* of suction, quadrangular cartilage to the *left*.)

4. The deviated portion of the cartilaginous septum is removed with a Ballenger swivel knife or through-cutting straight Blakesley forceps taking care to preserve the cartilaginous strut.

5. Deviation of the bony septum is removed by creating a cut superiorly

with double-action scissors. The double-action scissors should be introduced into the flap with the jaws oriented in a vertical fashion to prevent injury laterally to the middle turbinates.

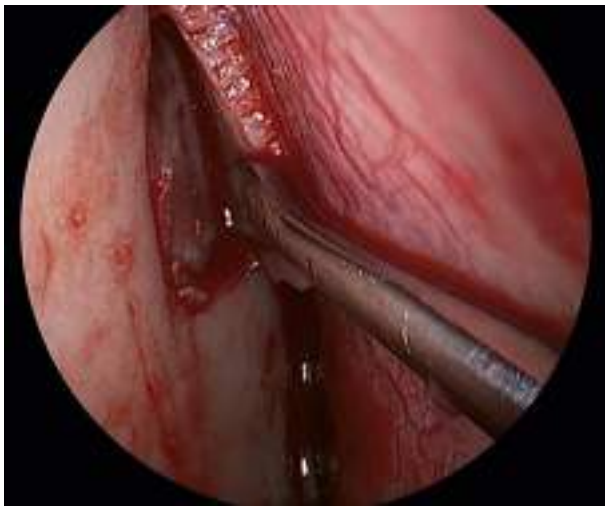

FIG. 95.8 Flap elevation bilaterally is performed with a Cottle elevator.

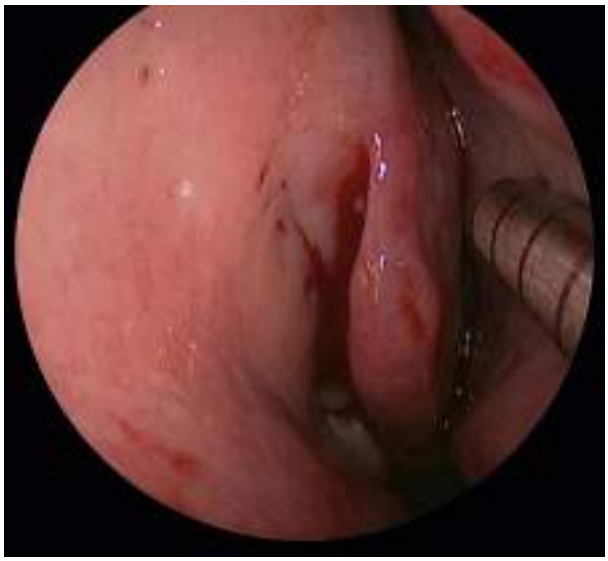

FIG. 95.9 The axilla of the middle turbinate can now be visualized, which allows for access to the paranasal sinuses, especially to the frontal sinus.

6. Once the deviated portion of the septum is removed appropriately, the

axilla of the middle turbinates should be visible bilaterally (Fig. 95.9). This is important should the patient require a frontal sinus surgery.

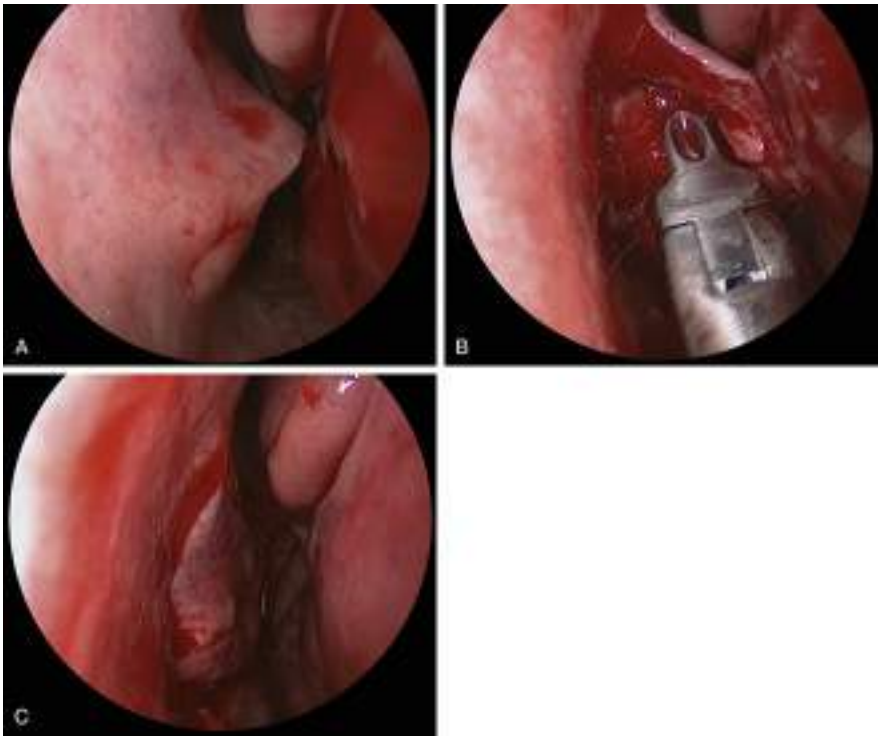

FIG. 95.10 **A** to **C,** Localized flaps can be raised to remove obstructive bony spurs, obviating the need for large flap elevation.

7. Isolated septal spurs can be removed by elevating a C-shaped flap anterior to the spur in appropriate cases and removal of the spur with through-cutting Blakesley or Gruenwald forceps while preserving the overlying mucosa (Fig. 95.10A to C).

8. The anterior hemitransfixion incision is closed with a series of interrupted 5-0 fast-absorbing suture, and the septal flaps are reapproximated with a quilting 4-0 plain gut suture.

9. The middle turbinates can also be included in the quilting suture by pexy to the septum to prevent lateralization.

10. Doyle splints are then placed into the nose bilaterally and secured anteriorly with 3-0 Prolene. The endoscope is used to ensure that the splints do not cause lateralization of the middle turbinate. The most superior/posterior portion of the splint can be trimmed to ensure that the

splint does not disrupt the pexy suture.

Common Errors in Technique

1. Improper elevation of the mucosal flap

2. Failure to achieve complete exposure of the septal deviation

3. Inadequate resection of the bony deviation leading to persistent septal deviation

4. Inattention to septal shift dorsally or caudally leading to persistent septal obstruction at the internal or external valve, respectively

Postoperative Period

Postoperative Management

1. Patients are typically discharged the day of surgery.

2. Antibiotic coverage for *Staphylococcus aureus* is used while splints are in place.

3. Patients are instructed to irrigate the intranasal splints with a high-volume (8 oz) saline solution 3 to 4 times daily. After each rinse, the nasal vestibule is cleaned of any loose/clotted blood with a cotton swab soaked in hydrogen peroxide, following which an over-the-counter antibiotic ointment is applied inside the nares to moisturize the nose. This regimen helps keep the splints clear, thus maximizing comfort and enabling the patient to breathe through the splints.

4. The intranasal splints are removed at 5 to 7 days postoperatively.

Complications

1. Excess postoperative bleeding: Bleeding may respond to a topical vasoconstrictor spray (e.g., oxymetazoline) or gentle packing over the splints with absorbable woven hemostatic mesh (e.g., Surgicel). Continued bleeding will require splint removal and cauterization if the focal site is identifiable or exploration in the operating room.

2. Sinusitis: Should the patient develop sinusitis, culture-directed antibiotics are preferable. If not available, amoxicillin-clavulanate is recommended per current guidelines or, in penicillin-allergic patients, doxycycline.

3. Septal perforation: This is generally preventable with meticulous elevation of intact mucosal flaps and repair of any incidental mucosal tear.

4. Septal hematoma: Suture quilting the septal flaps from one side to the other eliminates the surgical dead space and minimizes the chance of septal hematoma. If intraoperative bleeding or oozing between septal flaps is felt to be excessive, a small venting stab incision should be made in the septal mucosa posteriorly if there are no inadvertent mucosal tears. Should a hematoma develop, as suggested by increasing pain, nasal congestion, and visible bilateral distention or swelling of the septum, aspiration with an 18-gauge needle is reasonable in an effort to evacuate the hematoma. If drainage is incomplete or limited, early surgical exploration and drainage are essential. An unrecognized hematoma can lead to pressure ischemia, loss of the remaining septal cartilage, and a saddle nose deformity.

5. Toxic shock syndrome: This has been reported in patients with and without nasal packing following nasal septoplasty and is thought to be due to colonization of the nasal packing by *S. aureus*, which produces exotoxin. There does not appear to be an absolutely certain way to prevent this complication. If a patient reports early fever, serious diarrhea, or ischemia of the limbs, evaluation for toxic shock syndrome should be done immediately. The packing should be removed and cultured, antistaphylococcal antibiotics should be administered, and careful observation and intervention should be done as needed. Nasal packing post septoplasty is rarely necessary, however, with the availability of silastic splints.

6. Cerebrospinal fluid (CSF) leak: This situation is very uncommon and is likely attributable to avulsion of the perpendicular plate of the ethmoid and its attachment to the cribriform plate. This can be avoided by not avulsing any bone or cartilage unless a superior cut has already been made from the perpendicular plate of the ethmoid bone.

7. Anosmia: This condition is rare and spurious, with a quoted incidence

of 1 in 1,000,000.

8. Need for secondary/revision surgery: Such surgery might be required for persistent symptomatic obstruction.

9. Change in external appearance: Loss of height of the dorsal septum (mild saddle deformity) can result from disarticulation of the quadrangular cartilage from the perpendicular plate of the ethmoid bone at the keystone area (rhinion), from posterior settling of the caudal and dorsal septal struts, or from overly aggressive reduction of dorsal strut height. Although infrequent, a crushed cartilage onlay graft placed over the dorsal septum through an intercartilaginous incision can camouflage the external deformity.

Alternative Management Plan

1. Medical management
   a. Screening and evaluation for allergic rhinitis or inferior turbinate hypertrophy
   b. Trial of a topical nasal steroid spray and oral antihistamine if a history of allergic rhinitis is present
   c. Patients whose conditions warrant exception from a preoperative trial of medical therapy include those without obvious history of inflammatory disease and a significant anatomic deformity that suggests that surgical correction would be best suited for the patient.

Discussion

Evidence-Based Medicine Question

Has septoplasty been shown to be an effective intervention for the relief of symptomatic nasal obstruction in patients with a deviated septum?

Prior to 2004, most reports of outcomes of septal surgery were limited by study design: They were often retrospective, relied only on chart reviews or telephone follow-up surveys, depended on physician-rated outcomes rather than patient-reported satisfaction, and used nonvalidated outcome measures. In 2004, Stewart et al. developed and

validated a disease-specific outcome instrument to evaluate interventions in patients with nasal obstruction.[1] The nasal obstruction symptom evaluation (NOSE) scale has since become a useful tool in that regard. The NOSE scale has been used to show that patients undergoing primary[2] or revision[3] septoplasty demonstrate statistically significant improvements in nasal obstruction and corresponding NOSE scores postoperatively, with high degrees of patient satisfaction. As with any operation, however, proper patient selection and an individualized surgical plan are paramount.

Editorial Comment

Drs. Gillman and Lee have written a very practical and useful review of the endonasal and endoscopic approach to septoplasty. During residency training it is often felt that septoplasty is a very "doable" procedure, even for junior residents with little prior exposure to nasal surgery. However, those of us who have struggled with a challenging septoplasty know this is not the case! Septoplasty surgery can be humbling to the surgeon and unsatisfying to the patient due to inadequate planning or execution. Many of the classical errors of septoplasty surgery can be avoided by heeding the conceptual pathways presented in this chapter. In addition to providing an overall approach to the procedure, the authors provide many nuanced points that are commonly gleaned only after years of experience. The section on endoscopic septoplasty will be of particular interest to surgeons not familiar with this approach.

Review Questions

1. Disproportionate and increasing postoperative pain, congestion, and nasal swelling should make one think of which option?

   a. Septal perforation

   b. Excessive postoperative edema

   c. Munchausen syndrome

d. **Septal hematoma**

e. Drug-seeking behavior

2. The most common sites of failure in routine septoplasty surgery are persistent deviation within which of the following?

   a. Dorsal septum

   b. Maxillary crest

   c. Caudal septum

   d. Ascending process of the maxilla

   e. **(a) and (c)**

3. Which option is an intranasal anatomic reference point frequently used in endoscopic septoplasty?

   a. Crista galli

   b. Head of the inferior turbinate

   c. Septal body

   d. **Axilla of the middle turbinate**

   e. Infundibulum

Nasal Septal Perforation

Brian Lee, Thomas J. Willson, and Stella E. Lee

Introduction

The nasal septum plays an important role in the structural and physiologic functions of the nose, contributing to nasal shape, appearance, and laminar airflow. The septum is made up of three distinct layers. Superficially, the mucosa is made up of ciliated respiratory epithelium. High in the nasal vault, in the region of the olfactory cleft, the mucosa is incorporated with specialized olfactory epithelium. Deep to this layer lies the mucoperichondrial/mucoperiosteal layers that contain the vascular network. Finally, the deepest layer is made up of a caudally located quadrangular cartilage and a confluence of bony projections posteriorly (vomer, perpendicular plate of the ethmoid, maxillary, and palatine bones).

The blood supply of the septum is a complex and robust anastomotic network derived from multiple sources. The primary supply is derived from terminal branches of the external carotid system, chiefly the internal maxillary artery, with secondary supply from the facial artery. The internal maxillary artery traverses the pterygopalatine fossa and enters the nose via the sphenopalatine foramen as the sphenopalatine artery. Posteriorly, the posterior septal branch of the sphenopalatine artery traverses the sphenoid rostrum to supply the septum. Inferiorly, the greater palatine artery, a branch of the internal maxillary artery, anastomoses with the inferior septal branches after traversing through the incisive foramen. Superiorly, the anterior and posterior ethmoid arteries, both branches of the ophthalmic artery, descend into the septum. Anteriorly, the superior labial artery, a branch of the facial artery, provides additional vasculature to the septum. Blood courses through this anastomosing network enveloped within the perichondrial and periosteal layers (Fig. 96.1).

Disruption of this blood supply to the underlying avascular cartilage may lead to subsequent necrosis. If this occurs bilaterally, in opposing locations, a perforation may form. A nasal septal perforation is a sagittal-oriented, three-dimensional defect that involves the quadrangular cartilage and/or bone (perpendicular plate of the ethmoid, vomer, maxillary, and palatine bones), as well as the bilateral overlying respiratory epithelium (mucoperichondrium and mucoperiosteum) (see Fig. 96.1). The numerous causes of septal perforations can be categorized into traumatic, iatrogenic, infectious, inflammatory, neoplastic, vasoconstrictive, and caustic etiologies (Box 96.1). Of all these listed, iatrogenic injury during septoplasty and nasal septal cauterization are the two most common causes.[1]

Nasal septal perforations can also be categorized by size (in largest diameter) and location. Small perforations are defined as less than 5 mm, medium-sized perforations between 5 and 20 mm, and large perforations greater than 20 mm. Perforations may be located posteriorly or anteriorly. The middle turbinate attachment to the lateral nasal wall can be used as a landmark to differentiate anterior from posterior perforations.

Symptoms of nasal septal perforations are dependent on both the size and location of the perforation. In general, large and anterior perforations are the most symptomatic. Perforations located posteriorly tend to be asymptomatic even when large due to the high intranasal humidification within the posterior nasal cavity. Symptomatic patients often present with paradoxical nasal obstruction due to airflow turbulence created by diversion through the perforation. A consequence of this alteration in flow is mucosal desiccation at the margin of the perforation. This often leads to additional symptoms, such as chronic nasal crusting (at the perforation margins), recurrent epistaxis (mild to moderate in severity), exposed cartilage, pain (low-grade chondritis), malodor/cacosmia (infection), and rhinorrhea (compensatory) (Box 96.2). Small anterior perforations can be a source of annoyance, causing nasal whistling, whereas large anterior perforations can lead to cosmetic deformity via loss of dorsal and columellar support. The reduction in nasal support leads to saddle nose deformity and columellar retraction respectively.

Key Operative Learning Points

1. Freshening of the margin of the perforation is important in promoting re-epithelialization.

2. Elevation of intranasal flaps in the correct submucoperichondrial and submucoperiosteal plane is critical.

3. Tension-free closure of the mucosal flaps is important in preventing flap retraction.

4. Incorporation of an interposition graft during the repair of the septal perforations can provide a scaffold for re-epithelialization.

Preoperative Period

History

1. "What symptoms are you experiencing?"
   a. Asymptomatic patients are not treated.
   b. Symptomatic patients may be treated with conservative therapy or surgical repair.
2. "How severely do your symptoms impact your quality of life?"
   a. Minor symptoms are treated conservatively.
   b. Significant symptoms that do not respond to medical therapy may be treated surgically.
3. "What is your surgical history?"
   a. This will determine whether the perforation was due to an iatrogenic injury and if there was a previous attempt at repair.
4. "What is your medical and facial trauma history?"
   a. This will determine if the perforation was due to a traumatic, infectious, inflammatory, or neoplastic etiology.
   b. In addition, significant comorbidities may reveal that a patient is not a candidate for a surgical procedure.
5. "Are you a smoker?" "Do you have a history of using cocaine, drug abuse, or the misuse of topical nasal medication?" "What is your

occupation?"

a. Current smoking, nasal drug abuse, topical nasal medication misuse, and exposures in the work environment will affect the outcome of surgical repair.

6. "What medications do you take?"

a. Patients taking anticoagulants and herbal supplements that contribute to increased bleeding will make surgical repair difficult due to poor visualization.

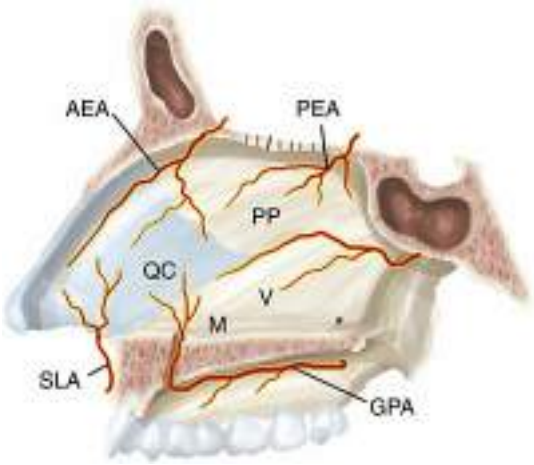

FIG. 96.1 Anatomy of the nasal septum. Quadrangular cartilage *(QC)*, perpendicular plate of the ethmoid bone *(PP)*, vomer *(V)*, maxillary bone *(M)*, palatine bone *(*)*, superior labial artery *(SLA)*, anterior ethmoid artery *(AEA)*, posterior ethmoid artery *(PEA)*, posterior nasal septal artery *(PNA)*, and greater palatine artery *(GPA)*.

Physical Examination

1. Nasal endoscopy is the most important part of the physical examination.

a. Determine the location of the perforation.

1) Is it anterior, posterior, superior, or inferior?

2) Is there one perforation or multiple perforations?

b. Determine the shape of the perforation.

1) Is it circular or elliptical?

2) If the latter, is the longest dimension oriented anteriorly-posteriorly or superiorly-inferiorly?

c. Determine the size of the perforation.

1) Place a ruler in one nostril with the markings toward the septum. Place an angled rigid nasal endoscope in the contralateral nostril, and visualize the ruler through the perforation.

d. Assess the presence of underlying cartilage.

1) Palpate the septum manually and with a cotton-tip applicator.

e. Assess the mucosa.

1) Identify abnormalities that may suggest an underlying infectious, granulomatous/inflammatory, or neoplastic process.

Based upon the patient's history and physical examination findings, we follow the treatment algorithm depicted in Fig. 96.2. The first decision point is determining if the patient requires treatment. Asymptomatic patients do not require treatment. The second decision point is determining whether the symptomatic patient is a surgical candidate. Poor surgical candidates include patients who have medical conditions that prevent safe surgery, who continue to abuse nasal drugs, continue to misuse topical nasal medication, have an active infection, have uncontrolled inflammatory disease, or have untreated sinonasal neoplasms.

Symptomatic patients who are poor surgical candidates are offered conservative management. Conservative management focuses on alleviating symptoms through the routine use of nasal saline irrigations, nasal saline sprays, nasal saline gels, water-based emollients, room humidification, and, if needed, intermittent office visits for débridement.

Conservative management also includes the insertion of a nasal prosthesis after excellent topical anesthesia. Low-profile grommet buttons are easily cut and shaped to the patient's needs and are typically well tolerated (see Chapter 1). Placement of the button is not difficult if done properly. The button may be purse-stringed using a suture or cut

along one of the flanges so that it may be placed in a corkscrew fashion. Additional options include magnetic septal prosthetics that may allow easier clinic placement and removal, as well as adjustable two-piece buttons that accommodate multiple septal widths. Because septal buttons are foreign bodies, patients may experience nasal obstruction due to the thickness of the prosthesis, debris accumulation, or a local inflammatory reaction (i.e., mucosal edema, granulation tissue).

BOX 96.1 Causes of Nasal Septal Perforations (*Most Common)

1. Traumatic
   a. External
      1) Nasal septal fracture
      2) Septal hematoma
   b. Internal
      1) Chronic nose picking
      2) Nasal piercing
2. Iatrogenic*
   a. Cautery*
   b. Cranial base surgery
   c. Intranasal packing
   d. Nasal intubation
   e. Nasogastric tube
   f. Rhinoplasty
   g. Septal splints
   h. Septoplasty*
   i. Sinus surgery
   j. Turbinate surgery

3. Infectious
   a. Invasive fungal sinusitis
   b. Inflammatory
   c. Nasally inhaled drugs (acetaminophen, opioids, methamphetamines, topical nasal corticosteroids)
   e. Septal abscess (tuberculosis, syphilis, leprosy, rhinoscleroma, rhinosporidiosis)
   f. Systemic disease (granulomatosis with polyangiitis, systemic lupus erythematosus, sarcoidosis, Churg-Strauss, polychondritis)
   g. Vasculitides (granulomatosis with polyangiitis)
4. Neoplastic
   a. Adenocarcinoma
   b. Lymphoma
   c. Melanoma
   d. Squamous cell carcinoma
5. Vasoconstrictive
   a. Cocaine
   b. Topical nasal decongestants (oxymetazoline, phenylephrine)
6. Caustic
   a. Agricultural dust (rice, grain)
   b. Chemical (batteries, sulfuric acid, hydrochloric acid)
   c. Heavy metal (chromium)
   d. Industrial dusts (glass, lime)

BOX 96.2 Symptoms of Nasal Septal Perforations

1. Chronic nasal crusting
2. Cosmetic deformity (i.e., saddle nose, columellar retraction)

3. Malodor (cacosmia)

4. Nasal obstruction

5. Nasal whistling

6. Pain

7. Recurrent epistaxis

8. Rhinorrhea

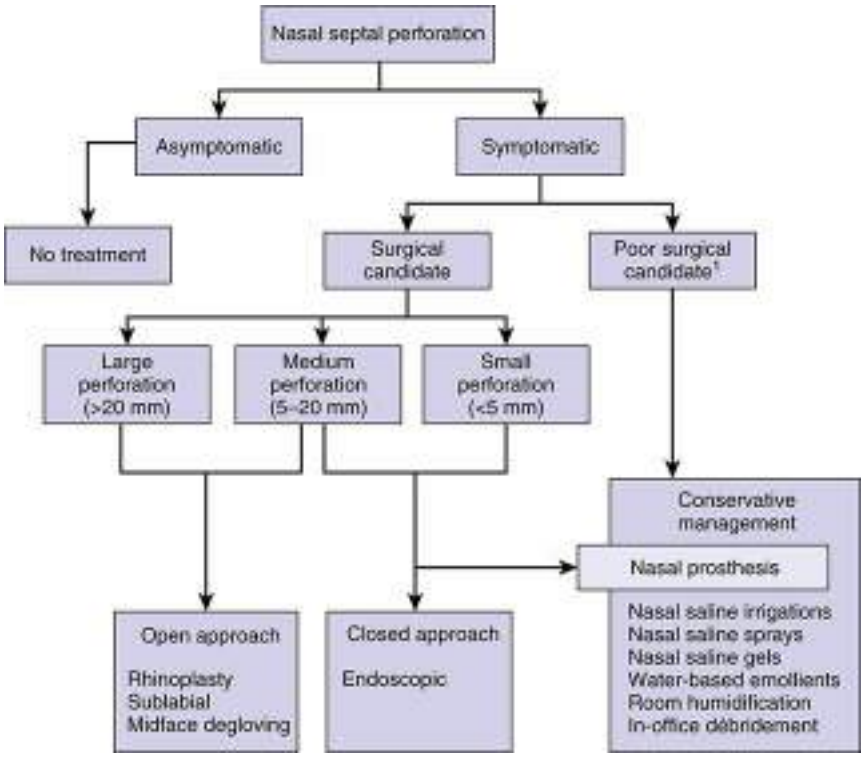

FIG. 96.2 Nasal septal perforation treatment algorithm.

[1]Poor surgical candidate: has medical conditions that prevents safe surgery, continued nasal drug abuse, continued topical nasal medication misuse, acute infection, uncontrolled inflammatory disease, or untreated sinonasal malignancy.

The third and final decision point is determining how to manage symptomatic patients who are surgical candidates. We recommend that small- and medium-sized perforations be treated with either a nasal prosthesis or through a closed (endoscopic) approach using intranasal

flaps with an interposition graft. Large perforations are typically treated through an open approach using intranasal flaps with an interposition graft.

Imaging

1. None. Imaging is not routinely performed unless there is concern for an underlying systemic, granulomatous, or neoplastic process that may be contributing to the septal perforation.

Indications

1. Nasal obstruction

2. Recurrent epistaxis

3. Chronic nasal crusting

4. Pain

5. Malodor/cacosmia

6. Rhinorrhea

7. Nasal whistling

8. Cosmetic deformity (i.e., saddle nose, columellar retraction)

Contraindications

1. Medical comorbidities that would preclude general anesthesia

2. Continued nasal drug abuse (i.e., cocaine, opioids, methamphetamines)

3. Continued misuse of topical nasal medications (i.e., oxymetazoline, phenylephrine)

4. Acute infections (i.e., acute rhinosinusitis, invasive fungal sinusitis)

5. Uncontrolled inflammatory disease (i.e., granulomatosis with polyangiitis, sarcoidosis, systemic lupus erythematous)

6. Sinonasal malignancies

Relative Contraindications

1. Controlled inflammatory disease
2. Previous sinonasal radiation therapy
3. Active tobacco smoking

Preoperative Preparation

1. Discontinue antiplatelet drugs if possible
2. Discontinue herbal supplements that may increase the risk of bleeding.
3. Medical and cardiac clearance for high-risk patients

Operative Period

Anesthesia

1. General anesthesia is preferred for patient comfort and protection of the airway from active bleeding.
2. 1% lidocaine with 1:100,000 epinephrine:
    a. Transnasal injections provide hemostasis and hydrodissection, which assist in elevating bilateral submucoperichondrial and submucoperiosteal flaps.
3. Oxymetazoline nasal pledgets:
    a. Inserted into both nasal cavities for decongestive and hemostasis purposes
    b. Acceptable alternatives that are also used include 1:1000 epinephrine and topical 4% cocaine.

Positioning

1. The patient is positioned as in an endoscopic sinus procedure with the head elevated slightly and turned slightly toward the surgeon.

Perioperative Antibiotic Prophylaxis

1. First-generation cephalosporin
2. Clindamycin if allergic to penicillin

Monitoring

1. None necessary

Instruments and Equipment to Have Available

1. Basic endoscopic sinus surgery set
2. Septoplasty set
3. #15 blade
4. #12 blade
5. Extended, needle tip, monopolar cautery (tip bent to a 30-degree angle)
6. Acellular human dermis (AlloDerm, LifeCell) × 1
7. Silastic sheets (0.02-inch thick) × 2
8. 5-0 fat-absorbing gut 4-0 plain gut on a straight 11-mm needle
9. 3-0 nylon

Key Anatomic Landmarks

1. Middle turbinate pneumatization
    a. The transverse level at which the vertical lamella of the middle turbinate begins to broaden. This marks the limit of the superior incision of the nasoseptal flap. Incisions superior to this line may compromise olfactory function postoperatively.
2. Hasner valve
    a. Located within the inferior meatus on the lateral nasal wall. This

marks the lateral limit of a nasal floor flap. Incisions superior to this may result in postoperative epiphora.

Prerequisite Skills

1. Endoscopic sinus surgery
2. Endoscopic septoplasty
3. Open rhinoplasty

Operative Risks

1. Failure of the repair
2. Enlargement of the perforation
3. Creation of a new perforation
4. Intranasal synechiae
5. Dysosmia
6. Epiphora
7. Bleeding
8. Infection/abscess

Surgical Technique

Many surgical techniques, each with its own advantages and disadvantages, have been published since the 1970s (Box 96.3).[2-9] Techniques can be categorized in several ways: open versus closed (endoscopic); unilateral intranasal flaps versus bilateral intranasal flaps; primary closure versus healing by secondary intention; use of interposition grafts versus not; and single-stage procedures versus multistage procedures. Intranasal mucosal flaps are quite useful but can be both complex to elevate and translocate for closure. These must be meticulously planned so as not to cause unintended bilateral devascularization of support-bearing portions of healthy septum. It is also important to understand the limits of the selected flaps to ensure

that appropriate length and mobility may be achieved. Furthermore, many different interposition graft materials have been described and used. Common graft materials include autografts (septal bone, auricular cartilage), homografts including acellular dermis, xenografts (porcine submucosa, bovine pericardium), and synthetic materials such as polyglactin. Grafts may also be placed as composite grafts or single layer grafts based primarily on surgeon preference and technique.

Although there is no consensus on how best to repair nasal septal perforations, we advocate the use of bilateral intranasal mucosal flaps (we prefer to use a combination of superior and inferior advancement flaps on one side and an anterior ethmoidal artery based flap contralaterally[3]), tension-free mucosal closure, and incorporation of an interposition graft (acellular dermis).

1. Hemostasis and hydrodissection

    a. Inject both sides of the nasal septum in a submucoperichondrial and submucoperiosteal plane and the nasal floor bilaterally with 1% lidocaine with 1:100,000 epinephrine. Inject in a posterior to anterior direction to prevent visual obstruction due to bleeding. Use the "pull-flash" technique to prevent intravascular injection. The mucosa will elevate away from the underlying cartilage and bone and will blanch. Injections should be performed not only along septal mucosa but also in the region of the columellar artery (caudal septum) and floor/inferior meatus region if an inferior advancement flap is to be used. If an open rhinoplasty approach will be used, then infiltration appropriate for that procedure should also be performed. Wait 10 minutes after injection to maximize the effect of vasoconstriction.

2. Nasal decongestion

    a. Insert cotton pledgets soaked in oxymetazoline into both nasal cavities for hemostasis and decongestive purposes. Remove the pledgets after adequate mucosal decongestion is achieved (2 to 3 minutes).

3. Nasal cavity débridement

    a. Using a 0-degree rigid nasal endoscope, examine both nasal cavities and the perforation site. Débride any intranasal crusting or dried

blood using straight forceps and/or a Frazier tip suction. Irrigation with warm 0.9% nasal saline (110°F) may help to loosen debris and control bleeding, if present.

4. De-epithelialization of the perforation margin

   a. Use a straight through-cutting instrument to de-epithelialize the posterior margin of the perforation; use a #12 blade or curved beaver blade in a posterior to anterior direction to de-epithelialize the superior and inferior margins; use a backbiting antrum punch (backbiter) to de-epithelialize the anterior margin. Failure to de-epithelialize the perforation margin will lead to flap failure. Note: Take care to minimize the enlargement of the perforation during this step.

5. Hemitransfixion incision

   a. A left hemitransfixion incision is made using a #15 blade as in a septoplasty.

   b. Dissect posteriorly above and below the perforation directly on the cartilage remnant.

   c. Slowly and gently sweep the Cottle elevator inferiorly and superiorly to separate the flaps from each other at the margin of the perforation. Note: Caution is required when elevating flaps in post-septoplasty patients because there will be scarring between both layers, thus increasing the risk of tearing the mucosa.

BOX 96.3 Nasal Septal Perforation Repair Techniques

Approaches, repair techniques, and interposition graft material

1. Approaches

   a. Open approaches

      1) Open rhinoplasty approach

      2) Sublabial approach

      3) Midface degloving approach

b. Closed approach

1) Endoscopic approach

2. Repair techniques

a. Bilateral intranasal flaps (with or without primary closure; with or without an interposition graft)

1) Bilateral, single advancement flaps

a) Superior releasing incision high in the nasal vault or an inferior releasing incision in the inferior meatus

2) Bilateral, bipedicled, double advancement flaps

a) Superior and inferior releasing incisions

3) Bilateral, unipedicled, posterior based (posterior nasal artery), rotational flaps

4) Nasal floor flap rotated superior-medially with a contralateral nasoseptal flap rotated inferiorly

5) Bipedicled, double advancement flap with a contralateral unipedicled, inferior based (superior labial artery), rotational flap

6) Bipedicled, double advancement flap with an ipsilateral hinged flap (posterior perforation rim based) that is rotated into the contralateral side

7) Cross-steal technique

a) A right flap above the perforation and hinged on the right superior perforation margin is rotated inferiorly into the left nasal cavity. A left flap below the perforation and hinged on the left inferior perforation margin is rotated superiorly into the right nasal cavity.

b. Unilateral intranasal flap (with or without primary closure; with or without an interposition graft)

1) Unilateral, single advancement flap

2) Unilateral, bipedicled, double advancement flap

3) Unilateral, unipedicled, posterior-based (posterior nasal artery), rotational flap

4) Unilateral, unipedicled, inferior-based (superior labial artery), rotational flap

5) Unilateral, unipedicled, superior-based (anterior ethmoid artery), rotational flap

6) Inferior turbinate, anterior-based flap (two-stage procedure)

7) Bullous middle turbinate flap (two-stage procedure)

8) Facial artery musculomucosal (FAMM) flap

9) Radial forearm free flap with anastomosis to the ipsilateral facial artery

10) Fascia lata free flap with anastomosis to the ipsilateral facial artery

c. Flapless closure

1) Posterior septum resection

2) Posterior perforation redraping

a) Posterior perforation margin cartilage is trimmed. Local mucosa is used to redrape the posterior perforation margin.

3) Backwards extraction-reposition technique of the quadrangular cartilage

4) Septal cartilage remnant is removed and reinserted backwards

5) AlloDerm interposition graft insertion

6) Titanium mesh interposition graft insertion

7) Temporalis fascia interposition graft insertion

8) Inferior turbinate mucoperiosteal interposition graft insertion

9) Conchal cartilage with bilateral periochondrium interposition graft insertion

10) Conchal cartilage and bilateral temporalis fascia composite interposition graft insertion

11) Polydioxanone (PDS) plate, temporoparietal fascia, and deep temporal fascia composite interposition graft insertion

12) Oral mucosa and auricular perichondrocutaneous composite interposition graft insertion

13) Auricular chondrocutaneous composite interposition graft insertion

3. Interposition Graft Material

a. Allograph

1) Acellular human dermis (AlloDerm, LifeCell)

b. Implant

1) PDS plate

2) Bioactive glass

3) Titanium mesh

4) Polyethylene orbital implant (MEDPOR, Stryker)

c. Xenograft

1) Porcine small intestine mucosa

6. Anterior ethmoid artery flap, with contralateral advancement flaps

a. Mucosal flap margins are inspected endoscopically and then incised using a needle-tipped monopolar cautery at a setting of 15. b. For the anterior ethmoid artery flap, two vertical incisions are made.

b. The posterior incision starts 0.5 to 1.0 cm posterior to the middle turbinate axilla. The incision is carried inferiorly to the nasal floor. The incision then traverses laterally into the inferior meatus. Care must be taken not to incise through the delicate bony septum into the contralateral nasal cavity during this step.

c. The anterior incision starts high in the nasal vault in the sagittal plane that passes through the posterior aspect of the perforation. This incision is extended to match the length of the posterior incision.

d. The incisions are connected by a joining incision in a posterior to anterior direction within the inferior meatus.

e. A Cottle elevator is used to elevate the mucosal flap in the correct plane.

f. On the contralateral side, an inferiorly based flap and a superior advancement flap may be required to allow straight line closure across the perforation. The margins of these flaps vary based on

perforation size; however, the concept is to allow transposition of the superior septal mucosa and inferior nasal floor mucosa toward one another to meet at the perforation.

g. The superior releasing incision can be made high in the nasal vault anterior to the axilla of the middle turbinate; however, if the defect dictates releasing posterior to this, the superior limit should drop to the level of the axilla to avoid injuring the olfactory epithelium. Inferiorly, the releasing incision can be made in the inferior meatus just below the axilla of the inferior turbinate. Note: Not every perforation requires both of these flaps, although many do. The inferior flap is preferred, given lower morbidity of the donor site and relatively quick healing. Again, it is useful to confirm that the incisions are through the mucosa by mobilizing the flap's edges with a Cottle elevator.

7. Interposition graft insertion

a. Rehydrate a thick sheet (>1 mm) of acellular human dermis (AlloDerm, LifeCell), and insert it between the septal cartilage and the flaps.

b. Be sure that the interposition graft covers the entire perforation with at least 1 cm of overlap if possible.

c. Secure the graft to the nasal cartilage remnant using 4-0 plain gut on a straight 11-mm needle. Place interrupted "tacking" mattress sutures posteriorly, superiorly, and anteriorly to secure the graft and prevent movement during final closure.

8. Hemitransfixion incision closure

a. Close with 5-0 fast-absorbing gut suture in an interrupted fashion.

9. Reapproximation of the flap

a. The anterior ethmoid artery flap is then sutured into position at the anterior edge of the perforation, followed by superior and then inferior sutures. The contralateral flaps are then closed in straight-line fashion, with interrupted or running technique.

b. The bipedicled flaps are then sutured transseptally using a quilting 4-0 plain gut suture.

10. Insertion of Silastic sheets

a. Trim two Silastic sheets (0.02-inch thick), insert into both nasal cavities, and lay them against the nasal septum and on the nasal floor. The Silastic sheets should cover all closure sites, incisions, and areas of denuded cartilage and bone. This helps to retain moisture, which will aid in re-epithelialization. Secure with two 3-0 nylon interrupted sutures superiorly and inferiorly. Silastic sheets are maintained for 3 weeks and removed in the office.

Common Errors in Technique

1. Inadequate de-epithelialization of the margins of the perforation

2. Failure to elevate the intranasal flaps in the submucoperichondrial or submucoperiosteal plane. This is particularly difficult in patients who have had a previous septoplasty.

3. Creating a short or narrow intranasal flap. Not accounting for flap contracture especially in the anteroposterior dimension

4. Not suturing the interposition graft to the septal cartilage remnant resulting in graft displacement during closure

5. Not suturing the free edges of the mucosa together

Postoperative Period

Postoperative Management

1. Pain medication

   a. Pain may be managed with oral opioids or acetaminophen. Nonsteroidal anti-inflammatory drugs should be avoided.

2. Anticoagulant/antiplatelet medication

   a. Patients on anticoagulation may resume treatment 24 hours after surgery.

3. Nasal saline irrigations

   a. Patients are instructed to irrigate both nasal cavities with 240 mL of nasal saline twice daily starting the morning after surgery. They will

continue this through the postoperative period until nasal mucosal healing is completed.

4. Nasal saline sprays/gels
    a. Patients are instructed to use nasal saline or saline gel in both nostrils 3 to 4 times daily to provide nasal moisturization and promote healing.
5. Mupirocin nasal ointment
    a. Patients are instructed to apply the ointment to both nostrils twice daily to provide nasal moisturization and prevent localized infection.
6. Oral antibiotics
    a. A first-generation cephalosporin is used to cover for *Staphylococcus aureus* while the splints are in place.

Complications

1. Hemorrhage
    a. Early intraoperative identification, control with cauterization, warm water irrigation, thrombin base products, and nasal packing
2. Septal hematoma/abscess
    a. Early postoperative identification, drainage, and elimination of dead space with mattress sutures
3. Synechiae
    a. Early postoperative identification and lysis in the office
4. Dysosmia
    a. Avoid nasal septum mucosal injury superior to the middle turbinate pneumatization.
5. Epiphora
    a. Avoid lateral nasal wall injury superior to Hasner valve.
6. Infection
    a. Patients are treated with postoperative oral antibiotics, such as a

first-generation cephalosporin while splints are in place.

7. Flap failure, worsening of the perforation, or creation of a new perforation

   a. Insertion of a nasal septal prosthesis

   b. Second repair attempt after 6 months of healing. Consider an open rhinoplasty approach for improved exposure if an endoscopic approach was attempted first.

Alternative Management Plan

1. Conservation management

   a. Nasal saline irrigations, nasal saline sprays, nasal saline gels, water-based emollients, room humidification, in-office débridement, nasal septal prosthesis

Discussion

Evidence-Based Medicine Question

Are nasal septal perforations best repaired with bilateral intranasal flaps with an interposition graft?

The majority of publications on nasal septal perforation describe various closure techniques dependent on the author's preference. Very few studies, all with low power, directly compare the outcomes of different closure techniques. Despite this, the general consensus is that long-term closure is best achieved through primary closure using bilateral mucoperichondrial flaps and an interposition graft.

Editorial Comment

The repair of a septal perforation remains a challenging procedure despite improved visualization techniques and biomaterials to support the reconstruction. The relative paucity of reconstructive tissue within the nose and the constant airflow dynamics are barriers to successful repair. Before any decision is made to undertake the repair of a septal

perforation, underlying conditions, such as autoimmune disease, repeated digital trauma, and the use of intranasal illicit drugs, must be controlled. In addition, prior surgical attempts can further limit the reconstructive options and should be considered before revision surgery. Finally, the benefits of the reconstruction must also be balanced against the drawbacks of the repair, namely the potential for worsening nasal airflow. Despite these challenges, successful repair of septal perforation can greatly reduce or eliminate noisy nasal breathing, epistaxis, and nasal crusting, resulting in a significant improvement in the patient's quality of life. As with any fistula closure, the use of opposing mucosal vascularized flaps, watertight interpositional grafts, and meticulous soft tissue handling optimize the chances of success.

Eric W. Wang

- Access the review questions online at http://www.expertconsult.com

Review Questions

1. Components of the nasal septum include all of the following, except

   a. Quadrangular cartilage

   b. Perpendicular plate of the ethmoid

   c. **Nasal bone**

   d. Vomer

   e. Maxillary crest

2. The nasal septum is vascularized by all of the following, except

   a. Anterior ethmoid artery

   b. Posterior ethmoid artery

   c. Superior labial artery

   d. **Inferior palatine artery**

   e. Sphenopalatine artery

3. Nasal septal perforation treatment strategies include all of the following, except

   a. Nasal saline sprays/gels

b. **Petroleum-based ointments**

c. Nasal septum prosthesis

d. Intranasal pedicled flaps

e. A and B

4. The most common cause of nasal septal perforations is:

a. Chronic nose picking

b. Intranasal medications/drugs

c. Collagen vascular disease

d. Septal hematoma

e. **Iatrogenic**

5. Although there is no consensus on how to best repair nasal septal perforations, high closure rates have been achieved through:

a. Unilateral flap with primary closure and contralateral healing by secondary intent

b. Bilateral flaps with primary closure and incorporation of an interposition graft

c. Use of an interposition graft only

d. A and B

e. **All of the above**

Surgery of the Turbinate

Bradley A. Otto, and Christie Barnes

Introduction

Surgical therapy for the inferior or middle turbinates is most commonly indicated in the setting of turbinate hypertrophy and chronic nasal obstruction that has failed to improve with medical therapy. Surgery of the turbinate may be an isolated stand-alone procedure or carried out in conjunction with a nasal septoplasty in which compensatory inferior turbinate hypertrophy may be present on the concave side of a significantly deviated septum.

Abnormally large turbinates may be related to anatomic variance or due to pathophysiology, such as rhinitis or rhinosinusitis. The goals of turbinate surgery should include not only the improvement of nasal airflow but also the maintenance of normal physiology. Hence surgery should be performed in a manner that preserves the ability of the turbinate to condition inspired and expired air, assist in mucociliary flow, and sense nasal airflow.

One area of concern in turbinate surgery is overresection of the turbinates. This is theorized, though not proven, to damage the perception of airflow, possibly by disrupting innervation and mucosal surface receptors. This may result in the subjective paradoxical experience of nasal obstruction in an objectively widely patent nasal cavity, otherwise referred to as “empty nose” syndrome. Hence mucosal sparing techniques should be used whenever possible.

Many techniques have been described for reduction of the inferior turbinate, including diathermy, radiofrequency ablation (RFA), partial and complete turbinectomy, submucosal resection, and powered submucosal resection. The last is our preferred method.

Middle turbinate surgery may be necessary as part of a procedure to address nasal airway obstruction in the case of a concha bullosa and may also be necessary as a key complementary component of nasal septoplasty, as a large concha can prevent efforts to correct a septal deviation. In some cases, a large concha bullosa may be dissected to improved access to the uncinate process and ethmoid bulla during sinus surgery.

Key Operative Learning Points

1. Nasal airflow studies have revealed that the majority of airflow occurs along the middle of the nasal cavity, across the superior surface of the inferior turbinate and body of the middle turbinate into the nasopharynx.

2. There appear to be marked changes in turbulent flow, negative pressure, and maximum shear stress in patients with turbinate hypertrophy in studies of nasal computational fluid dynamics.

3. Subjective nasal obstruction may not correlate with objective obstruction. The reverse is also true. Surgery to reduce turbinates in an already objectively patent airway is not likely to benefit patients with subjective obstruction. In such cases, an alternative etiology, such as nasal valve collapse, should be sought. Furthermore, especially in patients who have undergone multiple previous procedures, somatization or psychosocial issues that might contribute to the patient's complaints should be considered. In these situations, demonstrating to the patient an objectively patent airway, either with acoustic rhinometry or video endoscopy, may be of benefit. In addition, a lack of response to nasal decongestants may also help to convince this patient of the baseline patency of his or her nasal airway.

4. There are multiple techniques for reduction of the inferior turbinates, but there is no universally accepted best method. Contemporary methods of turbinate reduction should maintain a functional mucosal surface that conditions inspired and expired air and senses airflow.

5. Overresection of the inferior turbinate mucosa may lead to significant bony exposure with excessive crusting or could place the patient at risk for empty nose syndrome.

6. The approach to the patient with nasal obstruction should include an

assessment of the external nasal framework, inferior turbinates, middle turbinates, and nasal septum.

7. It is essential to respect the uncinate process and ethmoid bulla during lateral laminectomy of a concha bullosa in order to prevent iatrogenic sinus disease.

8. Medial laminectomy has been demonstrated to be as effective as lateral laminectomy for aeration of the middle turbinate (i.e., a concha bullosa).[1]

9. Olfactory epithelium may be more prevalent on the lateral aspect rather than the medial aspect of a concha bullosa.

Preoperative Period

History

1. History of present illness

   a. Is the nasal obstruction fixed or variable? Fixed obstruction may occur in the setting of severe septal deviation or hypertrophy of the inferior turbinate, nasal polyps, or tumor. Variable obstruction may occur due to the same factors already noted in less severe form, such that the nasal cycle and positioning of the patient contribute to further compromise of the nasal airway in varied proportions. Patients in whom obstruction is worse when the patient is supine likely are experiencing an increase in the size of the inferior turbinates due to sinusoidal engorgement, suggesting that turbinate hypertrophy is contributing to obstructive nasal symptoms. Variable obstruction may also be related to the intensity with which air is inspired. Patients with nasal valve collapse may complain of nasal obstruction that is most bothersome during more intense inspiration, such as sniffing or during exercise.

   b. Is the nasal obstruction unilateral or bilateral? If unilateral, which side? Unilateral nasal obstruction may be related to the etiologies already described. In some cases septal deviation toward the side of the complaint may be the underlying etiology. However, compensatory hypertrophy of the inferior turbinate contralateral to the side of a septal deviation may also be significant enough that it

contributes to a perception of unilateral nasal congestion contralateral to the side of the deviation. In such cases, the obstruction may be more dynamic, with fluctuations in severity related to the nasal cycle. The patient with unilateral nasal obstruction, especially if new and associated with epistaxis, deserves special attention in order to rule out neoplasia as the etiology.

c. What are the aggravating factors? Nasal obstruction that worsens when the patient is supine may be related to turbinate hypertrophy, as noted earlier.

d. What are the alleviating factors? Nasal obstruction that improves with topical decongestants may suggest that turbinate reduction should be a part of the overall surgical strategy, particularly soft tissue submucosal resection. Patients for whom external nasal manipulation has helped (tip elevation, Breathe-Right Strips, nasal cones) may benefit from alternative or complementary techniques that address the external nasal framework and/or nasal valves.

2. Past medical history

a. Prior or current medical treatment:

1) As noted earlier, the use of topical decongestants and the perceived efficacy by the patient give insight into the potential success of turbinate surgery.

2) It is important to review the physician-directed medical therapy the patient has completed up to this point. It is prudent to first perform a trial of topical and/or oral therapy, as success with such medications may allow the patient to avoid surgery.

b. Comorbid disorders

1) Certain disorders, such as allergic rhinitis, contribute to nasal obstruction due to mucosal edema. Failure to appropriately manage comorbid inflammatory conditions with medication may decrease the long-term efficacy of nasal airway surgical procedures.

2) See Box 97.1 for a list of some contributors to nasal obstruction that may require medical therapy in addition to surgical intervention.

c. Vasculitis or other inflammatory conditions that affect mucosal integrity

1) These patients may require more delicate dissection and resection to prevent tearing and bony exposure. Because of their underlying medical condition, these patients may be at risk for significant crusting.

3. Surgery

a. Previous turbinate or other nasal airway surgery

1) It is important to identify the specific procedures previously performed and to determine the perceived degree and period of efficacy experienced by the patient.

4. Medications

a. Antiplatelet and anticoagulant medications should be identified. Decisions related to temporary suspension of these medications should be made in consultation with the prescribing physician.

b. Herbal products that might lead to excessive bleeding, such as ginkgo biloba or ginseng, should be discontinued prior to surgery.

c. In patients with rhinitis medicamentosa, discontinuing topical decongestants prior to surgery, with the addition of topical and/or oral steroids as a method to aid in weaning, might help improve efficacy of the topical decongestants used on the day of surgery.

BOX 97.1 Comorbidity Associated With Nasal Obstruction

1. Allergic rhinitis

2. Chronic rhinosinusitis

3. Mucositis related to chemotherapeutic drugs

5. Nasopharyngitis and/or adenoid hypertrophy

6. Nonallergic rhinitis

7. Rhinitis medicamentosa

8. Vasculitis and granulomatous disorders

Physical Examination

1. Observe restful and exaggerated inspiration. This may help to determine if dynamic nasal valve collapse contributes to the patient's nasal obstruction.

2. Perform an anterior rhinoscopy. This allows for assessment of the caudal septum and columella as well as the anterior nasal cavity structures, including the nasal valve.

3. Perform a sinonasal endoscopy. This procedure allows for a more detailed evaluation of the sinonasal cavity and the nasopharynx. Evaluate for concha bullosa, posterior septal deviation or spurs, nasal polyps, nasopharyngeal lesions or tumors, or other pathologic process that may contribute to nasal obstruction.

4. Examine the oral cavity. This may reveal other causes for generalized airway obstruction and snoring, such as tonsillar hypertrophy. Occasionally antrochoanal polyps will be visible on oropharyngeal examination.

5. See Table 97.1 for a list of some of the causes of nasal obstruction.

Imaging

- When surgery solely for the purposes of relieving nasal obstruction is being considered, imaging is generally not necessary.
- In certain situations, a maxillofacial computed tomography (CT) scan may aid in the accurate diagnosis of disorders such as chronic rhinosinusitis, which may contribute to nasal obstruction and other associated symptoms.

Indications

Inferior Turbinate

- Nasal obstruction due to hypertrophy of the inferior turbinate

Middle Turbinate

- Large concha bullosa causing nasal obstruction
- Large concha bullosa with obstruction of the ostiomeatal complex

Contraindications

1. Medical comorbidities with unacceptable risk for elective surgery

2. Previous turbinate surgery resulting in adequate objective nasal airway parameters but with subjective nasal obstruction. These patients likely suffer from a lack of sensation (empty nose syndrome) or other disorders, as noted earlier, rather than nasal obstruction.

TABLE 97.1

Causes of Nasal Obstruction

Common	Uncommon
Benign tumors	Adenoid hypertrophy
Inferior turbinate hypertrophy	Foreign body
Large concha bullosa	Malignant tumors
Nasal polyps	Septal abscess
Nasal valve collapse	Septal body edema
Septal deviation	Septal hematoma
	Synechiae (postsurgical, posttrauma, or disease-related)

3. The presence of sinonasal malignancy should warrant primary treatment of the tumor.

Preoperative Preparation

1. Institute a trial of medical therapy including management of comorbid disease that could contribute to nasal congestion.

2. Discontinue medications that could interfere with hemostasis as deemed appropriate via consultation with the prescribing physician.

Operative Period

Anesthesia

- Submucosal resection of the turbinates, either with the microdébrider or through-cutting instruments, is best performed under general anesthesia. This optimizes patient comfort and protection of the airway.
- Awake sedation may be an option for less invasive procedures associated with minimal risk of hemorrhage, such as submucosal coblation. This may be best performed in the operating theater (monitored anesthesia care) in order to manage the airway optimally in the event of brisk bleeding and/or airway compromise due to the level of sedation.
- Local anesthesia may be an option for less invasive procedures associated with minimal risk of hemorrhage, such as submucosal coblation. In this situation, the patient should have full faculty to maintain a sufficient airway in the event of brisk bleeding.

Positioning

- The most appropriate position depends on the surgical technique and anesthetic used.
- For patients undergoing submucosal resection of the inferior turbinates or middle turbinate surgery, through-cutting instruments or a microdébrider may be used with the patient in the supine position and under general anesthesia.
- The beach-chair position may be an option in procedures performed with awake sedation or in-office procedures using local anesthesia.
- The sitting position may also be an option for patients having procedures using local anesthesia only.

Perioperative Antibiotic Prophylaxis

- Antibiotic prophylaxis is not definitively indicated for turbinate surgery without the use of packing material or splints.[2] If antibiotics are utilized, a first-generation cephalosporin (or clindamycin for

penicillin-allergic patients) is appropriate.

Monitoring

- No monitoring specific to turbinate surgery is required.

Instruments and Equipment to Have Available

1. For inferior turbinate submucosal resection:
   a. Sharp-tipped periosteal elevator or scalpel to make initial incision (some prefer to use a needle-tip electrocautery needle)
   b. Elevator for submucoperiosteal elevation (the authors prefer a Cottle elevator)
   c. Through-cutting instruments (to remove turbinate bone if required)
   d. Microdébrider with 3.5-mm or smaller blades (turbinate-specific blades that are 2.9-mm in diameter may be used)
   e. Frazier tip suction
   f. Electrocautery on standby for hemostasis
   g. 0- and 30-degree endoscopes and camera
2. For middle turbinate surgery:
   a. Sickle knife to pierce middle turbinate
   b. Turbinate scissors
   c. Through-cutting forceps
   d. Microdébrider
   e. Cautery on standby for hemostasis
   f. Endoscopes and camera

Key Anatomic Landmarks

Inferior Turbinate

- Anterior head of the inferior turbinate. This forms the inferior portion of the internal nasal valve (INV). Hypertrophy of this portion of the inferior turbinate can significantly affect airflow, as the INV is the most restricted area of the nasal cavity. Hence appropriate reduction in this region can significantly affect airflow.
- Turbinate bone
- Path of the inferior turbinate branch of the posterior nasal artery. The arteries generally pass within the bone or in a mixed pattern within bone and submucosa in the majority of cases. The inferior aspect of the turbinate is comparatively void of major vessels.

Middle Turbinate

- Hiatus semilunaris and the associated uncinate process and ethmoid bulla. Minimal disruption of the ostiomeatal complex during removal of the lateral aspect of a concha bullosa will help maintain proper physiology of the middle meatus (Fig.97.1).

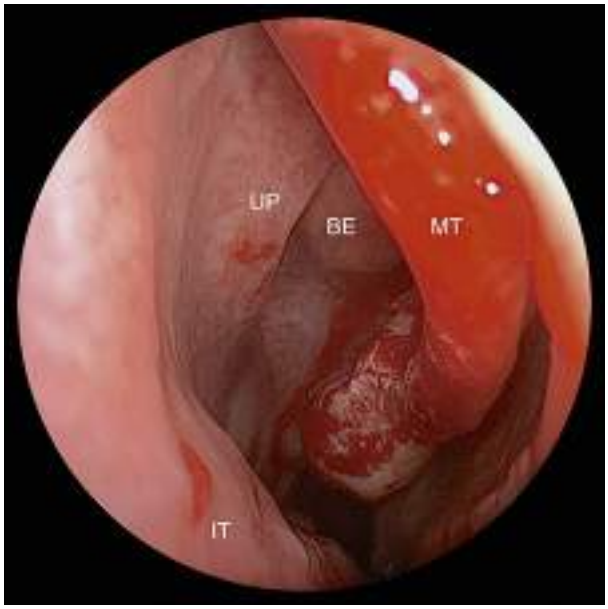

FIG. 97.1 Salient anatomy related to middle turbinate (MT) surgery. The lateral aspect of the right concha bullosa has been resected. Care should be taken to avoid damage to the uncinate process (UP) and bulla ethmoidalis (BE) in order to preserve the functional

integrity of the hiatus semilunaris and ethmoid infundibulum. *MT*, middle turbinate, *IT*, inferior turbinate.

- Cribriform plate. It is essential to maintain visualization of and respect for the cribriform plate during resection of the concha bullosa in order to avoid damage to the horizontal or vertical plate of the cribriform plate with an associated leak of cerebrospinal fluid.
- The basal lamella of middle turbinate serves as a general landmark for the posterior limit of conchal dissection.

Prerequisite Skills

- Basic endoscopic sinus surgery skills. Although inferior turbinate surgery may be performed using a nasal speculum and headlight, we prefer to use endoscopes for optimal visualization of the turbinate tissue and surrounding structures.
- Epistaxis management skills

Operative Risks

Inferior Turbinate

- Intraoperative hemorrhage. This can be addressed with packing and/or selective cautery.
- Although rare, injury to the nasolacrimal duct can occur if the lateral wall of the inferior meatus is damaged 30 to 40 mm posterior to the nasal sill.
- Through-and-through injury to inferior turbinate: If this occurs, it may create a hole or window through which a patient may experience whistling and/or crusting. This can be avoided with careful dissection and judicious use of the microdébrider.

Middle Turbinate

- Avulsion of the middle turbinate from its attachment at the skull base during concha bullosa surgery can cause a leak of cerebrospinal fluid.

- Mucosal injury to the hiatus semilunaris, uncinate process, or ethmoid bulla can create synechiae and disrupt the maxillary sinus ostium or infundibulum, resulting in sinusitis.

Surgical Technique

Decongestion and Vasoconstriction

- Topical application of 0.05% oxymetazoline hydrochloride helps to decongest nasal tissue and aids in visualization.
- Injection of 1% lidocaine with 1:100,000 epinephrine helps with vasoconstriction. We prefer to inject the inferior turbinate along its inferomedial surface and at the anterior tip. The middle turbinate is usually injected near the anterior axilla, along the anterior face, and posteriorly at the inferior aspect of the basal lamella.

Inferior Turbinate Reduction: Surgical Technique

Incision and Elevation

- Use the sharp end of a Molt elevator or scalpel to make a stab incision in the anterior inferior turbinate at the level of the attachment to the lateral nasal wall. Some prefer to use a needle-tipped electrocautery device or turbinate-specific microdébrider blade to do this.
- Elevate the mucosa away from the medial, inferior, and superior aspects of the inferior turbinate.
- The turbinate bone is often irregular, and use of the endoscope to visualize the elevating instrument is critical at all times.

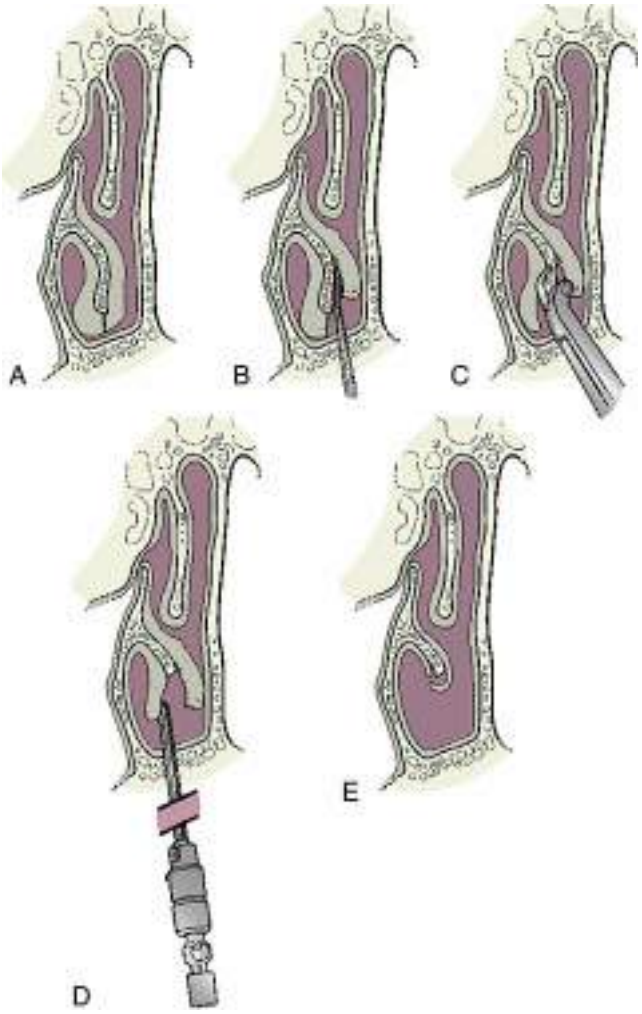

FIG. 97.2 **A,** Incision in the mucosa of the turbinate. **B,** The mucosa is elevated off the turbinate bone. **C,** The bone is removed with biting forceps. **D,** A microdébrider is used to remove the lateral wall. **E,** The medial mucosa is rolled laterally.

- While the mucoperiosteum is being elevated away, the bone may be outfractured as the dissection proceeds posteriorly. This helps to improve visualization for the remainder of the procedure.
- A turbinate-specific microdébrider blade may also be used to elevate in the submucosal plane.

Submucosal Resection

- Once the submucosa is elevated along the length of the turbinate, a 3.5-mm or smaller microdébrider blade is inserted into the trough thus

created.

- The redundant mucosa laterally and/or bone is removed, ensuring that the blade is well visualized as it moves beneath the mucosal surface.
- If more aggressive turbinate reduction is required, the lateral mucoperiosteum of the anterior aspect of the inferior turbinate may be removed along with the bone. In these cases, it is usually more efficient to remove the bony aspect of the turbinate with through-cutting instruments. The medial mucoperiosteum may then be draped laterally to cover abraded tissue.
- See Fig.97.2.
- See Video 97.1: Inferior turbinate submucosal resection technique.

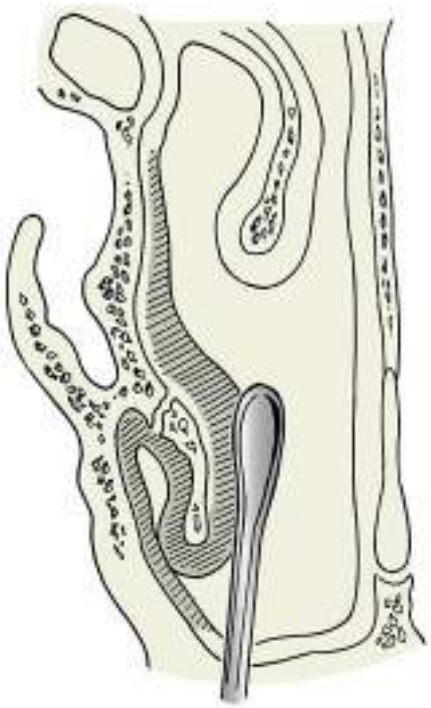

FIG. 97.3 Outfracture of a prominent inferior turbinate.

Outfracture

- With the use of an elevator or septal displacer, the turbinate may be outfractured. This maneuver is usually made easier when the turbinate has previously been outfractured from within the submucoperiosteal plane during the elevation phase, as noted previously. This maneuver

should also be performed under direct visualization (Fig. 97.3).

Splint Placement

- If desired, splints may be placed to buttress the inferior turbinates.

Surgical Technique for Resection of the Concha Bullosa

Incision

- A sickle knife is used to incise the anterior head of the turbinate into the inner airspace of the concha bullosa. This is done lateral to the medial vertical attachment of the turbinate to avoid any torque at the cribriform plate.
- In cases where the airspace is more posterior, a lateral or medial insertion point may be required.
- The incision is then lengthened superiorly and inferiorly.

Removal

- Using a combination of through-cutting instruments and/or a microdébrider, the lateral or medial aspect of the concha bullosa is removed. This may be done in a piecemeal fashion, or a dominant portion may be removed via superior and inferior cuts extended in a posterior direction along the medial or lateral layer of the concha bullosa.
- The basal lamella serves as a general landmark for the posterior limit of dissection.
- When the lateral aspect of the concha bullosa is being removed, care should be taken to prevent damage to the uncinate process and ethmoid bulla. This may be facilitated by using a blunt elevator to gently infracture the lateral lamella of the concha bullosa as dissection proceeds posteriorly.

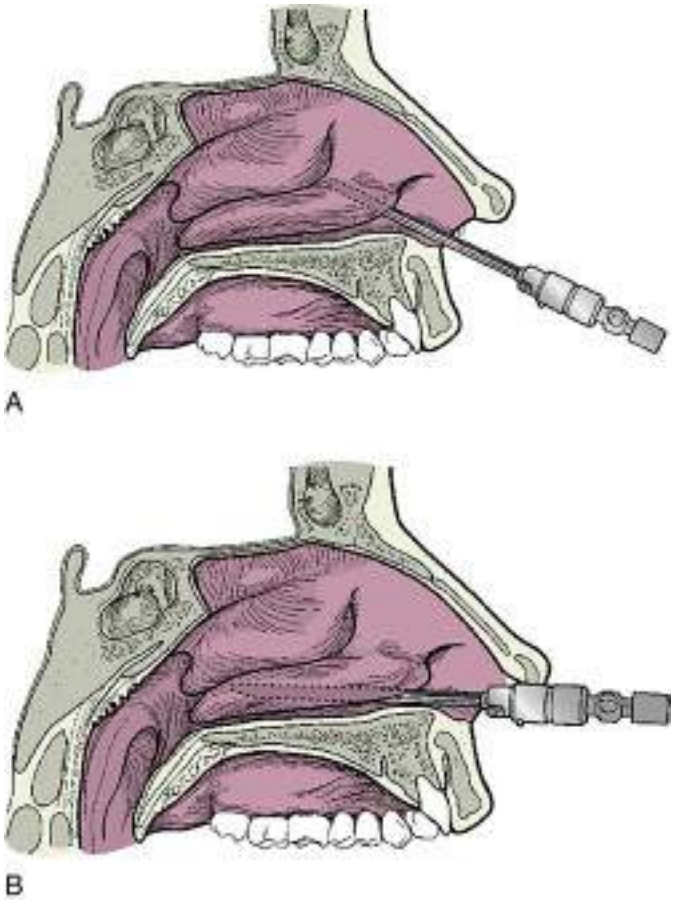

FIG. 97.4 **A,** A microdébrider is inserted into the inferior turbinate, inappropriately angled so that it will potentially go through inferior turbinate superiorly and engage middle turbinate. **B,** The microdébrider is inserted correctly into inferior turbinate pocket, minimizing risk of injury to the middle turbinate.

- The microdébrider is used to remove any free edges made by the cutting instruments.

Common Errors in Technique

1. Inadequate removal of tissue (bony or soft) will lead to persistent nasal obstruction. In cases where the turbinate is very large, it may be necessary to conservatively remove the antero-lateral aspect of the turbinate, as noted previously.

2. Perforation of the mucosa is usually due to overresection or incorrect positioning of the microdébrider blade. It may also be due to inadequate

elevation of the submucosal flap, which can lead to bleeding or crusting.

3. Perforation of the inferior turbinate can occur if the dissection is extended too far superiorly, leading to damage of the middle turbinate (Fig. 97.4).

Postoperative Period

Postoperative Management

- Pain management is usually easily achieved with a low-dose opioid or acetaminophen. Nonsteroidal anti-inflammatory drugs such as ibuprofen may be administered starting on postoperative day 7.
- Irrigation with saline solution helps to keep the nasal passages and/or splints clear of loose mucus, debris, and clot.
- If splints are being used for inferior turbinate surgery or concomitant septal surgery, we prefer to remove them on postoperative day 3 to 5 in most cases. We prefer to use splints to help minimize venous congestion and edema in the early postoperative period.

Complications

Inferior Turbinate

- Hemorrhage

  This may occur at the incision site or at sites of mucosal disruption, particularly at the posterior mulberry tip, as this is at high risk of bleeding. Intraoperatively, this may be controlled with pressure or selective electrocautery. Postoperative hemorrhage can usually be controlled in the office using targeted absorbable packing or cautery. Early studies suggest that this is the most common complication, in the range of 10%, followed closely by the formation of synechiae in 2.9% to 8.6% of cases.[3]

- Synechiae

  This complication is more common when the turbinate surgery is done

in conjunction with septoplasty and there are apposing areas of excoriation that heal together. It is usually addressed with lysis of the adhesion in the office using topical or local anesthesia.

- Acute bacterial sinusitis

  This may be idiopathic or may occur if the superior aspect of the inferior turbinate is violated and the dissection continues into the middle meatus, leading to scarring and obstruction. Antimicrobial therapy is indicated. Endoscopically guided cultures may help guide antibiotic choice.

- Injury to the lacrimal duct

  This may occur if dissection extends beyond the lateral aspect of the inferior turbinate into the inferior meatus and lateral nasal wall. Dacryocystorhinostomy may be necessary and should be considered after referral to an Ophthalmologist.

- Empty nose syndrome

  With the use of contemporary techniques, this is an uncommon but potentially devastating complication of nasal airway surgery, characterized by diminished or absent sensation of airflow. Treatment is controversial and is beyond the scope of this chapter.

Middle Turbinate

- Hemorrhage

  This is uncommon but may occur along incision sites or from the middle turbinate branch of the sphenopalatine artery if exposed. Intraoperatively, this may be controlled with pressure in the form of Afrin-soaked pledgets or selective cautery.

- Synechiae

  This is an uncommon complication that is usually addressed with lysis of the adhesion in the office under topical anesthesia. Synechiae to the lateral nasal wall may lead to iatrogenic rhinosinusitis.

- Acute bacterial sinusitis

  As noted earlier, this may occur due to contamination during surgery or as a sequela of synechiae. It is treated in the same manner as

described for the inferior turbinate.

- Leak of cerebrospinal fluid

  This may occur secondary to avulsion of the middle turbinate or if dissection is carried too superiorly on the middle turbinate. It should be repaired immediately with appropriate endoscopic techniques.

Alternative Management

- Medical management of concomitant inflammatory conditions, such as chronic rhinitis, should be undertaken prior to surgery. If effective, this is an excellent alternative to surgery.
- Immunotherapy may suffice in patients with significant allergic rhinitis.

Discussion

Evidence-Based Medicine Question

Of the techniques used to address the inferior turbinate for the purposes of improving nasal airflow, which is best?

Alternative Inferior Turbinate Resection Techniques

The ideal inferior turbinate reduction procedure has enduring results, minimal side effects, and is straightforward to perform. No universally accepted consensus exists regarding a single approach to achieve these goals.

As noted by other authors, the sheer fact that multiple techniques exist without a clear preferred method points to no ideal technique without short- and long-term complications. It is felt that failures of inferior turbinate procedures may not be due to cross-sectional widening of the airway, as all techniques potentially do, but rather to mucosal dysfunction following the procedure.

Long-Term Results

Of the described techniques, submucosal resection has the best reported long-term results.[3,4] Partial turbinectomy has fallen out of favor due to potential devastating postoperative complications. Approaches that use diathermy or coagulation—such as laser, cryotherapy, coblation, radiofrequency ablation (RFA), and cautery—have poorer long-term rates of symptomatic control.[3-5]

Mucosal Function

Total and to some degree partial turbinectomies have fallen out of favor due to damage to the conditioning functions with these procedures, which may increase the risk for postoperative atrophic rhinitis. Submucosal turbinate reduction has been shown to lead to normalization of saccharin transit time at 6 months postoperatively, which is sustained to 3 years.[4] Additionally there have been histopathologic studies and mucociliary function testing with radiofrequency ablation and coblation that have demonstrated a negative impact on the postoperative function of the inferior turbinate.[3-5] Laser and ultrasonic bone aspirators still require further investigation into long-term, objective, and histopathologic findings.

Complications

Procedures involving the removal of mucosa not only increase risk of damage to function of the turbinate but also have potentially higher rates of bleeding and the formation of synechiae. Early reports of complications have noted higher rates of epistaxis and synechiae with partial and total inferior turbinoplasty than with submucosal procedures.

In summary, of the techniques described for inferior turbinate reduction, submucosal turbinate reduction has the desirable components of mucosal preservation, a low complication rate, and superior long-term results and, as a result, is our preferred technique.

Editorial Comment

Several techniques are advocated for reduction of the inferior turbinate. In appropriately selected patients, the procedure can be highly effective

in relieving nasal obstruction due to hypertrophy of the inferior turbinate. Controversy still exists regarding the best technique, although preliminary studies suggest that submucosal resection is more effective in long-term symptomatic control compared with radiofrequency coblation, as discussed in this chapter. Techniques designed to spare the mucosa, careful preservation of the anterior head of the inferior turbinate, and avoidance of cautery are important to prevent injury to the cilia and maintain the important functions of the nasal cavities. The authors provide practical guidance regarding patient selection, preparation, and technique to perform safe and effective surgery involving the turbinates.

Review Questions

1. What is the most common complication following turbinate reduction?

   a. **Hemorrhage**

   b. Hyposmia

   c. Atrophic rhinitis

   d. Nasolacrimal duct obstruction

2. Which of the following techniques has been found to have the best long-term results in terms of improving the nasal airway?

   a. Partial turbinectomy

   b. Radiofrequency ablation

   c. Submucosal resection

   d. Laser resection

   e. **a and c**

   f. Evidence is still lacking in this area, more studies are needed

3. A postoperative inferior turbinoplasty patient seen 2 weeks following the procedure complains of left maxillary sinus pressure, discolored postnasal drainage, and cough. Which of the following errors may

have contributed to this uncommon postoperative complication?

a. Avulsion of the middle turbinate

b. **The ostiomeatal complex has been injured, leading to acute bacterial rhinosinusitis (ABRS)**

c. Dissection into the inferior meatus

d. Electrocautery to the mulberry tip

e. Submucosal coblation

4. In which situation is a CT scan most likely to be of benefit to a patient considering inferior turbinate reduction surgery?

a. To evaluate for posterior septal deviation that may contribute to nasal obstruction

b. To evaluate the posterior aspect of the turbinate tissue

c. **To evaluate for chronic rhinosinusitis in a patient with nasal obstruction and other symptoms suggestive of chronic rhinosinusitis for whom nasal endoscopy is negative for signs of rhinosinusitis**

d. To evaluate adenoid hypertrophy

5. In which of the following circumstances is management of the middle turbinate indicated?

a. Large concha bullosa with nasal obstruction

b. Paradoxically curved middle turbinate

c. Large bilateral concha bullosa

d. Large concha bullosa with obstruction of the middle meatus

e. Both b and c

f. **Both a and d**

Sphenopalatine Artery Ligation for Epistaxis

Carl H. Snyderman, and Aron Z. Pollack

Introduction

Most episodes of epistaxis are minor and self-limited and originate in the anterior nasal cavity. Posterior epistaxis, however, can be life threatening and is usually associated with bleeding from branches of the sphenopalatine artery (SPA). Rarely, the ethmoidal arteries or internal carotid artery (ICA) may be a source of severe epistaxis. Proper evaluation of the patient can usually reveal the source of the bleeding and identify contributing factors. Treatment options for severe epistaxis include nasal packing (anterior and posterior), angiography with embolization of branches of the external carotid artery, or surgical ligation/cauterization of the sphenopalatine artery and/or the anterior and posterior ethmoidal arteries. In comparison to nasal packing, surgical ligation is better tolerated and more cost-effective. Angiography with embolization is almost as effective as surgical ligation but cannot address the ethmoidal arteries and has significant potential risks (blindness, stroke, internal carotid injury). Although surgical ligation of the terminal branches of the SPA can be performed using open or endoscopic techniques, endoscopic ligation is the preferred technique. Ligation of the anterior ethmoidal artery (AEA), whether endoscopic or open via a Lynch incision, can be performed at the same time if necessary. The posterior ethmoid artery is rarely, if ever, the source of significant bleeding.

Key Operative Learning Points

1. The sphenopalatine foramen is located at the posterosuperior corner of

the maxillary sinus deep to the posterior attachment of the middle turbinate.

2. The SPA frequently branches proximal to the sphenopalatine foramen and may exit through separate foramina.

3. A maxillary antrostomy can facilitate exposure of the SPA and provides additional space for instrumentation.

4. The SPA can be occluded by bipolar electrocautery or placement of hemoclips.

5. If the source of the bleeding is not confirmed, endoscopic bipolar cautery of the AEA is performed at the same time.

Preoperative Period

History

1. History of present illness

   a. How did it start?

      1) Epistaxis following external nasal trauma (blunt force) is more likely to originate from the AEA.

      2) Spontaneous severe epistaxis is more likely to originate from the SPA.

   b. Is it severe? The volume of the bleeding should be assessed: number of cups or tissues. What is the duration? Severe bleeding is usually from a larger vessel such as the AEA or SPA.

   c. What is the source of the bleeding?

      1) Is the bleeding on one side or both sides? Bleeding that is bilateral may indicate multiple sites or the blood is starting on one side and then crossing to the other side in the nasopharynx. Even with brisk posterior bleeding, one side usually predominates.

      2) When the patient is sitting upright, does the bleeding primarily run from the front or the back of the nose? Anterior drainage of blood may indicate bleeding from the AEA, and drainage into

the pharynx may indicate posterior bleeding from the SPA. Severe epistaxis, however, often drains anteriorly and posteriorly at the same time.

d. How is it controlled? If the epistaxis is controlled with anterior compression of the nose, then the source is likely to be the small vessels of the anterior nasal septum. If bleeding continues down the back of the throat with anterior nasal compression, the AEA and SPA are likely sources.

e. Associated symptoms. It is important to ask about associated symptoms such as nasal obstruction, visual changes, facial hypesthesia, pain, or trismus. Such symptoms may indicate a neoplasm, and the epistaxis may be secondary to the tumor.

2. Past medical history

a. Age. Severe epistaxis in a young patient (<20 years) is unusual and suggests a neoplasm or hereditary bleeding disorder. In older individuals, spontaneous hemorrhage is often associated with multiple medications, particularly anticoagulants.

b. Prior treatment. Previous episodes of epistaxis should be explored. Were they similar in location and severity? What is the frequency? How were they treated? Failure of prior surgery or embolization may indicate improper identification of the source or incomplete occlusion and may affect treatment choices. Failure of surgical ligation is typically due to missed terminal branches or dislodgement of hemoclips. Failure of embolization suggests bleeding from the AEA.

c. Medical illness. Medical illnesses such as liver or renal failure and hematologic cancers are associated with bleeding disorders due to impaired platelet aggregation and coagulation. Overt hypothyroidism has been linked to an increased risk of bleeding. Hypertension may contribute to epistaxis, but this theory is controversial. A cross-sectional, population-based study showed no association between hypertension and epistaxis; in a prospective study of patients with hypertension who had epistaxis, the incidence of epistaxis was not related to the severity of hypertension.

d. Surgery. A history of recent sinus surgery should alert the surgeon to a possible injury to the ICA, especially if there is documentation of

brisk intraoperative hemorrhage that required packing for control. A sphenoidotomy is also likely to injure the posterior septal branch of the SPA, which courses over the anterior face of the sphenoid sinus.

e. Family history. A family history of recurrent epistaxis may indicate a bleeding diathesis from an inheritable coagulation disorder. In particular, a family history of epistaxis in the absence of other bleeding problems may be associated with hereditary hemorrhagic telangiectasia (HHT) or Osler-Weber-Rendu syndrome.

f. Medications. Many medications are associated with an increased risk of epistaxis. A thorough history is necessary to elicit this information because it is often not volunteered by patients. Categories of products with antiplatelet effects include the following:

1) Antiplatelet drugs. These include over-the-counter nonsteroidal anti-inflammatory drugs as well as the newer long-acting antiplatelet prescription medications.

2) Herbal products. Remember the 4 G's: garlic, ginger, gingko biloba, and ginseng. There are many other herbs and nutritional supplements (fish oil, vitamin E) that also affect bleeding.

3) Alcohol. Episodes of epistaxis are often associated with recent alcohol ingestion.

Physical Examination

1. Nasal endoscopy

Nasal endoscopy is the most important part of the examination. It may be limited by the presence of nasal packing or active bleeding. Prior attempts at treatment (cautery and packing) may result in secondary sources of bleeding.

Examination of the nasopharynx is important to rule out cancer or other tumors such as angiofibromas. In the absence of active bleeding, a small clot may signify the site of the bleeding. A small angioma on a turbinate or lateral nasal wall can be easily overlooked. Multiple telangiectasias are indicative of HHT (see Chapter 100).

2. Oral cavity

Examination of the oral cavity may reveal other causes of epistaxis

such as HHT or a neoplasm of the palate or maxilla.

3. Orbit

Proptosis or restriction of extraocular movements suggests a neoplasm with extension to the orbit.

4. Trigeminal nerve

Neoplastic involvement of the trigeminal nerve may result in decreased sensation or weakness of the muscles of mastication (decreased contraction, jaw drift with forceful opening).

5. Neck

Cervical metastases are a late presentation of sinonasal malignancy.

Imaging

None

Most patients with severe epistaxis do not require any imaging prior to surgical intervention.

Computed tomography

A computed tomography (CT) scan with contrast should be considered in patients with concerning symptoms or physical findings suggestive of a neoplasm.

Computed tomography angiogram

If there is a history of recent sinus surgery, a CT angiogram rules out a possible injury to the ICA with formation of a pseudoaneurysm.

Angiography is reserved for patients undergoing embolization or who have failed prior surgical therapy. Angiography is essential if there is concern for ICA injury following trauma or surgery.

Indications

1. Severe epistaxis from the posterior nasal cavity

The primary indication for endoscopic ligation of the SPA is severe unilateral epistaxis that appears to be posterior or without an obvious

source. It is often difficult to differentiate bleeding from the AEA and SPA in the absence of active bleeding, and both vessels may need to be addressed at the time of surgery. Rarely, an inability to localize the bleeding to one side of the nasal cavity requires bilateral SPA ligation.

2. Recurrent acute epistaxis from the posterior nasal cavity

Some patients give a history of multiple episodes of significant unilateral epistaxis controlled with nasal packing and without treatable risk factors. In such cases, elective SPA ligation may be considered.

3. Vascular tumor

As an alternative to embolization, SPA ligation may be used to devascularize a tumor prior to surgical excision. Most commonly, this is performed for early-stage angiofibromas but may be considered for sinonasal malignancies as well. Rarely, SPA ligation may be performed emergently for the treatment of a bleeding neoplasm prior to radiation therapy. This may be performed at the same time as a biopsy or palliative debulking of the tumor to relieve obstructive symptoms.

4. Transpterygoid surgical approach

A transpterygoid approach is a common starting point for many endoscopic approaches to the skull base. Ligation of the SPA allows displacement of the contents of the pterygopalatine space to gain access to the base of the pterygoid and lateral recess of the sphenoid sinus.

Contraindications

1. Correctable coagulopathy

In a patient with a correctable coagulopathy, nonoperative treatment is preferable.

2. Medical comorbidities with increased risk for general anesthesia

If a patient is a poor medical risk for general anesthesia, alternative therapies for epistaxis should be considered (nasal packing or embolization).

3. Large vascular tumor with variable vascular supply

A large vascular tumor may block access to the SPA and have multiple

sources of vascular supply from branches of the external carotid artery and ICA. In such cases, angiography with embolization is preferred.

Preoperative Preparation

1. Discontinue antiplatelet drugs if possible. SPA ligation can be safely performed in patients who are anticoagulated or on antiplatelet drugs in an emergency situation. In an elective situation, these drugs and supplements should be discontinued prior to surgery.

2. Control acute bleeding with nasal packing. Bleeding from the SPA can be temporarily managed with anterior and posterior packing with an Epistat balloon or a Foley catheter and sponge/gauze packing.

3. Control the airway. If active bleeding persists, emergent intubation may be necessary to secure a safe airway.

4. Monitor hemoglobin/hematocrit, coagulation parameters, and transfuse if necessary.

5. Base-level hemoglobin and hematocrit are necessary, and type and cross for blood transfusion may be necessary based upon the results.

Operative Period

Anesthesia

General

Although this procedure can be done with awake sedation, general anesthesia is preferred for patient comfort and protection of the airway. In an emergent situation, these patients pose a risk for aspiration due to swallowed blood or active bleeding, and awake fiberoptic intubation or rapid sequence intubation may be indicated. An orogastric tube should be passed following intubation for suctioning of blood and stomach contents throughout the procedure. A throat pack is optional.

Positioning

Supine

The patient is positioned in the same way as for any endoscopic sinus procedure with the head turned slightly toward the surgeon. The endotracheal tube is positioned on the opposite side of the mouth. The reverse Trendelenburg position with at least 15 degrees of head elevation reduces mucosal bleeding during surgery.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

A single dose of antibiotic is sufficient unless there is evidence of sinusitis secondary to nasal packing. In such cases, antibiotic coverage of *Streptococcus* species and *Streptococcus aureus* is preferred.

Use clindamycin if the patient is allergic to penicillin.

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Basic endoscopic sinus surgery set

2. Monopolar suction electrocautery: Monopolar suction electrocautery can be used for surface bleeding within the nasal cavity.

3. Endoscopic bipolar electrocautery: A pistol-grip endoscopic bipolar electrocautery is the preferred instrument and is more effective than monopolar electrocautery for cauterization of larger vessels.

4. Pistol-grip endoscopic clip applier: Standard disposable clip appliers have a large shaft and are too cumbersome for endonasal surgery. Several companies make adjustable clip appliers (accommodate different clip sizes) with a flat shaft.

Key Anatomic Landmarks

1. Crista ethmoidalis: The crista ethmoidalis is a triangular projection of bone just anterior to the sphenopalatine foramen.

2. Sphenopalatine foramen: The sphenopalatine foramen is located at the posterosuperior corner of the maxillary sinus and is formed by the junction of the palatine bone and sphenoid bone (Fig. 98.1).

3. Greater palatine nerve (descending palatine nerve): The greater palatine nerve descends vertically in the lateral nasal wall, inferior to the sphenopalatine foramen.

Prerequisite Skills

1. Endoscopic antrostomy (see Chapter 103)

Operative Risks

1. Intraoperative hemorrhage from SPA:

If the sphenopalatine foramen is approached directly, there is greater risk of injury to the branches of the SPA. This can be avoided by exposing the lateral nasal wall inferior to the sphenopalatine foramen. A 1-mm Kerrison rongeur should be used to enlarge the sphenopalatine foramen superficial to the SPA. If a larger rongeur is used, it is more likely to transect the vessel.

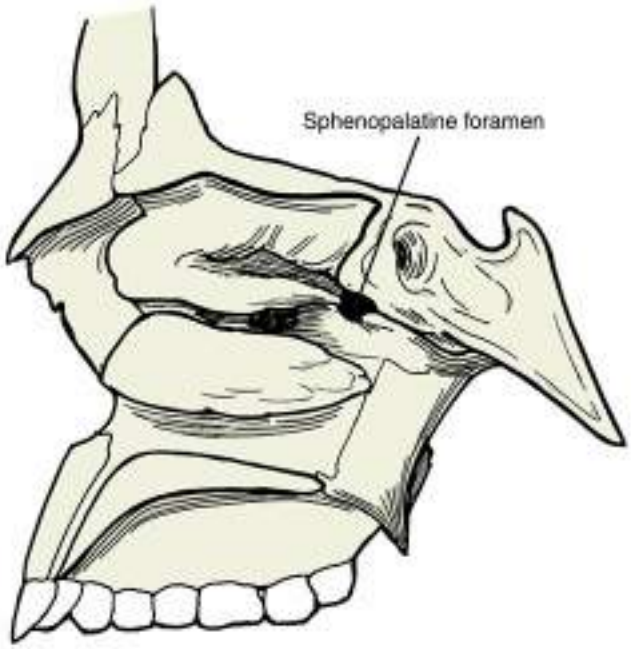

FIG. 98.1 Relationship of the sphenopalatine artery to the posterior attachment of the middle turbinate.

2. Injury to greater palatine nerve:

The nerves are in a deeper plane than the vessels in the pterygopalatine space. The greater palatine nerve can be injured if the bone inferior to the sphenopalatine foramen is instrumented with a drill or rongeurs. Injury results in hypesthesia of the palate.

3. Injury to sphenopalatine ganglion or vidian nerve:

The vessels are superficial to the nerves in the pterygopalatine space. Dissection or cauterization of tissues deep to the SPA can injure the sphenopalatine ganglion or vidian nerve. This can result in intranasal dryness and decreased lacrimation.

Surgical Technique

- Vasoconstriction of the nasal mucosa with oxymetazoline (0.05%)

Once anesthetic preparations are concluded, nasal packing is removed and replaced with cottonoids soaked in oxymetazoline (0.05%) solution. It is rare that patients continue to bleed actively at this time due to the effects of hypotensive anesthesia, head elevation, and topical

vasoconstriction.

• Maxillary antrostomy (Fig. 98.2)

Nasal endoscopy with a 0-degree endoscope is performed to identify normal landmarks and look for evidence of active bleeding. If visualization is impaired due to active bleeding, temporary hemostasis can be achieved with monopolar suction electrocautery. The middle turbinate is medialized to gain access to the middle meatus. If there is obstruction secondary to a concha bullosa, it is partially resected to improve access. In the instance of severe septal deviation precluding visualization, septoplasty is performed to allow unhindered access to the middle meatus.

A maxillary antrostomy facilitates exposure of the proximal SPA and provides additional space for instrumentation. The uncinate process is resected with backbiting forceps, the natural ostium is identified, and the antrostomy is widened posteriorly and inferiorly.

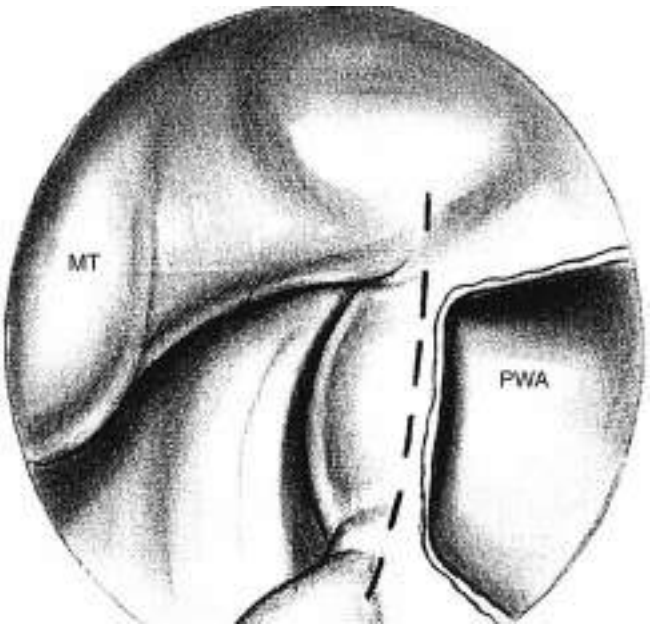

FIG. 98.2 After left middle meatal antrostomy, the mucoperiosteum posterior to the antrostomy is elevated from the lateral nasal wall. *MT,* Middle turbinate; *PWA,* posterior wall antrum. Reprinted with permission from Waring M, Padgham N: Osteologic classification of the SP foramen. Laryngoscope 108:125-127, 1998.

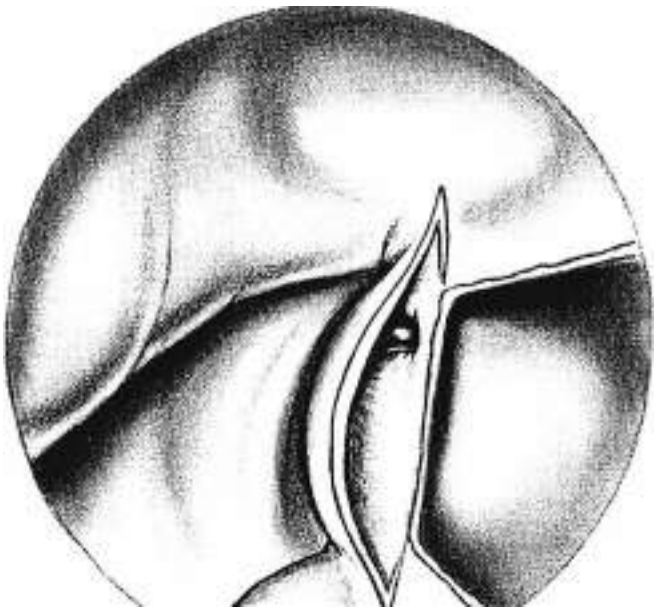

FIG. 98.3 The sphenopalatine artery is exposed at the posterosuperior corner of the maxillary sinus. Reprinted with permission from Waring M, Padgham N: Osteologic classification of the SP foramen. Laryngoscope 108:125-127, 1998.

- Identify the sphenopalatine foramen (Fig. 98.3).

A Cottle elevator is used to elevate the mucoperiosteum from the lateral nasal wall inferior to the antrostomy. Dissection continues posteriorly below the level of the sphenopalatine foramen. The projection of the crista ethmoidalis is superficial to the sphenopalatine foramen. The level of the foramen typically corresponds to the posterior attachment of the middle turbinate. As the periosteum is elevated, there is stretching of the branches of the SPA, which aids in identification (Fig. 98.4). It is helpful at this time to replace the Cottle elevator with a 7-Fr Frazier suction, which maintains tension on the vessels and suctions blood from the surgical field. The suction can be left in this space unattended; this frees up the surgeon's hand for further instrumentation.

FIG. 98.4 Endoscopic view of the right sphenopalatine artery *(asterisk)* at the point where it exits the foramen.

• Enlarge the sphenopalatine foramen (Fig. 98.5).

A 1-mm angled Kerrison rongeur is then placed into the sphenopalatine foramen superficial to the SPA, and the overlying bone is removed. Care is taken to avoid injury to the branches of the SPA by remaining superficial to the periosteum enveloping the pterygopalatine fossa (PPF) space contents. If active bleeding from the vessels is encountered, it can be temporarily controlled with bipolar or monopolar electrocautery. Cadaveric studies demonstrate that there is proximal branching of the SPA with separate foramina approximately 40% of the time. This is another advantage of a wide exposure; the surgeon is less likely to miss a branch exiting through a separate foramen. Removal of bone continues into the pterygopalatine space with partial removal of the posterior wall of the maxillary sinus. A 2-mm Kerrison rongeur is ideal for this step. Enough bone should be removed to identify the main trunk of the SPA.

• Dissect distal branches of the sphenopalatine artery.

A blunt dissector (Cottle instrument or nerve hook) is used to separate the adipose tissues surrounding the vessels. If necessary, bipolar electrocautery can be used to shrink the adipose tissue and achieve venous hemostasis. It is not necessary to dissect all of the branches of the internal maxillary artery.

• Place hemoclips or cauterize vessels (Fig. 98.6).

Using an adjustable clip applier, a medium-sized hemoclip is placed securely across the main trunk of the SPA lateral to the foramen. If possible, a second clip is placed. It is better to palm the hemoclip applier as it is introduced to avoid premature bending of the hemoclip, causing it to fall out of the clip applier. The two distal branches of the SPA are also identified and ligated. If the vessel is torn or the hemoclips cannot be applied securely, thorough bipolar electrocauterization of the vessel is performed.

• Cover with Gelfoam.

The surgical site is irrigated with warm saline and a small piece of Gelfoam is placed over the hemoclips at the surgical site. Silastic septal splints are sutured to the nasal septum to prevent synechiae. Nasal packing is usually not necessary. If packing (Merocel tampon) is placed for additional hemostasis due to nonarterial bleeding, it is important to do so under endoscopic visualization to avoid dislodging the hemoclips.

FIG. 98.5 The foramen is enlarged with a rongeur to expose the main trunk of the sphenopalatine artery. Reprinted with permission from Waring M, Padgham N: Osteologic classification of the SP foramen. Laryngoscope 108:125-127, 1998.

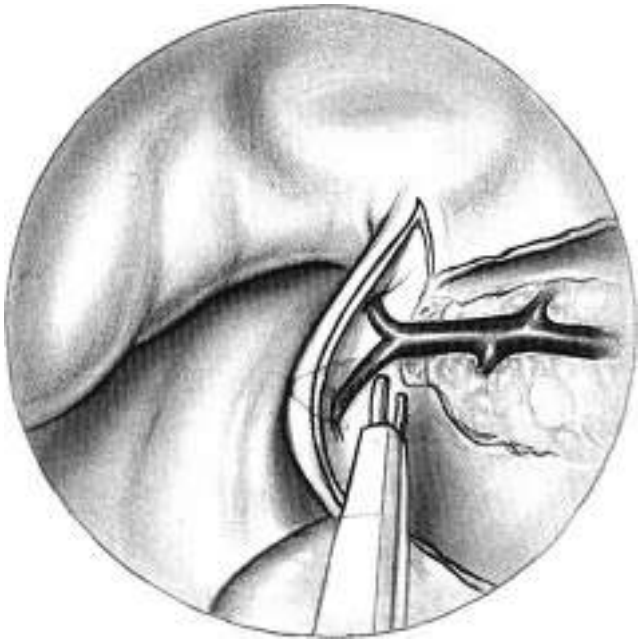

FIG. 98.6 Hemoclips are placed on the main trunk of the sphenopalatine artery and its terminal branches. Reprinted with permission from Waring M, Padgham N: Osteologic classification of the SP foramen. Laryngoscope 108:125-127, 1998.

Common Errors in Technique

1. Inadequate exposure of the lateral nasal wall

Inadequate exposure limits visualization and does not provide adequate room for instrumentation. A maxillary antrostomy can be helpful for exposure and access to the vasculature. If the middle turbinate is restricting access, the anterior-inferior portion can be resected without any adverse sequelae. A branch of the SPA may be missed if the proximal trunk is not identified before it branches.

2. Approaching the sphenopalatine foramen too high

A direct approach to the sphenopalatine foramen makes identification of the vessels more difficult and risks further injury to the vessels. Rather, dissection in the subperiosteal plane inferior to the sphenopalatine foramen provides space for a suction instrument with stretching of the vessels. Occasionally, an aberrant branch of the SPA exits the bone in this area and may be a source of bleeding.

3. Using a Kerrison rongeur that is too large

Attempting to use a 2-mm Kerrison rongeur to open the sphenopalatine foramen risks injury to the vessels; rather, a 1-mm angled Kerrison rongeur should be used.

4. Failure to identify both branches of the SPA

Recurrent epistaxis can occur if only one of the terminal branches of the SPA is ligated. This is most commonly seen when the surgeon attempts to ligate the vessels with limited exposure (without performing an antrostomy).

5. Wrong hemoclip applier

The disposable hemoclip applier that is used by general surgeons has a barrel-shaped shaft and is too large for intranasal use. An adjustable pistol-grip hemoclip applier with a flat shaft is preferred.

6. Hemoclips are not secure

Hemoclips that are too small for the vessel will not completely occlude the vessel and may become dislodged. Hemoclips do not close completely at the apex of the clip. The proper technique is to use the distal part of the hemoclip for compression of the vessel.

7. Placement of a Merocel tampon (for nonarterial bleeding) at the end of the case may dislodge the hemoclips if it is done without visualization.

Postoperative Period

Postoperative Management

1. Monitor for acute blood loss anemia.

Check hemoglobin/hematocrit postoperatively and follow guidelines for blood replacement. An iron supplement may be prescribed for several weeks if indicated.

2. Pain medication

Patients are not expected to have much pain following this operation. Minor pain can be treated with acetaminophen. If bleeding is controlled, nonsteroidal anti-inflammatory drugs such as ibuprofen may be started several days following surgery.

3. Antibiotics

Continuation of antibiotic therapy postoperatively is not necessary unless the patient had nasal packing and is being treated for sinusitis.

4. Saline irrigations

Liberal use of saline spray and irrigations helps remove blood clots and maintain a clear nasal airway.

5. Resumption of anticoagulants/antiplatelet drugs

Essential medications may be resumed on the first postoperative day if there is no active bleeding.

Complications

1. Hemorrhage

Postoperative hemorrhage is usually due to mucosal trauma, and management depends on the severity. Minor epistaxis can be managed conservatively with topical decongestant spray or anterior nasal packing. Severe epistaxis indicates failure of the surgical ligation or bleeding from a different site. If nasal endoscopy suggests that the bleeding is from the SPA on the same side as the surgery, options include re-exploration in the operating room or angiography with embolization. The same considerations apply as discussed previously. Surgery provides the opportunity to address both the SPA and AEA. Common reasons for failure include a displaced hemoclip, bleeding from the SPA proximal to the hemoclip, or failure to recognize a branch of the SPA. Rarely, bleeding from the contralateral SPA will require SPA ligation on that side.

2. Synechiae

Synechiae can be prevented with the use of silastic septal splints for 1 to 2 weeks. If synechiae form, lysis is not necessary unless they are symptomatic (airway or sinus obstruction).

3. Sinusitis

Sinusitis may result from mucosal edema from nasal packing and instrumentation and can be managed with oral antibiotics, topical steroid spray, and saline irrigation. Chronic rhinosinusitis may occur secondary

to postoperative scarring of the ostiomeatal complex.

4. Palatal hypesthesia from injury to the descending palatine nerve

Most nerve damage is partial and transient. Patients are reassured that sensation will return over a period of weeks to months.

5. Septal necrosis

Rarely, necrosis of the nasal septum will occur following SPA ligation. Potential risk factors include bilateral SPA ligation and extensive cauterization of the septum and nasal packing prior to surgery.

Alternative Management Plan

1. Angiography and embolization

Embolization is preferred when the patient is not a candidate for general anesthesia due to medical comorbidities. The site of bleeding cannot be identified unless there is active bleeding at the time of angiography. For that reason, all of the contributing vessels on the side of the epistaxis are often embolized: internal maxillary artery and facial artery. The ethmoidal arteries cannot be embolized without risk of blindness. Further, embolization carries a small risk (<2%) of stroke, blindness, and soft tissue ischemia. Overall, embolization is less cost-effective than surgical ligation, and the required expertise is not available at many institutions. If someone has already failed SPA ligation, embolization is an option, but repeat surgery is preferred in most situations. If a patient is anticoagulated, embolization may have an advantage. Lastly, embolization avoids trauma to the nasal mucosa by avoiding surgical manipulation.

2. Transmaxillary ligation of the internal maxillary artery (IMA)

An alternative to endonasal SPA ligation is transmaxillary ligation of the IMA. It has greater morbidity, however, and risks failure due to missed branches of the IMA with collateral circulation. An anterior maxillotomy via a sublabial approach provides access to the proximal trunk of the IMA behind the posterior and lateral walls of the maxilla. This approach can be used instead of embolization to devascularize small or medium-sized angiofibromas or for devascularization of a malignant neoplasm prior to biopsy or debulking.

Discussion

Evidence-Based Medicine Question

Is SPA ligation as effective as other hemostatic techniques?

According to several case series and literature reviews, success rates for SPA ligation are equivalent to or better than success rates for embolization.

A comprehensive literature review of endovascular treatment for intractable posterior epistaxis reports an immediate success rate between 93% and 100%. However, this rate drops to 77% to 95% when early rebleeds were taken into account. Furthermore, when retrospective reviews that take late rebleeds into account are included, success rates drop further to between 71% and 89.2%.[1]

Reported success rates for SPA ligation range from 87% to 98%. The three largest retrospective series (50, 45, and 45 patients) report long-term success rates between 87% and 93%; in a pooled series of 127 patients from 11 case series, SPA ligation was reported to control epistaxis in 98% of cases. In these series, there were no major complications; minor complications included nasal crusting and paresthesias of the palate and nose. Furthermore, inability of SPA ligation to control epistaxis may represent an incorrect choice of procedure rather than a failure of the procedure: A significant number of rebleeds were successfully managed with subsequent anterior ethmoid artery ligation.[2]

In a review of data reported by hospitals to the Nationwide Inpatient Sample (2008–2010), comprising over 57,000 patients admitted with a primary diagnosis of epistaxis, no significant differences in clinical outcomes were noted between SPA ligation and embolization in the population studied. Total hospital costs, however, were significantly higher for patients undergoing embolization.[3]

A 2013 standard decision analysis model found first-line SPA ligation to be the most cost-effective strategy in management of posterior epistaxis when compared to current posterior nasal packing algorithms.[4]

The results from a recent modeling-based economic evaluation suggest that for patients with intractable epistaxis, when both SPA ligation and

arterial embolization are viable options, SPA ligation is the more cost-effective treatment strategy. In a follow-up study examining the risk profile of various laddered management algorithms involving posterior packing, SPA ligation, and embolization, the lowest-risk strategies were found to be those that use SPA ligation as a first-line strategy. When risk outcomes were combined with cost-effectiveness data, the authors concluded that SPA ligation should be considered as the first-line strategy for intractable epistaxis, because it minimizes patient risk and promotes the most efficient use of health care resources.[5]

Editorial Comment

Transnasal endoscopic SPA ligation is a highly effective method for controlling refractory posterior epistaxis. SPA ligation appears to have a favorable outcome and increased cost-effectiveness compared to arterial embolization. The techniques described in this chapter provide practical guidance for safe and effective endoscopic SPA ligation, which in appropriately selected patients, is emerging as the preferred method for controlling intractable posterior epistaxis and in skull base surgery, a necessary skill for the transpterygoid approach.

Review Questions

1. Which option is *not* a landmark for the sphenopalatine foramen?

   a. Posterior attachment of the middle turbinate

   b. Crista ethmoidalis

   c. **Pterygoid canal**

   d. Posterosuperior corner of the maxillary sinus

2. Which option is *not* a potential complication of SPA ligation?

   a. Loss of emotional tearing

   b. Palatal numbness

c. Septal necrosis

d. **Blindness**

3. Which option is *not* a possible reason for failure of SPA ligation?

a. **Hypertension**

b. Limited exposure with clipping of only one vessel

c. Bleeding from the anterior ethmoid artery

d. Dislodged hemoclip

Operative Otolaryngology

Anterior and Posterior Ethmoid Artery Ligation for Epistaxis

Andrew Thamboo, Evan S. Walgama*, and Jayakar Nayak**

Introduction

Epistaxis is a common medical problem; however, the exact prevalence of this condition is unknown because patients themselves manage many cases conservatively. It is believed the prevalence may be as high as 30% in children younger than 5 years old and up to 50% in children aged between 6 and 15 years.[1] In adults, the prevalence of epistaxis has not been as well documented but most commonly occurs between the ages of 70 and 79 and in the winter months when the inhaled air is driest.[2]

The location and source of epistaxis can be quite variable, the majority occurring along the anterior nasal septum. The anterior septum contains a plexus known as Kiesselbach's plexus or Little's area, which is made up of minor vessels branching off of the anterior ethmoid artery (AEA), sphenopalatine artery (SPA), and facial artery. Posterior epistaxis arises primarily from the SPA and its associated branches, but the posterior ethmoid artery (PEA) may also be a possible source.[3] Although many of these nosebleeds are managed conservatively by pinching the nose, inserting absorbable or nonabsorbable packs, using topical vasoconstrictors such as adrenalin or oxymetazoline, or even warm water irrigation,[4,5] epistaxis coming directly off the AEA, SPA, and PEA may require more definitive management.

Key Operative Learning Points

1. The AEA and PEA branch off the ophthalmic artery; therefore arterial embolization and/or endovascular coiling are not options because this may result in blindness.

2. When viewing the skull base from below, the AEA is best identified just posterior to the supraorbital ethmoid (SOE) cell.

3. The AEA neurovascular bundle can be approached externally as it enters the high ethmoid complex from the orbit approximately 20 to 24 mm posterior to the anterior lacrimal crest, and the PEA is approximately 9 to 16 mm posterior to the AEA foramen. The optic nerve is 4 to 7 mm posterior to the PEA foramen.

4. The AEA or PEA can be ligated using bipolar cautery, but hemoclips are preferred when possible for the PEA given its proximity to the optic nerve.

5. The direction of arterial blood flow through the AEA and PEA is lateral (orbital) to medial (skull base), making lateral control of the vessel essential during ligation. Retraction of either vessel laterally back into the orbit can contribute to rapid hematoma and intraocular pressure (IOP) shifts.

History

1. History of present illness

   a. Obtaining the history of presenting illness can be performed only after the patient is stable. In the unstable patient, institutional trauma protocols should be used to resuscitate the patient with appropriate fluid and/or blood.

      Determine the source of bleeding: Is the bleeding primarily arising anteriorly or posteriorly? On which side did the bleeding begin? If patients can provide a clear history that the bleeding is primarily occurring anteriorly, one should assess the anterior septum followed by the AEA, although rare, as the possible source. If the patient states that the bleeding seemed to arise "somewhere in the back," one should consider the source to be the SPA or its associated branches, followed by the PEA (rare). Patients often have difficulty identifying the side of the bleeding

unless it is a recurrent or bleeding slowly, but if laterality can be determined, this may save time in managing the bleeding.

b. Determine the severity and quality of the bleeding: How profuse was the bleeding—torrential, sudden, and aggressive (suggestive of an arterial source) or steady/continuous but low grade (perhaps more venous)? When did the bleeding begin? Does the patient feel weak or light headed? Is the bleeding experienced every winter and/or seasonal? Is this bleeding recurrent and readily managed? (The latter three points all suggest Kiesselbach plexus as the likely source from ambient air changes in humidity, seasonal allergies, and anterior, low-grade bleeding.)

c. Patients are often anxious about events related to epistaxis, and therefore the general amount of blood lost might be requested in terms of "teaspoons," "tissues," "cups," or "buckets." The patient's presentation and how long he or she has been bleeding will also assist the clinician to determine the severity of the bleeding. If the severity is unclear, the associated symptoms may indicate how he or she is coping with the blood loss. Any symptoms such as light headedness, "hot and clammy," palpitations, or feeling weak should alert the clinician to hemodynamically assess and/or resuscitate the patient before completing the history.

d. Determine where there are any associated symptoms: Do you have facial numbness/hypesthesia, unilateral nasal obstruction, or diplopia? Do you have fevers, sweats, or weight loss? Any of the aforementioned symptoms may indicate a possible more serious etiology as the underlying cause of the epistaxis. One should always consider nasopharyngeal cancer in those of Southeast Asian decent and juvenile nasopharyngeal angiofibroma in adolescent males as the source of persistent unilateral epistaxis.

e. Additional questions should be asked based on clinical suspicion to help determine the etiology of the nosebleed (Table 99.1).

2. Past medical history

a. Previous epistaxis: How often do you have episodes? Does the onset occur during a particular time of day, season, or activity? Do you know what aggravates your bleeding? How have you managed your previous episodes? Have you seen a doctor regarding epistaxis, and

how was it managed?

TABLE 99.1

Common Etiologies of Epistaxis

Local Causes	Systemic Causes
Chronic rhinosinusitis	Congenital coagulopathies
Digital trauma	Hypertension
Foreign bodies	Leukemia
Irritants	Liver dysfunction
Neoplasm	Medications
Septal deviation	Platelet dysfunction
Septal perforations	
Trauma	
Vascular malformations	

b. Medical illness: Do you have a bleeding disorder? Do you have a history of bruising? Is there a history of liver disease, immunosuppression, or vitamin deficiency? If the underlying source of the bleeding is due to a medical source, a hematologist should be consulted to help in the management. Recurrent epistaxis despite management is another reason to consult a hematologist.

c. Surgery: Have you had sinonasal surgery or rhinoplasty?

Recent surgery will guide the clinician in determining the possible source of the epistaxis. If a patient has had a septoplasty or rhinoplasty, one should be cautious when cauterizing the anterior septum because this may lead to a slightly increased chance of a septal perforation.

d. Family history: History of bleeding disorder?

e. Medication:

1) Anticoagulants (numerous families of agents)

2) Herbal products such as omega-3 supplements, garlic, ginseng, and ginkgo biloba

3) Alcohol—heavy intake

Physical Examination

1. Self-protection/universal precautions

Proper protective equipment including face shield, eye shield, gown, and gloves should be worn.

2. Preparing the nose for examination

The entire nasal cavity should be copiously irrigated with saline solution to remove clots. This can be done with a 60-mL syringe or other squeeze bottle irrigation with the patient's head tilted over a large basin.

3. Anterior rhinoscopy and nasal endoscopy

Anterior rhinoscopy followed by rigid nasal endoscopy with a 30-degree endoscope should be used to evaluate the entirety of the nasal cavity—anteriorly and posteriorly. Any site of anterior nasal crusting should be removed because the site of spot hemorrhage is often located underneath these "biologic dressings." The nasopharynx should always be assessed to rule out nasopharyngeal cancer. A rigid endoscope is used preferentially over a flexible scope because it allows the ability to suction and use instruments in the nasal cavity if a bleeding site is seen. Topical decongestants mixed with lidocaine/benzocaine can be placed after the first assessment. Placing a topical decongestant prior to one's first assessment may put the arterial source under temporary vasospasm, resulting in a negative examination.

If the source of the epistaxis can be visualized, cautery (e.g., silver nitrate, bipolar electrocautery) can be used directly on the mucosa. If the bleeding is coming from a superior source, dressing material or any version of nasal packing placed under endoscopic visualization can help ensure that the appropriate site is tamponaded. In all cases, especially when the patient is coagulopathic with diffuse mucosal bleeding, minimizing trauma to the mucosa will help prevent further bleeding. It is advised to use absorbable packs in these individuals. If a direct source is seen in these patients and a nonabsorbable pack will not tamponade the source, cautery can be used but with caution because this may cause further bleeding. Alternatively, nasal balloon systems that atraumatically contain the active hemorrhage can be used.

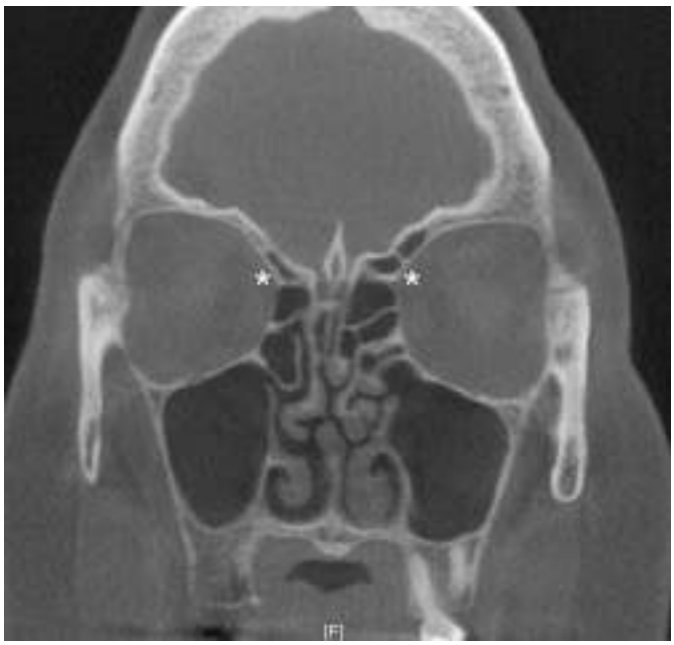

FIG. 99.1 Computed tomography (CT) landmark for anterior ethmoid artery. Coronal CT scan of sinuses, showing bilateral "nipple signs" *(*)* that typically arise between the superior oblique and medial rectus muscles.

4. Oral cavity

Examination of the oropharynx will often reveal whether blood is draining posteriorly. The examination of the oral cavity should also be evaluated for telangiectasias or tumors of the hard palate, maxilla, or tonsil as the cause of the epistaxis.

5. Examination of the cranial nerves

A complete neurologic examination should be performed to rule out malignancy extending from the sinonasal cavity.

Imaging

None necessary

External approaches do not require imaging.

Computed tomography (CT)

Those performing an endonasal approach should consider obtaining a CT scan to help localize the AEA. If the institution uses a navigation

system, the CT scan can be registered to facial landmarks to help identify the artery intraoperatively. Using the coronal views, the "nipple" sign will help to identify the AEA (Fig. 99.1). This is a triangular evagination in the superomedial orbital wall that reliably falls between the densities of the medial rectus and superior oblique muscles. The PEA also has a nipple sign, which is nearly always in the skull base and not associated with any specific muscle group.

CT angiogram

Magnetic resonance imaging (MRI)

Angiography

Indications

1. Failed epistaxis management at bedside

If the bleeding site can be visualized endoscopically, chemical or electrocautery can be performed. However, occasionally the exact area from which the bleeding arises cannot be seen due to anatomic obstruction (deviated septum, between the middle turbinate and septum) or the artery in question is under vasospasm after the nasal pack has been removed. In these situations the approach to arterial ligation is institution dependent. In our institution, unilateral SPA ligation before AEA ligation is favored, but others perform combined SPA and AEA ligation as primary treatment. The clinical context may also change depending on history (i.e., facial trauma resulting in high suspicion for AEA injury, or recent SPA ligation been attempted), past medical history (anesthesia risk, requiring combined SPA and AEA ligations to prevent the need for any future general anesthesia), or even social history (i.e., patient lives alone in an area remote from access to medical care).

2. Refractory epistaxis

As noted previously, if the rare patient fails a properly performed SPA ligation, and there is convincing evidence of unilateral epistaxis, we may then proceed with an AEA ligation. The PEA is rarely a cause of epistaxis but should be considered a source of epistaxis in the exceedingly rare situation of failure of both SPA and AEA ligations.

3. Tumors

Resection of benign and malignant tumors may require ligation of the AEA and PEA before resection of particular anterior skull base tumors. These vessels are not amenable to endovascular approaches due to continuity with the internal carotid system.

Contraindications

Not medically fit for surgery (sometimes that consideration must also be waived in the setting of life-threatening epistaxis)

Preoperative Preparation

1. Stabilize the patient with nasal and, if necessary, postnasal packing.

2. Preoperative laboratory studies to assess hemoglobin/hematocrit, international normalized ratio, partial thromboplastin time

3. Rapidly reverse anticoagulation, if necessary, and optimize medically.

4. Reduce blood pressure (although data on the efficacy of this strategy are limited).

5. Obtain consent for surgery and possible transfusion.

Operative Period

Anesthesia

General

Protection of the airway is a priority of the surgeon and anesthesiologists. If the bleeding is ongoing and severe, intubation may be difficult; this can become more challenging depending on the patient's body habitus. Therefore it important that the surgeon and the anesthesiologist agree on each patient's difficult airway management algorithm to secure the airway if problems arise.

Positioning

Supine

The patient is positioned the same as in any endoscopic sinus procedure with the head turned slightly toward the surgeon with the operating table in reverse Trendelenburg.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Second-generation cephalosporin

Clindamycin if the patient is allergic to penicillin

FIG. 99.2 Endoscopic view of anterior, middle, and posterior ethmoid arteries at skull base. *AEA,* Anterior ethmoid artery; *MEA,* middle ethmoid artery; *PEA,* posterior ethmoid artery. Image courtesy of Dr. Ricardo Carrau, Ohio State University, and used with permission from Wang L, Youseef A, Al Qahtani AA, et al: Endoscopic anatomy of the middle ethmoidal artery. Int Forum Allergy Rhinol 4(2):164-168, 2014.

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Basic endoscopic sinus surgery set

Management of the AEA and PEA may require angled instrumentation and angled telescopes and should be a part of the basic endoscopic sinus surgery set.

2. Endoscopic bipolar electrocautery

A pistol-grip endoscopic bipolar electrocautery is preferred, given the proximity of the AEA and PEA to the dura. The use of monopolar cautery may result in excess current transmission through the dura and a challenging concurrent cerebrospinal fluid (CSF) leak. An angled pistol-grip endoscopic bipolar will assist in the uneventful management of the AEA.

3. Pistol-grip endoscopic clip applier

Specific pistol-grip endoscopic clip applier made for the sinuses may be used as a substitute to pistol-grip endoscopic bipolar. If an external approach is performed, the clip applier may be the preferred option for the PEA given its proximity to the optic nerve.

Key Anatomic Landmarks

1. SOE air cell

The degree of pneumatization of the frontal sinus or SOE can affect the position of the AEA, but the AEA is universally found posterior to the SOE.[6] Consequently, excellent understanding of frontal sinus and SOE anatomy will assist in accurate identification of the AEA, if endoscopic ligation is intended (Fig. 99.2). A middle ethmoid artery has also been identified between the AEA and PEA, but this is beyond the scope of this chapter.[7]

2. Basal lamella of the ethmoid bulla and axilla of middle turbinate

Historically, the AEA has been closely associated with the skull base attachment of the basal lamella of the ethmoid bulla,[8] but more recently a number of reports have effectively used other landmarks to identify the

location of the AEA endoscopically. The relationship of the AEA to the axilla of the middle turbinate has been measured to be approximately 17 to 25 mm.[9,10]

3. Sphenoid face

By contrast, the PEA is often not appreciated endoscopically. If present and visible, it is consistently (98% reliability)[9] found approximately 8.1 mm anterior to the sphenoid face. The caliber of the PEA is smaller than the AEA and often embedded in the skull base, whereas one-third of AEA can be found within a bony mesentery pendant in the sinus airspace, off of the skull base.

4. Anterior lacrimal crest

The AEA and PEA can also be identified before entering the ethmoid cavity. The AEA foramen is approximately 20 to 24 mm posterior to the anterior lacrimal crest. The PEA can then be found approximately 9 to 16 mm posterior to the AEA. It is important to note that the optic nerve is closely approximated to the PEA, arising approximately 4 to 7 mm posterior to the PEA foramen (Fig. 99.3).

Prerequisite Skills

1. Endoscopic maxillary antrostomy (see Chapter 103)

2. Endoscopic ethmoidectomy (see Chapter 108)

3. Endoscopic frontal sinusotomy (see Chapter 112)

Operative Risks

1. Retro-orbital hematoma

If unintentionally transected or avulsed before ligation, the AEA and PEA may retract into the orbit and potentially cause a retro-orbital hematoma. It is important that when applying cautery or hemoclips, the entire caliber of the vessel must be ligated 360 degrees. If a vessel retracts into the orbit, the surgeon should be prepared to perform an emergent lateral canthotomy and cantholysis if the affected orbit becomes asymmetrically proptotic or indurated.

2. CSF leak

When working along the skull base, the process of exposing the AEA or PEA may inadvertently breach the skull base and meningeal linings, leading to CSF leak. Gentle peeling of the bone off the medial lamina paprycea and then slowly proceeding up to the AEA or PEA will reduce the chances of skull base breach.

3. Orbital injury

The process of removing the lamina papyracea bone to expose the vessels puts the orbit at risk. The goal ideally is to keep the periorbital lining intact, which, if breached, may result in prolapse of orbital adipose tissue. Intraoperatively, it is important to identify orbital adipose tissue and work around the site of breach by protecting the area from further damage. Some practitioners gently bipolar cauterize the exposed adipose tissue to reduce the volume and cauterize any unnamed, minute orbital vessels in the process. Postoperatively patients are counseled to avoid the use of high-volume saline irrigation or cough or sneeze with their mouth closed to limit the possibility of air entry into the orbit.

4. Inability to control bleeding

The surgeon must be prepared for the need for alternative methods. If all methods have been exhausted and bleeding persists, the patient should be kept intubated and have a formal packing placed with close observation in a high acuity unit. If packing and time alone do not resolve the situation, options include embolization versus consultation of a second surgeon for assistance.

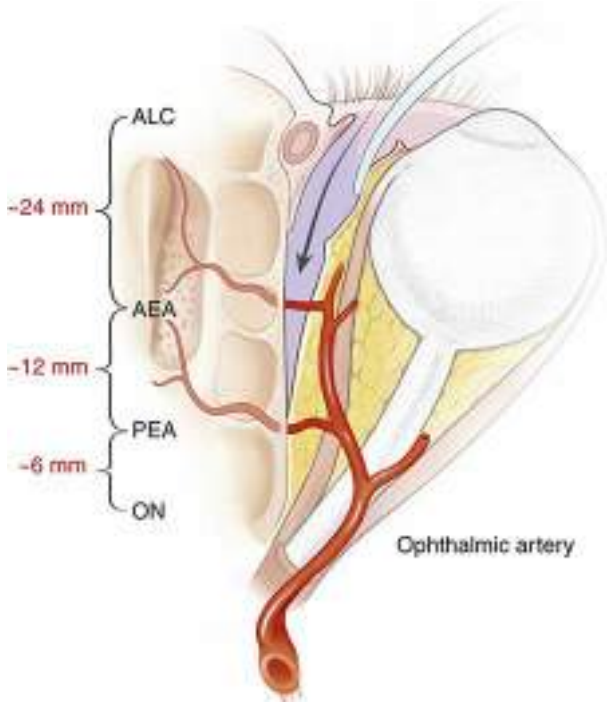

FIG. 99.3 Illustration in axial plane of the anterior and posterior ethmoid arteries and optic nerve. Distances of critical structures from the anterior lacrimal crest are shown on the left. *AEA,* Anterior ethmoid artery; *ALC,* anterior lacrimal crest; *ON,* optic nerve; *PEA,* posterior ethmoid artery.

Endoscopic Surgical Technique

- CT navigation system

  Before taking the patient to the operating room, a thin-cut CT scan (preferably <1.25 mm) can be obtained to help to identify the arteries. It should be calibrated to the patient after intubation.

- Nasal packs

  The nasal packs should be removed after intubation. The entire nasal cavity is then copiously irrigated with warm water to assist with endoscopic visualization of the nasal cavity. The nasal cavity should then be decongested with pledgets soaked in oxymetazoline or dilute topical epinephrine (1:1000 at the authors' institution).

- Uncinectomy

A standard uncinectomy is carried out to provide access to the ethmoid bulla. We prefer a posterior to anterior approach during uncinate removal to limit orbital complications. A backbiter is then used to expose the natural ostia, and then the uncinate is dissected off of its attachment along the maxillary line with through-cutting instruments.

- Anterior ethmoidectomy

The ethmoid bulla can be removed by placing the J-curette into the retrobullar space (also termed *hiatus semilunaris superior*) and the entire bulla cleanly resected through gentle push-pull maneuvers on the bulla using noncutting instruments. Remnant loose tissue edges can then be removed with use a microdébrider.

- Frontal sinus recess dissection—identifying frontal sinus and SOE

The frontal sinus recess should be completely dissected, and the frontal sinus and SOE should be identified with angled endoscopes and instruments. The frontal sinus is always anterior and medial to the SOE. The impression, or actual pedicled mesentery, of the AEA will be seen posterior to the SOE, and its location can additionally be verified using the CT navigation system.

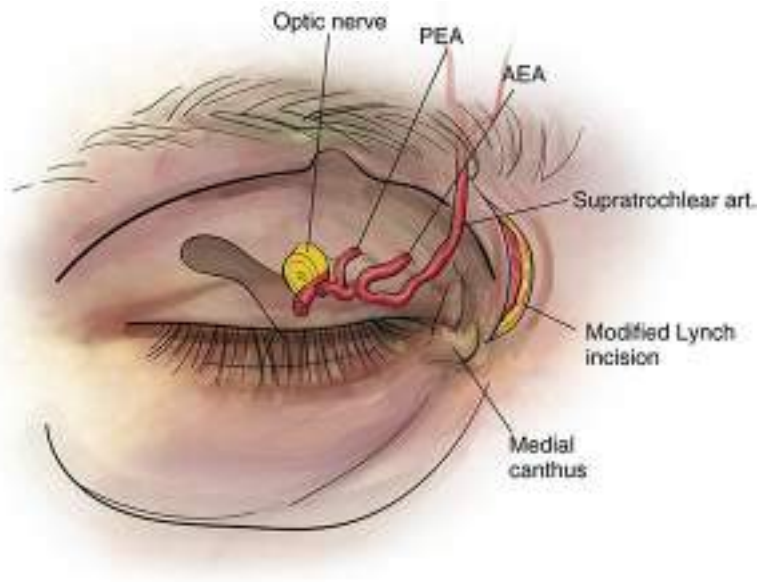

FIG. 99.4 Illustration in parasagittal view of the anterior and posterior ethmoid arteries and optic nerve. When

using an external approach to ligate the AEA and/or PEA, the modified Lynch incision is typically used, which spans medial brow to level of medial canthus, within the shadow line of the orbit. The foramina to the AEA and PEA arise from within the frontoethmoid suture line. *AEA,* Anterior ethmoid artery; *PEA,* posterior ethmoid artery;

- AEA exposure

  If the AEA is hanging within a mesentery, it can be directly circumferentially ligated with bipolar cautery. If the AEA is encased in bone, the exit of the artery from the orbit is the safest manner for gaining arterial control. The lamina papyracea is gently fractured with a Cottle elevator, and the maxillary sinus seeker/Lusk probe is then used to tease the bone flakes off of the underlying periorbita. The pyramidal neurovascular bundle exiting the orbital vault should now be evident. Using angled Kerrisons, additional bone can be removed around the AEA, including a small segment of the cranial base cortical bone. Circumferential exposure of the AEA is important to achieve prior to ligation.

- Ligation of AEA

  After adequate exposure has been obtained, ligation can be performed either with two medium-sized hemoclips or, in the authors' department, bipolar electrocautery. Circumferential exposure ensures that the entire arterial vessel is ligated (Video 99.1).

- Ligation of PEA

  If the PEA is to be ligated endoscopically, a posterior ethmoidectomy is first required. The PEA is most commonly completely encased in bone; therefore the lamina papyracea needs to be removed in a similar fashion to that described for the AEA. (Video 99.2)

- Nasal packing

  No formal nasal pack is typically required after ligation, but at the completion of the dissection, the middle turbinate should be medialized as done in routine endoscopic sinus surgery to prevent lateralization and iatrogenic sinusitis in the future.

External Surgical Technique

- Corneal protection

  After the patient is intubated, the nasal packing is left in place and the cornea is protected with either a temporary tarsorrhaphy or a corneal protection shield.

- Local anesthetic

  The incision site is infiltrated with 1% lidocaine with 1:100,000 epinephrine. The incision site will be located midway between the nasal dorsum and medial canthus, along the course of the frontoethmoid suture line.

- Lynch incision (Fig. 99.4)

  A curvilinear incision is marked out in the "upper shadow line" of the orbit, between the medial brow margin and the medial canthus. The incision is made with a 15-blade scalpel down to the periosteum. A bipolar cautery should be available at this time because the angular artery may be transected during this incision. A Cottle elevator is then used to gently elevate the periosteum in a posterior direction off of the nasal bone, the frontal process of the maxilla bone, and the lamina payracea.

- Soft tissue elevation

  It is important to identify three different landmarks in the initial elevation. The superior limit of the elevation is just beyond the frontoethmoidal suture line, the inferior limit is the lacrimal sac, and the lateral elevation is to the junction between the anterior lacrimal crest and the frontoethmoidal suture line. The identification of this junction guides the direction of the elevation along the contour of the medial orbital wall. Elevation should occur along or parallel to the frontoethmoid suture line (although this "line" is never actually visualized under dissection). Occasionally, small commissural venules between the periorbita and the underlying bone may be encountered. These may be confused for the AEA neurovascular bundle but tend to appear evanescent and small in caliber. Only occasionally do these vessels require bipolar cautery for management.

- Identification of AEA

The AEA should be identified approximately 24 mm from the anterior lacrimal crest, appearing as a thick "pyramid" of soft tissue surrounded by a fascia bundle clearly extending from lateral to medial through its foramen. The skin can be retracted with small skin hooks, and the orbital contents can be gently retracted laterally with a flat malleable retractor. After the AEA is identified, tissue planes should be elevated around and beyond the vessel to expose the AEA. At the authors' institution, we switch to a 3-mm endoscope to help to visualize and ligate the vessel.

- Ligation of AEA

  Ligation can be performed with two medium-sized hemoclips or bipolar cautery to control the entire caliber of the vessel in situ, without vessel retraction. The most proximal/lateral site of the AEA is essential to control (Video 99.3).

- Ligation of PEA

  If the PEA is also to be addressed through this approach, further periorbital elevation along the frontoethmoid suture line is required, and increased soft tissue retraction in the orbital vault is required. The additional depth of dissection required would be approximately 12 mm from the AEA foramen. Extreme caution should be exercised when ligating the PEA, given its proximity to the optic nerve (6 mm away from the PEA foramen). Ligation of the PEA should preferably be accomplished with hemoclips to avoid inadvertent heat transmission to the adjacent optic nerve. Care should be taken not to traumatize the optic nerve with the hemoclips.

- Assessment of hemostasis

  The wound site should then be irrigated while the packing is removed from the nasal cavity. The nasal mucosa lining will be engorged and should be decongested with oxymetazoline-soaked pledgets before endoscopic assessment of the entire nasal cavity.

- Closure of the incision

  The wound is then closed using a two-layered closure technique. Steri-Strips and/or tissue glue are then applied to the incision site.

Common Errors in Technique

1. Inadequate identification of SOE

If CT navigation is not used to help to identify the AEA, the ability to surgically identify the SOE should be a skill set comfortable for the individual surgeon to accurately identify the AEA.

2. Inadequate high or low soft tissue elevation

Identification of the frontoethmoid suture line is paramount in finding the AEA and ensuring the soft tissue elevation is not performed too high or low.

Postoperative Period

Postoperative Management

1. If arterial ligation is done endonasally, standard ESS postoperative instruction should be given, including avoidance of nose blowing and strenuous activity.

2. Start saline irrigation on postoperative day 1.

3. Patients should expect to be seen postoperatively for débridement and removal of any middle meatal spacer placed during surgery (usually postoperative day 7 to 14).

4. Pain tolerance can vary, and a small course of narcotics is prescribed for the first few days. Many patients manage discomfort following this procedure with over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs) in conjunction with acetaminophen.

5. Resumption of anticoagulants/antiplatelet drugs on postoperative day 2 in our practice

Complications

1. Retro-orbital hematoma

Remove all packs from the nasal cavity. The surgeon must be prepared to perform a lateral canthotomy and cantholysis. IOP measurements may be obtained. Additional agents such as dexamethasone and acetazolamide can be provided. Ophthalmology should be consulted

immediately, but the treatment of the hematoma should not be delayed.

2. CSF leak

Refer to Chapter 116.

3. Synechiae

Routine postoperative assessment and débridement will help to decrease synechiae formation. Scar bands can typically be removed in the clinic with through-cutting instruments.

4. Iatrogenic sinusitis

Patients should first be tried on medical treatment, including saline irrigation, antibiotics, and nasal steroids. If medical management fails, surgical correction may be considered if an anatomic concern/obstruction is identified, such as restenosis of a surgical maxillary antrostomy.

5. Facial scar contracture/web at the Lynch incision site

This can be addressed with an in-office Z-plasty procedure.

6. Hypesthesia over external incision site

Hypesthesia should resolve by 6 to 12 months. If there is no resolution by 1 year, hypesthesia is likely permanent.

Alternative Management Plan

1. Transcaruncular approach

Ocular/oculoplastic surgeons generally perform this approach. This approach leaves no skin incision.

2. Embolization

This alternate plan should be approached with extreme caution. Embolization of the AEA or PEA may result in visual loss. This should only be considered if all alternative plans have failed and has never been required in our institution.

Discussion

Evidence-Based Medicine Question

In what conservative ways can one manage AEA epistaxis?

Epistaxis seen in the Emergency Department is primarily managed with some form of nasal packing. Absorbable packs are preferred because they result in less pressure to the surrounding nasal mucosa and do not require another visit to the emergency department for the removal of the pack; however, they may not be as efficient as nonabsorbable packs in controlling serious epistaxis. Commonly used nonabsorbable packs are gauzes, Merocel sponges, or some form of inflatable intranasal device for titratable tamponade.

Balloons may have an anterior balloon (e.g., Rapid Rhino), an anterior and posterior balloon (e.g., Epistat), or a posterior balloon (e.g., Foley). Unfortunately, balloons can result in a number of complications, such as mucosal, soft palate, or cartilage necrosis in addition to the obvious discomfort to the patient. Despite physicians being aware of the discomfort and complications of balloons, most otolaryngologists still use balloons despite knowing that ligation techniques are a superior intervention. In the authors' institution, if a balloon is required to stabilize a nosebleed, it then acts as a bridge to the operating room in performing a surgical ligation technique.

The best solution for patients occurs when no nasal packs are used. Warm water irrigation is a well-documented technique in addressing epistaxis. The temperature of the water should be between 46°C and 52°C. It is believed that the hemostatic effect is secondary to edema, decrease in intravascular pressure secondary to vasodilation and capacitance, and improved efficiency of the clotting cascade.

Patients who fail conservative management for epistaxis or require a balloon nasal pack should be considered for arterial ligation.

Editorial Comment

Knowledge of safe and effective surgical ligation techniques of the AEA and PEAs is important in the armamentarium of the otolaryngologist because the usual alternative for control of bleeding (i.e., arterial embolization) is not an option when patients present with epistaxis

secondary to bleeding from these vessels or for anterior skull base approaches. The authors describe both endoscopic and open approaches to surgical ligation, as well as useful adjuncts to achieve successful control of epistaxis.

Review Questions

1. What is the distance of the anterior ethmoid artery (AEA) from the anterior lacrimal crest?

   a. **20 to 24 mm**

   b. 9 to 16 mm

   c. 4 to 9 mm

   d. 1 to 4 mm

2. What is the course of the AEA along the anterior skull base when viewed from below with an endoscope?

   a. Posterior medially, anterior laterally

   b. **Anterior medially, posterior laterally**

   c. No consistent course

3. On computed tomography (CT) imaging, which muscles are most closely approximated to the medial orbital exit site/nipple of the AEA?

   a. Superior rectus and superior oblique muscles

   b. Medial rectus and inferior oblique muscles

   c. **Superior oblique and medial rectus muscles**

   d. Inferior oblique and inferior rectus muscles

4. In which direction is the flow of blood through the AEA and posterior ethmoid artery (PEA) vessels?

   a. **Lateral (orbital) to medial (cribriform skull base)**

   b. Medial (cribriform skull base) to lateral (orbital)

c. Bidirectional

Surgical Management of Hereditary Hemorrhagic Telangiectasia

*Li-Xing Man, and Berrylin J. Ferguson**

Introduction

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant genetic disorder with incomplete penetrance that is characterized by arteriovenous malformations (AVMs) in various organs and mucocutaneous telangiectasias in the nose, oral cavity, gastric mucosa, and fingers. Diagnosis is based on the Curaçao criteria, established in 2000 (Table 100.1).[1] Recurrent epistaxis is the most common symptom, present in almost all patients who have HHT by the age of 40, and it is often the most troublesome manifestation for the majority of patients. Nevertheless, the severity of epistaxis is rarely immediately life threatening compared with other manifestations such as pulmonary or cerebral AVMs (Table 100.2). International guidelines for the workup and management of the various manifestations of HHT were established in 2011.[2] Therefore, it is useful to evaluate and manage patients with HHT or suspected HHT in a multidisciplinary setting.

A patient presenting with recurrent epistaxis and multiple telangiectasias should be referred to an HHT center, if possible, for comprehensive evaluation. The incidence of HHT occurs worldwide at approximately 1 in 5000 but is increased in some specific locations. Multiple genes have been implicated in HHT, but each family will have a constant genetic finding. Genetic tests are available for a few of the major mutations. Usually genetic testing is not required as the diagnosis may be made clinically.

The average age of onset for epistaxis is 12 years, and approximately 50% of patients will be affected by age 20.[2] Epistaxis may be unilateral or bilateral, minimally bothersome to life threatening. Mild epistaxis may be

managed medically with humidification of the nasal mucosa, avoidance of anticoagulants, and application of nasal pressure. Iron supplementation may be necessary for resulting anemia. The vascular endothelial growth factor A (VEGF-A) inhibitor bevacizumab has been used in an off-label manner via intranasal spray, submucosal injection, or intravenously.[3,4] Although the use of this monoclonal antibody is promising, the degree of efficacy, safety profile, and optimal delivery method and dosage have yet to be firmly established. Specifically for bevacizumab, none of the life-threatening side effects of systemic administration have been reported with topical nasal application.[4] However, two randomized clinical trials of bevacizumab nasal spray did not reduce the duration[5] or frequency[6] of the epistaxis compared with placebo (0.9% saline). Other medical therapies with limited evidence of efficacy include estrogen, timolol, thalidomide, tranexamic acid, and *N*-acetylcysteine.[6,7] Surgical management of HHT should be considered when severe epistaxis results in blood transfusions, emergency department visits, and significantly reduced quality of life. Surgical treatment options include coagulation, radiofrequency ablation, septodermoplasty, and nasal closure (Young procedure). The Epistaxis Severity Score is a validated, disease-specific questionnaire that may be used to measure disease severity and assess the effect of treatment.[8]

Key Operative Learning Points

- In-office coagulation of telangiectasias should be avoided.
- Choice of surgical treatment modality is tailored to the individual patient's disease severity.
- Patients should be assessed for other sites of potentially life-threatening telangiectasias, such as those in the brain, lungs, or gastrointestinal system.
- No surgical treatment technique is a cure for HHT-related epistaxis—telangiectasias will grow back with time. Many patients require coagulation, via laser, cautery, or radiofrequency ablation, under general anesthesia several times a year.
- The most invasive but durable procedure for controlling bleeding in HHT is the surgical closure of the nares (Young procedure). This

controls epistaxis in approximately 80% of patients, but the patient must forgo nasal breathing.

- Topical or submucosal therapies with medications such as bevacizumab or tranexamic acid may be combined with surgery.

Preoperative Period

History

1. History of present illness

Many of the following considerations are included in the Epistaxis Severity Score questionnaire:

a. Is the epistaxis unilateral or bilateral? When surgical management is being considered, epistaxis is typically bilateral, but bleeding from one side may be more severe.

b. How frequent are the nosebleeds? How long does the typical nosebleed last? Frequency and duration of the epistaxis are important to determine its effect on the patient's quality of life.

c. Is the epistaxis gushing or pouring?

d. How much blood is lost? The volume of bleeding should be assessed: for example, number of tissues, cups of blood, duration.

e. How is the typical nosebleed stopped? Although HHT patients are usually quite skilled at controlling epistaxis, newly diagnosed patients may require education on preventive measures, as well as techniques to manage acute epistaxis.

f. Is the patient anemic? Has he or she received red blood cell transfusions specifically for nosebleeds?

g. Determine if the patient meets criteria for HHT based on Table 100.1.

2. Past medical history

a. Prior medical and surgical treatments for episodes of epistaxis

b. Family history: First-degree relatives with recurrent epistaxis or HHT?

c. Medications:

1) Antiplatelet drugs

2) Herbal products and supplements

3) Alcohol use

TABLE 100.1

Diagnosis of Hereditary Hemorrhagic Telangiectasia: The Curaçao Criteria

HHT diagnosis is	
Definite	if 3 criteria present
Possible or suspected	if 2 criteria are present
Unlikely	if fewer than 2 criteria are present
Criteria	
Epistaxis	spontaneous and recurrent
Telangiectasias	lips, oral cavity, fingers, and/or nose
Visceral lesions	pulmonary, hepatic, cerebral, gastrointestinal, or spinal AVMs
Family history	first-degree relative with HHT

AVMs, Arteriovenous malformations; *HHT,* hereditary hemorrhagic telangiectasia

TABLE 100.2

Prevalence of Hereditary Hemorrhagic Telangiectasia Manifestations

Manifestation	Prevalence
Epistaxis	78% to 96%
Cerebral vascular malformations	23%
Pulmonary arteriovenous malformations	15% to 50%
Gastrointestinal Gastric or small intestinal telangiectasias Symptomatic gastrointestinal bleeding	80% 25% to 30%
Hepatic Liver venous malformations Symptomatic liver venous malformations (e.g., high-output heart failure, portal hypertension, biliary necrosis)	32% to 78% 8%
Spinal arteriovenous malformations	1%

Physical Examination

1. Face

There may be fine telangiectasias on the surface of the facial skin.

2. Oral cavity

Telangiectasias are common in the mucous membranes of the oral cavity, especially on the lips, palate, and buccal mucosa.

3. Nasal cavity

Nasal endoscopy is useful to document the size and number of AVMs (Video 100.1). Are the telangiectasias limited to the septum (Fig. 100.1), or do they extend along the lateral nasal wall and inferior turbinate? Is the middle turbinate involved (Fig. 100.2)? Is there a significant septal deviation that may limit surgical access to some of the telangiectasias? If the diagnosis of HHT is questionable, nasal endoscopy is helpful to assess for other causes of epistaxis, such as juvenile nasopharyngeal angiofibroma or other lesions. It is not always prudent to perform nasal endoscopy in the office because the procedure itself may precipitate difficult-to-control bleeding.

Imaging

1. None

No maxillofacial imaging is necessary when it is clear that the epistaxis is secondary to HHT and the patient has already received an evaluation to assess for visceral AVMs.

2. Computed tomography (CT) or magnetic resonance imaging (MRI) of the sinuses

If the diagnosis of HHT is doubtful and the epistaxis is thought to be secondary to a sinonasal or anterior skull base tumor, imaging of the sinuses or head may be indicated.

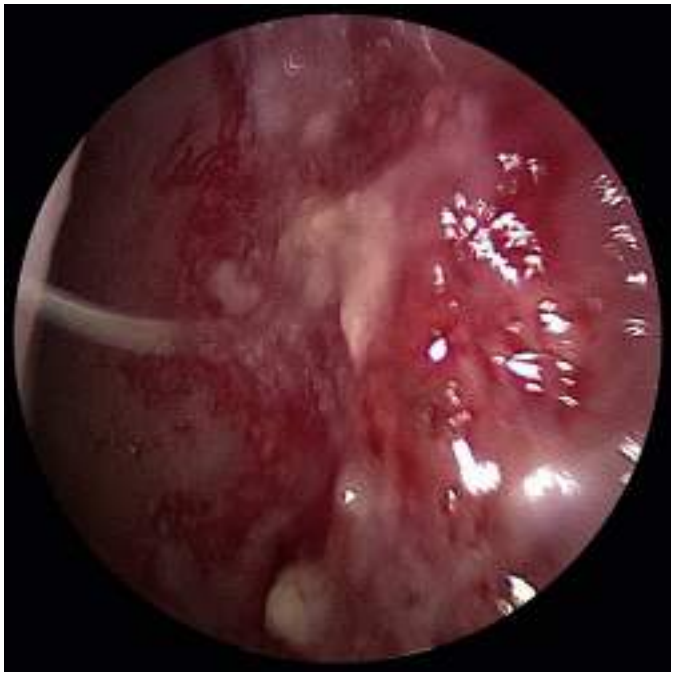

FIG. 100.1 Conglomeration of telangiectasias on the right anterior septum of a hereditary hemorrhagic telangiectasia patient.

FIG. 100.2 Telangiectasias involving the left middle turbinate.

3. Brain MRI

Adults with definite or possible HHT who have not undergone previous workup should receive a screening brain MRI with and without contrast to screen for cerebral vascular malformations. Children with definite or possible HHT who have not undergone previous evaluation should undergo unenhanced brain MRI to screen for cerebral vascular malformations.[2]

4. Transthoracic contrast echocardiography (TTCE)

Patients with definite or possible HHT who have not been previously evaluated should receive a TTCE examination to screen for pulmonary AVMs. Screening may need to be repeated every 5 to 10 years.[2]

Indications

1. Severe, recurrent, and debilitating epistaxis refractory to conservative medical management, such as humidification and nasal emollients, may require cautery or coagulation. Topical or submucosally injected medications such as bevacizumab may be also considered.

2. Severe, recurrent epistaxis requiring blood transfusions may suggest a more aggressive surgical approach, such as septodermoplasty or nasal closure.

Contraindications

- Medical comorbidities with increased risk for general anesthesia
- Presence of other contributors to epistaxis, such as coagulopathy or hypertension, that ideally should be optimized preoperatively

Preoperative Preparation

1. Identify the dominant bleeding side and site, if possible.

2. Control acute bleeding with direct pressure or nasal packing. If nasal packing is necessary, material that would cause trauma upon removal should be avoided. We prefer absorbable hemostatic dressing, such as Surgicel Fibrillar (Ethicon US, Somerville, New Jersey) or a lubricated low-pressure pneumatic packing (Rapid Rhino, Smith & Nephew, Inc.,

Austin, Texas). In-office techniques to control epistaxis, such as silver nitrate ($AgNO_3$), are best avoided to prevent time-consuming and difficult-to-control worsening of acute epistaxis.

3. Discontinue antiplatelet drugs, especially if visceral AVMs are present or suspected to be present.

4. Check hemoglobin and hematocrit. Transfuse with blood products if necessary.

5. Type and crossmatch if the patient is anemic and significant intraoperative blood loss is anticipated.

Operative Period

Anesthesia

- General anesthesia with oral endotracheal intubation is preferred for patient comfort and protection of the airway if there is active bleeding. If the anesthesiologist is comfortable with total intravenous anesthesia (TIVA), this may be preferable as there is usually less vasodilation compared to inhalational anesthesia. There is a lack of literature regarding the use of TIVA in the surgical management of HHT, and a few systematic reviews comparing the use of TIVA to inhalational anesthesia on the surgical field in endoscopic sinus surgery have shown mixed results.[9,10]
- If photocoagulation with a laser is planned, the segment of the endotracheal tube protruding from the oral cavity should be covered with wet gauze sponges. Taping of the endotracheal tube should be limited to the lower lip. For the right-handed surgeon an oral Ring-Adair-Elwyn (RAE) tube placed to the left of the tongue and taped to the left lower lip provides ideal access to the nares. This is reversed for the left-handed surgeon.

Positioning

- The patient is positioned supine in the same way as an endoscopic sinus surgery procedure per surgeon preference. A slight reverse

Trendelenburg position can be desired because it may decrease blood loss. The head should be turned slightly toward the surgeon so that the patient, surgeon, and monitor are coaxial.

Perioperative Antibiotic Prophylaxis

- There is no evidence-based indication for intraoperative antibiotics, although frequently a first-generation cephalosporin (or clindamycin if patient is penicillin or cephalosporin allergic) is used at induction per surgeon preference.
- If postoperative packing material is used, the surgeon may elect to prescribe a first- or second-generation cephalosporin. The first author will often prescribe 1 week of cefadroxil, a first-generation cephalosporin with twice daily dosing, to improve patient adherence rather than the more commonly prescribed cephalexin.
- For septodermoplasty, a broader-spectrum antibiotic with coverage for *Staphylococcus,* such as amoxicillin/clavulanic acid or sulfamethoxazole/trimethroprim, may be prescribed.

Monitoring

- No monitoring is necessary.

Instruments and Equipment to Have Available

1. Basic endoscopic sinus surgery set

2. Endoscopic bipolar electrocautery

A small bayonet bipolar may be effective for anterior nasal telangiectasias. However, for more posterior AVMs, a pistol grip endoscopic bipolar is preferred and is more effective than monopolar electrocautery.

3. Endoscopic clip applier

Although it is unusual to have to perform a sphenopalatine artery

ligation, a specially angled clip applier may be useful. Note that sphenopalatine artery ligation usually *does not* result in elimination of telangiectasias.

4. Coagulation
   a. Laser (neodymium-doped:yttrium-aluminum-garnet [Nd:YAG] or potassium titanyl phosphate [KTP])
   b. Radiofrequency ablation (Coblator II Surgery System, Smith & Nephew, Inc., Austin, Texas)
   c. Traditional Bovie or suction Bovie electrocautery, if neither laser nor radiofrequency ablation is effective
5. Septodermoplasty
   a. Straight microdébrider
   b. Suction Freer elevator
   c. Dermatome

Key Anatomic Landmarks

- Common sites of intranasal AVMs include the nasal septum, inferior turbinate, anterior floor of the nasal cavity, and the head of the middle turbinate.
- The septal perichondrium should be preserved in septodermoplasty.
- A septoplasty may be required to obtain adequate access to telangiectasias that are obstructed secondary to deviations or spurs.

Prerequisite Skills

- Basic endoscopic sinus surgery skills, if performing under endoscopic visualization
- Skill with headlight and instrumentation, if performing in the absence of an endoscope
- Laser safety course, if a laser is to be used

Operative Risks

- Intraoperative hemorrhage from AVMs
- Inability to control bleeding
- Injury to the septal cartilage resulting in septal perforation

Surgical Technique

Coagulation

For limited telangiectasias, bipolar cautery is a useful option. Laser photocoagulation is a popular option for more extensive AVMs. Usually a laser with deeper tissue penetration, such as the Nd:YAG (1064 nm) laser, or a laser with a wavelength that is well absorbed by hemoglobin, such as the KTP (532 nm) laser, is used. Diode and argon lasers also have been used for HHT epistaxis.

The endotracheal tube and eyes are protected with moist gauze or towels. Oxymetazoline 0.05% is applied intranasally either via spray or by ½-inch × 3-inch neurosurgical patties. If patties are placed, they must be inserted gently to avoid mucosal trauma. The greater palatine arteries may be vasoconstricted with lidocaine 1% with epinephrine 1:100,000 via the greater palatine foramen using a 25- to 27-gauge needle bent at 45 degrees 2.5 cm from the distal tip. The anterior palatine and facial artery vessels entering the nasal floor at the pyriform aperture also may be injected by submucosally advancing a 27-gauge needle for approximately 1 cm along the nasal floor. Under endoscopic guidance, a 22-gauge spinal needle bent at 45 degrees 1.5 from the tip on a 3-mL syringe is used to inject the area of the sphenopalatine artery at the lateral attachment of the middle turbinate to the palatine bone. It is important to draw back before injection to avoid direct administration into a vessel.

If the KTP laser is used, the laser is initially set to 8 watts, 20 milliseconds, and 2 pulses per second. The laser fiber is threaded through a straight suction or a curved olive-tipped suction depending on the desired angle. Telangiectasias seen on the septum, inferior turbinate, lateral nasal wall, middle turbinate, and nasal floor are spot lasered. Lesions that are raised and broad are more resistant to laser coagulation

and should be approached by applying the laser to the surrounding mucosa and the edges before moving in toward the center of the AVM.

Radiofrequency ablation, commercially termed as coblation (i.e., "controlled ablation"), may be used as an alternative to laser coagulation. This method uses radiofrequency energy to excite electrolytes in a conductive medium, typically saline solution. The energized sodium ions form a plasma field with sufficient energy to break molecular bonds in tissues at relatively low temperatures (typically 40°C to 70°C) while minimizing injury to surrounding tissues. In our experience, the coblation wand is more facile to use relative to the laser and often provides superior intraoperative results. The PROcise EZ View wand (EICA8875-01, Smith & Nephew, Inc., Austin, Texas) is a low-profile wand with a slightly angled tip designed for sinonasal procedures (Fig. 100.3, Video 100.2). Initially, the default settings are lowered to Coblate-4, Coagulate-2. These settings may be increased as the surgeon becomes more accustomed to the tissue properties of the patient during the procedure. The disadvantage of the low-profile wand is that it tends to clog more readily than thicker wands designed for tonsillectomy and adenoidectomy. The char that collects between the three wires and within the wand may be carefully cleaned using the stylet of the 22-gauge spinal needle used to inject the sphenopalatine artery area.

The nasal cavity is irrigated with saline after completing the coagulation. If bevacizumab is used, this may be injected submucosally or applied topically via surgical patties. An absorbable dressing may be placed, or a fibrin sealant (Evicel, Ethicon US) or topical gelatin-thrombin matrix (FloSeal Hemostatic Matrix, Baxter Healthcare Corporation, Deerfield, Illinois) may be applied at the end of the procedure.

FIG. 100.3 Radiofrequency ablation of intranasal telangiectasias.

Septodermoplasty

Septodermoplasty is considered when a patient continues to have severe epistaxis despite laser or radiofrequency coagulation of AVMs. The nasal cavity is decongested in the same way as it is described for coagulation. Lidocaine 1% with epinephrine 1:100,000 is injected along the septum in a submucosal plane. A split-thickness skin graft is obtained with an electric dermatome, with the donor site dependent on surgeon preference. The size of the graft is dependent on the desired septodermoplasty area. This may be measured, but usually a 6-cm × 3-cm graft is adequate to cover the septum and extend posteriorly to the anterior face of the middle turbinate. If bilateral septodermoplasty is performed, a 12-cm × 3-cm graft may be obtained and divided in two. The split-thickness skin graft is placed on paraffin gauze dressing with the skin side down and then fenestrated.

Using a 0-degree endoscope, a straight 4-mm microdébrider is used to remove the septal mucosa, working from posterior to anterior starting just anterior to the anterior face of the middle turbinate so that blood does not obscure the surgical field. Gentle pressure is applied to remove the mucosa while *preserving the perichondrium*. This step can result in

significant blood loss, and therefore bleeding may be controlled with a mix of topical epinephrine and thrombin. Although there are no HHT procedure-specific studies regarding systemic absorption, concentrated topical (1:1000) epinephrine has been shown to be safe and efficacious in endoscopic sinus surgery.

The split-thickness skin graft is then inserted intranasally, along with the paraffin gauze dressing for support. After the graft is maneuvered to its desired location, the paraffin gauze is removed. A 4-0 plain gut suture is used to quilt the suture to the nasal septum. Tacking sutures should be placed as superiorly as possible to prevent the graft from slipping inferiorly. Fibrin glue is used at the anterior edge of the graft to hold it in place. Either a Doyle splint or a bioresorbable dressing, such as NasoPore (Stryker Corporation, Kalamazoo, Michigan), is placed to support the graft. If a silastic splint is used, it is removed in the clinic 10 to 14 days postoperatively. Absorbable dressings do not have to be removed.

Alternatively, anterior clusters of telangiectasias may be treated with a buccal mucosal graft. This can be easily harvested from telangiectasia-free buccal mucosa of the desired size. The donor site is closed primarily with absorbable suture. Next, an incision as for a septoplasty is made anteriorly or anterior to the telangiectasias. Using a sharp elevator, the mucosa is elevated in a supraperichondrial plane. The buccal graft is secured, similar to a split-thickness skin graft, with through-and-through absorbable suture, and tacking sutures are placed at the anterior edges.

Septodermoplasty may be performed unilaterally or bilaterally. However, if there is question of injury to the cartilaginous septum, the contralateral side should be done as a staged procedure. If there are significant AVMs on the nasal floor or inferior turbinate, the graft may be extended to cover the nasal floor and lateral nasal wall. Resection of the inferior turbinate may be necessary to allow the graft to drape tension-free along the lateral nasal wall.

Nasal Closure (Young Procedure)

Young procedure, or surgical closure of the nares, is performed with the patient under general anesthesia. Lidocaine 1% with epinephrine 1:100,000 is injected into the lateral nares and septum for vasoconstriction. A circumferential incision is created in the

mucocutaneous junction in the anterior nasal vestibule. This is divided into three approximately equal separate anterior-based flaps. These flaps are elevated to the alar rim. Absolute hemostasis must be achieved before a tension-free approximation of the flaps is performed using dissolvable suture with vertical mattress stitches. Antibiotic ointment is placed on the suture line. The procedure may be performed either unilaterally or bilaterally. There is rarely bleeding behind the flaps, but if significant bleeding does occur, the closure will need to be opened to stop the bleeding source.

As a test of the patient's tolerance for the closure, one can try a Vaseline-coated cotton ball inserted into the nostrils, changing it three times a day. This form of occlusion is very useful for decreasing the bleeding dramatically by preventing airflow over the telangiectasias and is readily reversible. This form of occlusion may be used indefinitely.

Common Errors in Technique

Coagulation

- The laser fiber must be placed close enough to the AVM such that the vessel absorbs the energy but not so close that the resulting char sticks to the fiber, as this will invariably result in unwanted bleeding.
- Laser and radiofrequency ablation on both sides of the septum should be avoided to decrease the risk of septal perforation. Likewise, bevacizumab injected along the cartilaginous septum may cause septal perforation, especially if opposing sides of the septum are injected.

Septodermoplasty

- The surgeon should work swiftly when removing septal mucosa using the microdébrider to limit blood loss.
- Inadvertent removal of the perichondrium will result in graft loss and potential septal perforation.

All Surgical Techniques

- No matter what the procedure, avoid nonabsorbable packing that will require postoperative removal.
- If significant blood loss occurred during surgery, check postoperative hemoglobin and hematocrit. If these have fallen significantly from preoperative levels, then transfuse to bring the patient back to his or her baseline. At baseline, many patients have low hemoglobin (i.e., 8 g/dL).

Postoperative Period

Postoperative Management

- These surgical procedures are typically performed on an outpatient basis.
- Check hemoglobin/hematocrit if significant intraoperative blood loss was encountered.
- Patients may perform saline irrigations after coagulation procedures and administer saline nasal spray after septodermoplasty.
- Patients undergoing coagulation procedures follow up 2 to 3 weeks after surgery, whereas those who undergo septodermoplasty or nasal closure follow up after 10 to 14 days.
- Septodermoplasty patients may require ongoing cleaning of intranasal crusting long term.

Complications

1. Hemorrhage

2. Synechiae

3. Septal perforation

4. Graft loss, nasal congestion, nasal dryness, decreased sense of smell, and foul-smelling endonasal crusting may occur after septodermoplasty.

5. Dehiscence of the closure, bleeding posteriorly into the nasopharynx and oropharynx, xerostomia, anosmia, and decreased sense of taste may

occur after Young procedure.

Alternative Management Plan

- Endovascular embolization is rarely recommended for the treatment of epistaxis in HHT, and there is limited evidence to support its use as a management option.[7]
- Sphenopalatine artery ligation is unlikely to affect bleeding from telangiectasias.
- Bevacizumab may be used topically or intravenously with or without surgical techniques.

Discussion

Evidence-Based Medicine Question

What forms of bevacizumab have been shown in small studies to be effective, and what is the mechanism of action?

- Answer: Low-dose systemic (intravenous), submucosal intranasal injections, and topical sprays

What is and how durable is the Young procedure? What percentage of patients benefit from the Young procedure?

- Answer: Young procedure is the surgical closure of the nose, either unilaterally or bilaterally. It is effective in approximately 80% of patients.

Editorial Comment

There is a need for better understanding of the etiology of HHT to develop effective therapeutics in the treatment of this disorder, which not only affects the nasal cavity but multiple organ systems requiring a multidisciplinary approach. The establishment of HHT Centers of Excellence seeks to provide comprehensive care for the HHT patient. The authors describe several techniques for managing epistaxis in this

challenging patient population.

Stella E. Lee

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Approximately what percentage of patients with HHT will have epistaxis as a symptom?

   a. 35%

   b. 55%

   c. 75%

   d. **95%**

2. Which of the following is NOT routinely recommended in the workup of HHT?

   a. Hemoglobin/hematocrit to screen for gastrointestinal bleeding and anemia

   b. **Pulmonary CT or angiography to screen for pulmonary arteriovenous malformations**

   c. Brain MRI for cerebral vascular malformations

   d. Directed endoscopic gastrointestinal evaluation should be undertaken in patients with anemia disproportionate to epistaxis.

3. Common complications of septodermoplasty include all of the following, except

   a. Nasal dryness

   b. Endonasal crusting

   c. **Chronic rhinosinusitis**

   d. Recurrence of arteriovenous malformations

4. The following statements are all characteristics of the transmission and epidemiology of HHT, except

   a. Various gene mutations cause an increase in vascular endothelial

growth factor.

b. HHT occurs worldwide with an incidence of approximately 1 in 5000.

c. **HHT is inherited in an autosomal dominant manner with complete penetrance.**

d. Genetic testing is available for common forms of HHT.

5. The following are recommended surgical techniques for controlling HHT-associated epistaxis, except

a. **Sphenopalatine artery ligation**

b. Coagulation of telangiectasias with laser or radiofrequency ablation under anesthesia

c. Septodermoplasty

d. Closure of the nares

Rhinectomy

Sefik A. Hosal, and Canset Aydin

Introduction

The nose is the most prominent part of the face defining an individual's unique identity. It plays an important role functionally and aesthetically. However, the prominent position of the nose also accounts for its constant exposure to sunlight and thus for its predisposition to the development of cancer of the overlying skin. Thus surgical resection of the nose, rhinectomy, presents a difficult problem for both the patient and the surgeon. Rhinectomy is defined as the removal of the vast majority of the nasal framework and soft tissue. Rhinectomy involves not only surgical resection with adequate tumor margins but also reconstruction of the nose for satisfactory cosmesis. Surgical resection of the nose can be classified as a partial or total rhinectomy based on the extent of the excision. In head and neck surgery, the classical assumption of a wide surgical resection with control of margins is usually preferred; however, this may not be applicable for rhinectomy, due to anatomic limitations such as the orbit, skull base, and brain. Additionally, extensive resection may result in an unacceptable cosmetic defect that may cause rejection, depression, and other psychosocial problems.

The anterior nasal cavity is bounded by the bony pyriform aperture, hard palate, and external framework of the nose. The external nose is composed of bone and cartilage. The nasal septum divides the nasal cavity and connects with the nasal bones. It is continuous with the upper lateral cartilages anteriorly and medial crura of the alar cartilages inferiorly. The anterior nasal septum, lower lateral cartilages, and columella form the nasal vestibule. The nasal cavity is lined by ciliated mucosa and the nasal vestibule with stratified squamous epithelium.

Malignant tumors of the nose are quite rare and can be classified as

internal and external cutaneous tumors. The majority of nasal tumors comprise external cutaneous cancers including basal cell carcinoma, squamous cell carcinoma, and melanoma,[1] which commonly occur along the ala and dorsum of the nose.[2] Most cancers of the nasal cavity are squamous cell carcinoma and adenocarcinoma.[3] Among these cancers, squamous cell carcinoma is the most frequently encountered pathology that requires rhinectomy.

Rhinectomy is indicated only for extensive, aggressive, and recurrent cancers, including multicentric or large cancer, radiotherapy failures, or recurrent squamous cell carcinoma, or for palliative reasons such as in metastatic disease. In contrast to other locations, cancers originating from the columella or nasal vestibule behave aggressively. Because of the thin subcutaneous tissue along the columella and the vestibule, there is little soft tissue resistance against tumor spread. Therefore, cancers can easily invade bone and cartilage through periosteum or perichondrium and spread into the skin of the face. Infiltration of surrounding structures such as the upper lip, cheeks, and medial canthal regions may increase the risk of recurrence. Tumor eradication is much more complex, particularly in the medial canthal area due to the risk of orbital invasion. On the other hand, regional lymphatic metastasis is uncommon for both internal and external cancers of the nose.[4] Neck dissection is only considered in clinically or radiographically evident lymph node involvement, except for cutaneous melanomas in which sentinel lymph node biopsy should be performed.

Key Operative Learning Points

- Rhinectomy is not technically difficult, but reconstruction of the nasal framework is challenging.
- The procedure is usually reserved for extensive or recurrent cancers of the nose, particularly in multicentric or large tumors, radiation failures, recurrent cancer, or for palliation in metastatic cancer.
- Soft tissue invasion of the medial canthal region is challenging, due to the close proximity of the orbital structures.
- Intraoperative assessment of the surgical margins by frozen sections is critical in the prevention of recurrence.

- The patient should be informed preoperatively about the anticipated postrhinectomy defect and plans for reconstruction.
- Neck dissection is not a routine part of the procedure. However, possible metastasis to cervical lymph nodes should be evaluated carefully preoperatively and in postoperative follow-up, particularly in squamous cell carcinomas.

Preoperative Period

The important functions of the nose, including olfaction, respiration, humidification, and filtration, as well as aesthetics, when compromised may give rise to psychologic and functional problems. The decision to proceed with rhinectomy should be taken only after the patient is informed regarding the extent of the excision and the types of reconstruction available. History of the presenting problems, physical examination, and imaging is essential to accurately plan the surgery. Invasion of the following structures should also be evaluated prior to surgical resection:

- **Adjacent structures of the nose:** The hard palate, medial canthus, orbit, maxillary sinus, and skull base that broadens the extent of the dissection and results in extended rhinectomy
- **Regional lymph node metastasis:** Though regional lymph node metastasis is rarely reported, examination must be done carefully. Examination should include all levels of the neck as well as the parotid lymph nodes. Depending on the presence of lymph node involvement, unilateral or bilateral neck dissection must be added to the primary surgery. This depends on the tumor type, which is particularly important in squamous cell carcinoma.
- **Distant metastasis:** Positron emission tomography (PET)-CT is helpful to define the presence of regional lymphatic metastasis and rule out distant metastasis.

Once a rhinectomy has been performed, the greatest challenge is providing an acceptable nasal reconstruction plan. Preoperative planning for the type of the reconstruction is very important. Either reconstruction with a nasal prosthesis or flaps may be indicated.

History

- History of present illness
  - Risk factors:
    - Tobacco and alcohol consumption
    - Radiation exposure
    - Occupational exposure to chemicals and particulates, such as nickel, wood dust, radium, mustard gas, and asbestos
    - Drug abuse
  - Symptoms and signs:
    - The otolaryngologist must be cognizant of the potential for a nasal malignancy in patients presenting with chronic symptoms, which may also present in benign and inflammatory diseases of the nose. These symptoms include nasal congestion, nasal obstruction, nasal discharge, epistaxis, nasal crusting, intermittent bleeding, septal perforation, epiphora, headache, and erythema of the skin.
    - Other more obvious symptoms or signs include a visible nasal mass, ulceration, loss of vision, swelling of the palate, and problems with denture fit.
- Past medical history
  - In recurrent cancer, details of the previous treatment modality should be determined, including the extent and duration of surgery as well as treatment with chemoradiotherapy.
  - Comorbid diseases including systemic diseases and hemorrhagic diatheses
  - Family history
  - Medications, herbal products, and supplements taken by the patient

Physical Examination

- Face

  Inspection of the face, particularly for extension of the cancer from the

nose to surrounding structures such as the medial canthus or upper lip

- Nose

  Palpation of the nose is critical because even with normal appearing skin, there may be tenderness or induration that may indicate a more insidious process.

  Anterior rhinoscopy and bilateral nasal endoscopy are important for a comprehensive evaluation of the patient presenting with a nasal mass.

  Before nasal endoscopy, appropriate decongestion and application of a topical anesthetic should be performed to provide optimal examination of the nasal cavity, nasopharynx, and sinus outflow tracts.

- Oral cavity

  Examination may reveal a soft tissue submucosal mass, ulceration, or erosion of the bone of the hard palate.

  Inspection of the teeth and detection of dental disease are important for the patient being considered for adjuvant radiotherapy.

- Neck

  Palpation of the neck for detection of lymph node metastasis is of vital importance.

Imaging

1. Computed tomography (CT) scan with and without contrast

- A dedicated maxillofacial CT should be performed to evaluate the bony structures of the nose and involvement of the paranasal sinuses.
- Used to detect tumor extension to the cartilage and bone
- CT scan of the neck is necessary to evaluate whether there is cervical lymph node metastasis.

2. Magnetic resonance imaging (MRI)

- Should be performed in all cases and is complementary to the information that the CT scan provides
- Can help determine tumor extension to the soft tissues

FIG. 101.1 Extensive skin cancer of the nose extending through the cheek and the upper lip.

- Evaluate for intracranial extension
- Evaluate for perineural invasion
- Differentiate inflammatory tissue from the cancer
- Complementary to CT for evaluation of lymph nodes in the neck

3. Chest radiograph

- Important for preoperative assessment
- Detection of pulmonary metastases or primary cancer of the lung

4. PET-CT

- Not performed in all cases
- To detect distant metastases in recurrent cases, radiotherapy failure, and aggressive primary tumors with extensive regional involvement

Indications

- Extensive skin cancers of the external nasal framework (Fig. 101.1)

- The most common cutaneous basal cell and squamous cell carcinomas and rarely melanomas, adnexal tumors, and Merkel cell carcinomas

- Extensive malignant tumors such as SCCs and adenocarcinomas of the nasal cavity, columella, nasal vestibule, septum, or the lateral nasal wall
- Recurrent or multifocal cancers after surgery or radiation therapy (Fig. 101.2)
- Palliative treatment, including cases in which there are distant metastases to the nose from a distant site

Contraindications

- Distant metastasis (Relative) It may be appropriate for palliation for patients who have bleeding or severe pain in the primary site.
- Comorbid diseases with unacceptable risk for general anesthesia
- Patient preference for nonsurgical therapy

FIG. 101.2 Recurrent tumoral defect on the lateral side of

the nose.

Preoperative Preparation

- Incisional or punch biopsy to confirm the diagnosis
- Routine laboratory tests and preparation for transfusion, if necessary
- Cessation of antiplatelet/anticoagulant drugs, supplements, and herbal products
- The patient with cervical lymph node metastasis should be counseled regarding the need for neck dissection, alternatives, and expectations after the surgical resection and neck dissection.
- Consultation with an experienced maxillofacial prosthodontist for immediate reconstruction, with a prosthesis
- The patient should be counseled regarding the expected cosmetic deformity.
- The patient should discontinue smoking tobacco if a flap reconstruction is planned.

The decision of the reconstruction method depends on many factors:

- A prosthesis may be preferred in the following situations.
  - Age: Younger patients may find that a prosthetic has more acceptable aesthetic results. Older patients who may have significant comorbidities would benefit from shorter surgery duration and avoid the need for multistage procedures.
  - Size of defect: Cases without sufficient tissue to restore a large facial defect, especially in recurrent tumors or in cases with a compromised local vascular bed
  - Patients with poor prognosis, including the need for palliative surgery
  - Aggressive cancers, such as squamous cell carcinomas of the columella, which require close oncologic examination of the surgical bed, or in patients with planned postoperative radiation therapy
  - Patients who have compromise in vasculature due to comorbid

conditions and/or continued tobacco use, which increases the risk of flap failure

- Patient's preferences
- Experience of the surgical team

- Flap reconstruction may be preferred in the following situations:
  - Patients with psychiatric illness who may not be able to tolerate a prosthesis
  - Patients who cannot manage the daily care of a prosthesis
  - Patients with previous prosthesis-related complications
  - Patient's preferences
  - Experience of the surgical team

Nasal Prosthetics

- There are many methods for placement of the prosthesis to the nasal region:
  - Medical adhesives, mainly of silicone-based adhesives, are used to attach the prosthesis to the skin.
  - Anatomic undercuts are natural anatomic indents in the surgical area for physical retention of the prosthetic. In the presence of stable tissue support, an anatomic undercut is the most suitable choice for the patient. It is a noninvasive, easy-to-use, low-cost, and tissue-tolerant method.
  - Eyeglass frames are used for retention of the prosthesis. The prosthesis is fixed to an eyeglass frame, and they should be used together. The primary disadvantage is that the patient cannot remove the eyeglasses without also removing the attached prosthesis.
  - Osseointegrated implants are used to attach the prosthesis to span the nasal defect. Implants can be placed along the zygoma, floor of the nose, glabella, orbital rim, and maxilla. Implant failure is more common at the orbital rim and maxilla due to poor quantity and quality of bone and in patients with previous radiation therapy

treatment.[5] Preoperative CT scans are useful to determine whether there is sufficient bone (at least 3 mm) for implant placement. Implants are contraindicated in locations with the potential for persistent tumor involvement.

Advantages

- Better surveillance of the wound bed for recurrence
- A staged procedure is still possible with flap reconstruction performed after prosthesis placement
- Technically easier to perform than a flap reconstruction
- Inexpensive care
  - Anatomic undercuts, adhesives, and eyeglasses are preferred by the patients because of their low cost. However, a prosthesis with osseointegrated implants costs are much higher and may be comparable to the cost of free flap reconstruction.[6] Therefore there may be some cost differences between institutions or countries.
- Avoid additional surgical procedures and corresponding potential morbidity.
- Minimize psychologic distress to the patient if placed intraoperatively, which can mitigate the aesthetic repercussions of the surgery
- Shorter surgery duration

Disadvantages

- Potential dislodgement of the prosthesis
- Requirement of regular cleaning and maintenance
- Poor function, including humidification and filtration with potential obstruction of nasal breathing
- Infection in the implant region that may cause failure to retain the prosthesis
- Replacement of the prosthesis may be required due to changes from patient-related factors such as skin atrophy, radiotherapy sequelae,

dissatisfaction with the appearance, or related to the prosthesis itself, including color changes, material degradation with exposure to ultraviolet light, problems with fit, localized rhinorrhea, and dermatitis.

- Patients usually need one prosthesis for summer and one for winter, based on the tanning effect from exposure to sunshine.
- Need for an experienced maxillofacial prosthodontist

Flap Reconstruction

Advantages

- Provides a better match in terms of skin color, thickness, and texture, with less variation from the rest of the face (i.e., the paramedian forehead flap).

Disadvantages

- Requirement of donor site or sites with potential related complications
- Need for multistage surgery
- Increased risk of surgical morbidity
- Final aesthetic outcome may be unsatisfactory.
- May cause a delay in the initiation of postoperative adjuvant radiation if needed
- Multidisciplinary team may be required with experience in reconstructive surgery.

Operative Period

Anesthesia

- General anesthesia with orotracheal intubation

Positioning

- Supine position
  - The patient is placed in the reverse Trendelenburg position, with the head turned slightly toward the surgeon.

Perioperative Antibiotic Prophylaxis

- Rhinectomy is classified as a clean-contaminated surgical procedure, so a combination of antibiotic regimens covering anaerobes, gram-positive and gram-negative bacteria should be used.
  - First-generation cephalosporines + metronidazole
  - Clindamycin + gentamycin (in patients allergic to penicillin)
  - Our preference is ampicillin sodium/sulbactam sodium.

Monitoring

- Routine anesthesia monitoring

Instruments and Equipment to Have Available

- Standard neck dissection set
- Standard instruments for septoplasty/rhinoplasty set
- Bone cutting forceps
- Osteotomes/mallet
- Saws
- Drill
- Headlight
- Rigid endoscopes with high-definition camera/monitor

FIG. 101.3 *Arrow* indicates preservation of the nasal bone after resection.

- Bipolar electrocautery
- Monopolar electrocautery
- Bone wax
- Suture (usually 3/0 Vicryl)

Key Anatomic Landmarks

- Preservation of the nasal bone is helpful for prosthetic rehabilitation (Fig. 101.3); it does not interfere with surgical margins.

Prerequisite Skills

- Experience in head and neck surgery including the necessary soft tissue skills and experience in nasal reconstruction and/or collaboration with a reconstructive surgeon and/or a maxillofacial prosthodontist is critical.

Operative Risks

- Intraoperative hemorrhage from alar and septal branches of the facial artery, ophthalmic, and maxillary arteries
- Cerebrospinal fluid leak
- Inadvertent injury of the hard palate during osteotomies

Surgical Technique

- The surgical site should be marked appropriately, including the bilateral lateral rhinotomy incision lines that join together at the dorsum superiorly and base of the columella inferiorly (Figs. 101.4 and 101.5).
- Injection of local anesthetic with epinephrine subcutaneously under the skin incision lines, along the bilateral nasal vestibules, alar regions, gingivobuccal sulcus, and pyriform aperture

FIG. 101.4 Lateral rhinotomy incision extending to the base of the columella.

FIG. 101.5 Bilateral lateral rhinotomy incision lines joining together at the dorsum superiorly and the base of the columella inferiorly.

- Oxymetazoline pledgets are placed into the nasal cavity.
- The skin incision is initiated along the lateral edge of one nostril (Fig. 101.6).
- The incision is carried through the dorsum of the nose and joined with the inferior skin incision.
- The dissection is started from the lateral edge of one nostril, in which the alar cartilage is separated from the bony structures (lateral alatomy). Minor subcutaneous bleeding can easily be controlled with bipolar cautery.
- Retraction of both lateral sides of the nose allows identification of the septum and provides direct visualization of the extension of the cancer.
- The base of the columella is then next incised, and the caudal cartilaginous septum is exposed with monopolar cautery or scissors, according to the surgeon's preference (Fig. 101.7).
- Osteotomies along the bony septum and nasal bones are completed by through-cutting instruments.
- Resection is then completed with these osteotomies in caudo-cranial direction or vice versa.
- The remaining nasal cavity is examined with the aid of rigid endoscopes in order to detect any remaining tumor.

- Tumor margins are evaluated with frozen sections, and additional margins are obtained if necessary (Fig. 101.8).

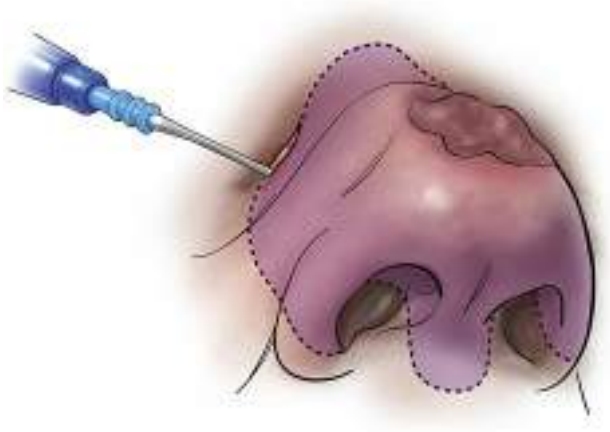

FIG. 101.6 Initial skin incision along the lateral edge of one nostril using electrocautery.

- Mucosal bleeding is controlled with cautery, and bleeding along the bone edges may require bone wax.
- The skin and mucosal edges are sutured together primarily with 3/0 Vicryl (Fig. 101.9).
- Placing Gelfoam around the cavity may prevent postoperative bleeding, and packing may not be necessary. The cavity may also be packed with gauze soaked in antibiotic ointment, according to the surgeon's preference. This can be removed in 3 days.
- The cavity is left open for healing via secondary intention; we do not use skin grafting (see Fig. 101.3).
- Rehabilitation with a prosthesis or reconstruction with flaps is then required to address the defect; the details for these procedures are beyond the scope of this chapter.
- If the rehabilitation method chosen is a prosthesis with osseointegrated implants, implants are placed at the end of surgery.
  - The estimated points should be defined preoperatively with CT.
  - The anterior part of maxillary crest, pyriform aperture, and inferior

turbinates are removed in order to provide a smooth surface for implant retention.

Common Errors in Technique

- Inadequate exposure as a result of starting the dissection from midline rather than the lateral edge of the nares
- Failure to manage bleeding, which may compromise visualization and resection margins. Intraoperative delicate cauterization is needed to control bleeding from the branches of facial, maxillary, and ophthalmic vessels.
- Fragmentation and seeding of the tumor due to inaccurate resection or handling of tissue margins
- Excessive resection of nasal bones results in instability of a potential base for a nasal prosthesis. If total nasal bone resection is required because of cancer invasion, and there is resulting inadequate nasal bone present for a prosthetic base, then it may be appropriate to reconstruct with flaps rather than prosthesis.

Postoperative Period

Postoperative Management

- Cool mist humidification and saline irrigations of the nasal cavity at least twice daily to prevent crusting and facilitate débridement

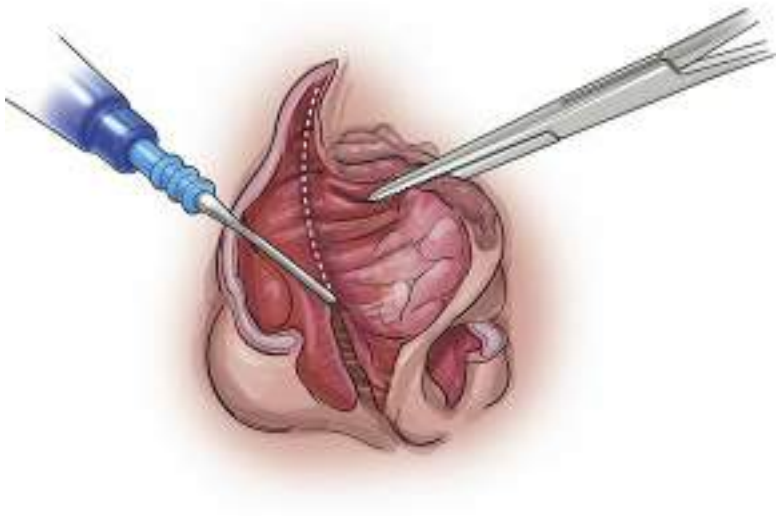

FIG. 101.7 Excision of the septum with monopolar cautery.

FIG. 101.8 En-bloc excision of tumor.

- Prophylactic intravenous or oral antibiotics in the perioperative period
  - First generation cephalosporines + metronidazole
  - Clindamycin + gentamycin (in patients allergic to penicillin)

- We prefer ampicillin sodium/sulbactam sodium.
- Assessment of hemoglobin and hematocrit levels
- Elevation of the head of the bed and ice application in order to minimize local edema
- Pain management: Opioid analgesics are used to control pain. Nonsteroidal anti-inflammatory drugs are avoided in the early postoperative period.
- Psychologic support for functional and cosmetic problems

Complications

- Hemorrhage
- Cerebrospinal fluid leak: This can occur with excessive manipulation or torque on the perpendicular plate of the ethmoid bone. It is important to recognize and reconstruct the defect promptly during the operation. Delayed diagnosis can lead to serious intracranial complications such as meningitis, encephalitis, or brain abscess.

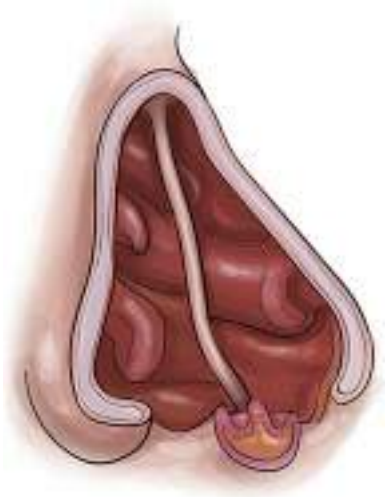

FIG. 101.9 Nasal cavity and defect after suturing skin edges; packing may not be necessary.

Alternative Management Plan

- Radiation therapy
- Concurrent chemoradiotherapy
- Chemotherapy is usually considered in unresectable tumors or in palliative treatment.

Discussion

Evidence-Based Medicine Question

When is rhinectomy necessary in the management of nasal tumors?

Rhinectomy is an effective treatment in extensive cancer of the nasal framework. However, it is generally performed after failed radiation therapy or prior inadequate surgery, since there are significant cosmetic consequences to this procedure. Because of the rarity of patients needing this type of procedure, there are only several small series in the literature, and to our knowledge there are no published randomized trials regarding different treatment regimens. Stanley and Olsen reported a recurrence rate of 43% and a mortality rate of 25% in 51 rhinectomy cases. They also noted that 61% of these patients had previous unsuccessful surgical attempts.[7] Mignogna and Garay reported a cure rate of 36% at 5 years in recurrent invasive squamous cell carcinoma of the columella with partial or total rhinectomy.[8] Chipp et al. presented a 50% survival rate in 14 patients.[9] Teichgraeber and Goepfert proposed that extensive rhinectomy is indicated in recurrent multicentric cancers, involvement of the ala, and squamous cell carcinoma greater than 4 cm. They found a 30% rate of recurrence and two-thirds of recurrences occurring within 2 years. On the basis of their findings, they recommended prosthetic rehabilitation and a 2-year wait prior to proceeding with definitive reconstruction.[2]

Editorial Comment

The authors have produced a highly detailed, very readable chapter on rhinectomy. Total rhinectomy is reserved for patients presenting with advanced cancer involving the skin, soft tissue, and bone, which makes up the nasal framework. Since most cancers of the nose do not present in

such an advanced state, partial rhinectomy offers an opportunity for complete excision of these cancers, most often squamous cell carcinoma, with reconstruction employing a wide variety of techniques including skin grafts, composit grafts, and bilobed, nasolabial, and forehead flaps. The key to success in curing these cancers lies in achieving clean surgical margins. For cancers involving skin, only excision with frozen section control using traditional surgical technique or Mohs cutaneous technique can provide this information so that immediate reconstruction can be carried out. However, when the cancer is very large or involves bone, it is best to delay reconstruction until clean margins can be ensured by a permanent pathologic report. If the margins are close or not clear, the patient must be returned to the operating room for further ablative surgery. Only when the margins are clear can reconstruction or the fabrication of a prosthesis proceed.

Patients who will undergo total rhinectomy should be seen preoperatively by a maxillofacial prosthodontist who will make a facial moulage from which a nasal prosthesis can be fabricated. Of course, the prosthesis may require modification based upon the facial configuration of the defect. No doubt in the future 3-D imaging will be used to create these prostheses.

A few words should be said about preparing the surgical defect for the prostheses. The standard technique described in the surgical literature is that once the specimen is removed and hemostasis is obtained the skin edges are sewn to the nasal mucosa. While this results in rapid epithelialization of the margin of the defect, it results in a very abnormal appearance of the mid face (Fig. 101.10).

My personal modification of the standard technique that avoids the distorted appearance includes the use of a split-thickness skin graft sutured laterally to the skin edge and medially to the nasal mucosa bilaterally. Silk sutures are used to stabilize the skin edges, and some are left long and are tied over a Xeroform bolster to immobilize the graft. The bolsters and the sutures are removed on the fifth postoperative day, and any excess skin graft is trimmed. Filling in the gap between the skin and the mucosa with a skin graft results in a re-epithelized wound without any distortion of the midface.

My experience with advanced cancer of the head and neck has led me to believe that individuals who let an obvious cancer destroy their nose,

which is the keystone of the face, have some severe self-destructive instinct. It may be true that other factors may play a role such as fear, ignorance, and limited access to medical care, either geographic or financial, but regardless of the possibility of these factors being the entire cause, I strongly suggest that a psychiatrist or psychologist can play an important role in the management of these patients.

FIG. 101.10 Skin edges and mucosa sutured together results in distortion of the midface.

Eugene N. Myers

Review Questions

1. The anatomic part of the nose that should be preserved for prosthetic rehabilitation after total rhinectomy includes which of the following?

   a. Nasal spine

   b. **Nasal bone**

c. Pyriform aperture

d. Bony septum

2. The true starting point of the dissection in order to obtain adequate exposure of the septum and visualize extension of the tumor includes one of the following:

a. Rhinion

b. Midline of the nose

c. **Lateral edges of nares**

d. Columella

3. Among the typical signs and symptoms of squamous cell carcinomas of the nasal cavity, all of the following are *true*, except

a. **Regional lymphatic metastasis is common**

b. Epiphora

c. Erythema of the skin

d. Bleeding

Balloon Sinus Dilation

Nadim Bikhazi, and Andrew N. Goldberg

Introduction

Sinus surgery continues to evolve, greatly enhanced by technological innovations. Thirty years ago, largely due to advances in endoscopic visualization, functional endoscopic sinus surgery (FESS) became less extirpative than traditional operative sinus surgery. Now another stage in this evolution is occurring toward minimally invasive sinus procedures such as office-based balloon sinuplasty. This technique, performed under local/topical anesthesia, affords several distinct benefits over sinus surgery under general anesthesia: less patient down-time, less bleeding, reduced need for postprocedure pain medication, and more rapid return to work. These advantages of balloon-sinuplasty, when coupled with equal efficacy for similar chronic sinusitis disease severity, provide a valuable alternative for patients and otolaryngologists.

Key Operative Learning Points

1. Balloon sinus dilation (BSD) is an operative procedure performed for medically recalcitrant recurrent acute sinusitis and chronic rhinosinusitis.

2. It can be safely performed in both the outpatient and inpatient settings.

3. Principles of BSD rely on expansion of narrowed sinus tracts while preserving sinus mucosa.

4. Success of the procedure requires appropriate patient selection and the use of proper technique.

5. Rate of success and revision of BSD are comparable to those achieved for FESS for properly selected patients.

Preoperative Period

History

1. History of present illness
   a. Has the patient experienced symptoms of chronic rhinosinusitis: nasal congestion, facial pressure, and/or nasal discharge?
   b. Are these symptoms chronic (>12 weeks) or recurrent with four or more episodes per year?
   c. Are there factors such as infections of high severity or duration, antibiotic intolerance, or associated medical conditions that warrant early intervention?
   d. What medical therapy has the patient tried? This may include nasal saline rinses, both oral and topical decongestants, antihistamines, nasal steroids, and antibiotics. Have these medical therapies been successful? Ask for the length of the symptom-free period.
   e. Has the patient undergone any prior imaging (computed tomography [CT] scan of the sinuses)?
   f. Has the patient undergone allergy testing?
   g. Does the patient have a dental (odontogenic) source of sinus pain?
2. Past medical history
   a. Are there associated medical conditions? Ask for history of allergies, gastroesophageal reflux, and headaches (particularly migraine).
   b. Surgical history. Have there been previous septal surgery and/or sinus surgical procedures?
   c. Family history
   d. Allergies to local anesthetics (lidocaine, bupivicane)
   e. Medications:
      1) Anticoagulants
      2) Antihypertensive

Physical Examination

1. Anterior rhinoscopy
    a. Are there enlarged inferior turbinates or anterior septal spurs that account for additional nasal obstruction? These may need to be addressed at the same time as the BSD and, if severe enough, may require that the procedure be done under general anesthesia.
2. Nasal endoscopy
    a. Are there other middle meatal anomalies that will make access to the meatus difficult? Examples include nasal polyps, concha bullosa, lateralized middle turbinate, and superior septal deviation.
    b. Is there polypoid tissue along the bulla ethmoidalis that will need to be addressed at the same time as the balloon dilation with a limited anterior ethmoidectomy? Limited nasal polyps may not preclude BSD, but more extensive polyposis may require consideration of larger sinus openings through FESS.

Imaging

1. CT of the sinuses without contrast
    a. Pay attention to narrowing of the ostiomeatal complexes and the nasofrontal recesses. Also note any large obstructive polyps that may make BSD inappropriate. Also, diffuse ethmoid disease (anterior and posterior) would preclude BSD and make FESS more appropriate. Hyperdense regions in the sinuses may indicate that fungal elements are present such as in a mycetoma or allergic fungal rhinosinusitis, making FESS more appropriate.

FIG. 102.1 Balloon sinus dilation of major sinuses.

Indications

1. Mild to moderate chronic rhinosinusitis of the maxillary, frontal, or sphenoid sinuses recalcitrant to medical therapy (Fig. 102.1)

2. Recurrent acute sinusitis of the maxillary, frontal, or sphenoid sinuses

3. Revision cases of scarring or stenosis of the maxillary, frontal, or sphenoid ostia

4. Can be used as a stand-alone technique or in conjunction with other sinus surgery (known as a hybrid technique)

5. Specific application to those with patients unfit for surgery: on anticoagulants, pregnant, age-related medical conditions (heart or lung problems)

Contraindications

1. Diffuse nasal polyposis or granulation tissue

2. Severe ethmoid disease (anterior and posterior)

3. Anatomic nasal obstruction that otherwise would require general anesthesia (large obstructive septal deviation)

4. Fungal sinusitis where removal of fungal debris is necessary

5. Concerns for sinus masses that need removal (large maxillary mucocoele)

Preoperative Preparation

1. Preoperative consent: Discuss risks of injury to the orbit, bleeding, cerebrospinal fluid (CSF) leak, scarring, and rates of revision.

2. For awake sedation

   a. Preoperative dosing of benzodiazepine (Valium 10 mg) and narcotic (hydrocodone 7.5 mg) 90 minutes prior to procedure

   b. Counseling that the patient may hear loud noises (cracking bones) during the procedure

Operative Period

Anesthesia

1. General

   a. BSD under general anesthesia would follow the same preparation as for FESS. Local anesthetic and epinephrine would be used in similar doses.

2. Awake sedation

   a. Topical decongestion/anesthesia: Using either cotton balls or ½- × 3-inch cotton pledgets, 2% pontocaine/phenylephrine is used. These are placed on the anterior surface of the inferior turbinate, the anterior surface of the middle turbinate, and the superior septum opposing the middle turbinate. They are left in place for 10 minutes.

   b. After this is done, topical 1:1000 epinephrine solution is placed on pledgets into the same locations. Care should be taken to wring the pledget out to make it damp and not saturated. These are left in place for 5 minutes.

   c. Local anesthetic: 2% lidocaine without epinephrine can then be selectively injected into the root of the middle turbinate, the posterior attachment of the middle turbinate, the superior septum, and the uncinate process superiorly. This field localization blocks all the nerves to sensation of the maxillary, frontal, and anterior ethmoid sinuses. If the sphenoid dilation is being performed, an

inferior injection along the inferior sphenoid face/posterior septum can block nerve sensation in this area.

3. Local: Some patients are relaxed enough that BSD can be performed with local anesthesia only.

Positioning

Supine: A low Fowler (semi-Fowler) position, which best approximates the position used in sinus surgery, provides the best position for BSD.

Perioperative Antibiotic Prophylaxis

No perioperative antibiotics are needed during BSD.

Monitoring

While monitoring is not required during BSD, having an oxygen tank and a pulse oximeter available is recommended. Some of the topical anesthetics, if used more than maximum dose (such as pontocaine), can cause seizures and airway distress. The surgeon should check for the maximum dose that can be used of each topical/injectable anesthetic.

Instruments and Equipment to Have Available

1. A basic endoscopic sinus surgery set with a Freer elevator, S-shaped double-ball probe, and Blakesley sinus forceps. A 30-degree nasal endoscope is used for maxillary and frontal sinus dilation, and a 0 degree is used for the sphenoid.

2. A television monitor

3. A BSD device. These come in various forms but should have the capacity to illuminate the sinus and pass a balloon over a probe/wire.

4. Additional equipment: A sinus microdébrider that can selectively remove solitary polyps and reduce enlarged inferior and middle turbinates.

Key Anatomic Landmarks

1. Root of the middle turbinate: The superior attachment of the middle turbinate bone

2. Bulla ethmoidalis: The anterior-most projection of the ethmoidal air cells, lateral to the middle turbinate

3. Maxillary ostium: The opening to the maxillary sinus, guarded laterally by the uncinate process

4. Uncinate process: The crescent-shaped lateral nasal wall projection that guards the opening of the maxillary sinus

5. Middle meatus: Curved anteroposterior passage lateral to the middle turbinate and medial to the uncinate process

6. Frontal recess: The spiral-shaped outflow tract of the frontal sinus

7. Ostiomeatal complex: A common channel that links the frontal sinus, anterior and middle ethmoid sinuses, and the maxillary sinus to the middle meatus that allows airflow and mucociliary drainage

8. Sphenoethmoidal recess: The space between the posterior nasal septum and the superior turbinate into which the natural ostium of the sphenoid sinus drains

Prerequisite skills

Thorough understanding of the surgical anatomy of the sinus

Operative Risks

The risks of BSD are the same as those of FESS, but they occur with reduced frequency. These include injury to the orbit with potential loss of vision, entering the CSF space with resultant CSF leak, bleeding, and scarring.

Surgical Technique

Often the balloon sinus probe is bent to perform the frontal sinus

dilation, first followed by the sphenoid and then finally the maxillary sinus.

Maxillary Balloon Dilation

1. Medialization of the middle turbinate.

2. Probe the maxillary sinus outflow tract with an S-shaped double ball probe. This creates space between the uncinate process and the posterior ostial wall.

3. Insertion of the balloon dilator probe at a 120-degree angle with transillumination of the maxillary sinus.

4. Bend the probe to 120 degrees using the bending device.

5. Balloon dilation three times at 12 atmospheres of pressure for 5 seconds each. The three dilations should be pulling anteriorly, inferiorly, and posteriorly.

6. Confirm the expanded maxillary ostial patency with a 30-degree rigid endoscope.

7. Suction any blood or mucus if indicated.

Frontal Balloon Dilation

1. Medialization of the middle turbinate

2. Clear visualization of the bulla ethmoidalis. Always stay *anterior* to the bulla ethmoidalis to find the nasofrontal outflow tract. This avoids inadvertent penetration of the roof of the ethmoid or cribiform plate.

3. Starting lateral to the middle turbinate and posterior to the uncinate process, probe the various superior recesses superiorly and laterally. Start on the medial most recess and work laterally illuminating the tracts along the way.

4. The probe should advance to the 2-cm mark on the probe prior to dilation.

5. Transillumination of the frontal sinus with rotation of the light source to confirm presence *within* the sinus

6. Balloon dilation once at 12 atmospheres of pressure for 5 seconds. A second dilation can be performed more distally to confirm adequate patency of the nasofrontal duct.

7. Suction away blood or mucus from the frontal sinus recess.

Sphenoid Balloon Dilation

1. Using a 0-degree rigid endoscope, lateralize the middle turbinate.

2. Identify the superior turbinate superiorly in the sphenoethmoidal recess.

3. Identify the sphenoid ostium. This is found medial to the superior turbinate.

4. Place the balloon probe within the opening and dilate to 12 atmospheres of pressure for 5 seconds.

5. Confirm patency of the dilated ostium with the endoscope.

6. Suction any blood or mucus from the opening.

Common Errors in Technique

1. Inadequate vasoconstriction resulting in excessive bleeding and poor visualization

2. Inadequate local anesthesia resulting in patient discomfort and movement

3. In sphenoid sinus dilation, not lateralizing the middle turbinate enough to provide adequate visualization

4. Poor patient selection due to severe anatomic restriction (severe septal deviation)

5. Inadequate confirmation of ostial dilation

Postoperative Period

Postoperative Management

1. Advise patients to sneeze with the mouth open for 1 week and to avoid nose blowing for 1 week.

2. Postoperative examination at 1 week

3. Begin nasal saline irrigations at 1 week postoperatively.

Complications

1. Inability to cannulate the sinus
   a. BSD should not be forced, as this can lead to inadvertent entry into unwanted spaces (orbital injury, CSF leak).
   b. If difficulty is encountered, the cannulation of that sinus should be abandoned.
2. Hemorrhage
   a. If bleeding is encountered during the procedure, use topical 1:1000 epinephrine solution (damp) on a cotton pledget on the area.
   b. If there is continued oozing, a variety of dissolvable middle meatal packs can be used to tamponade the bleeding site.
   c. Postoperative bleeding can be managed with topical decongestant sprays (vasoconstrictors) as needed.

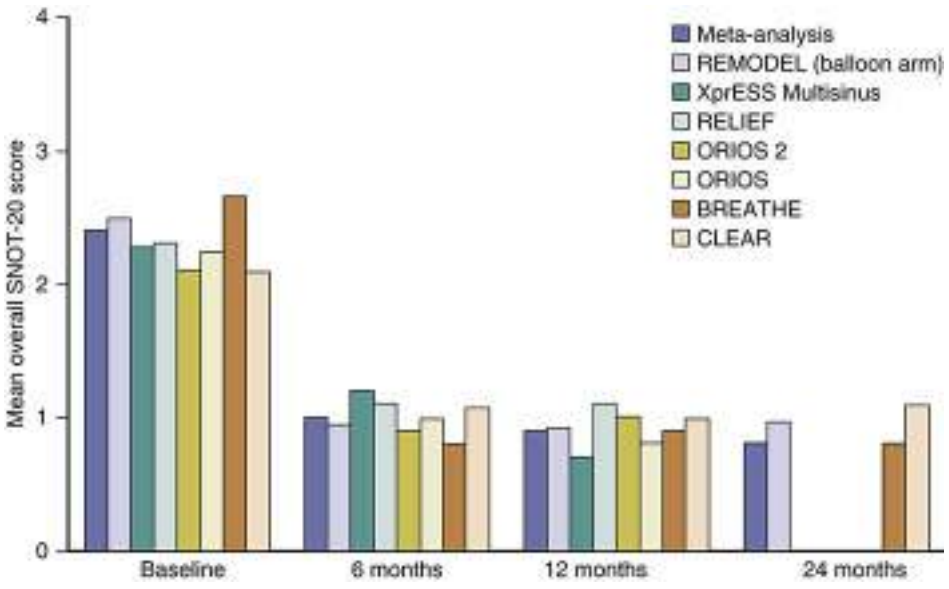

FIG. 102.2 Reduction in SNOT scores across multiple

balloon sinus dilation studies.

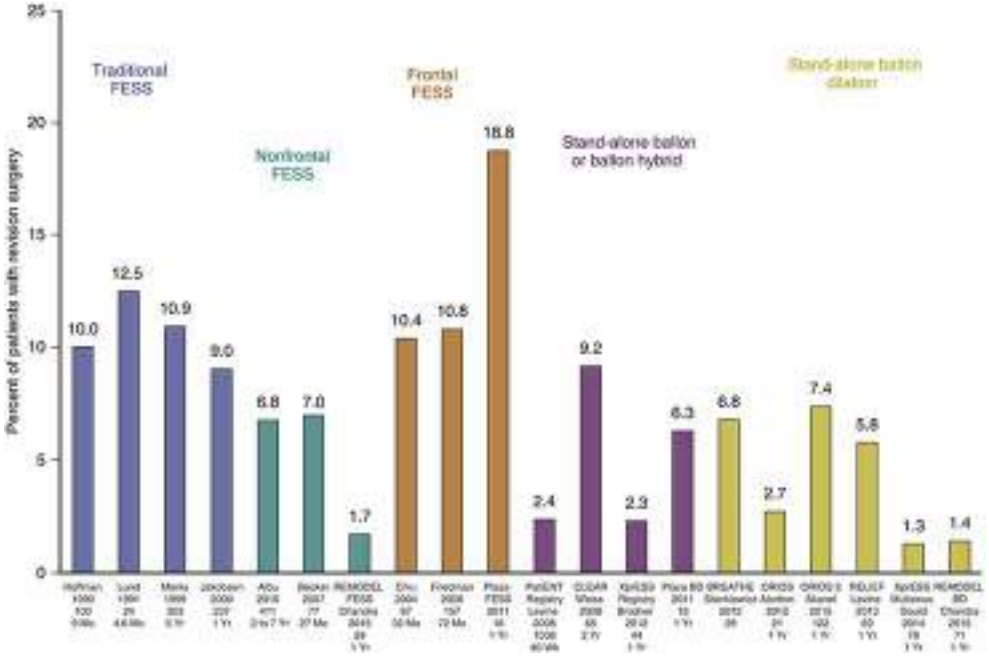

FIG. 102.3 Revision rates of functional endoscopic sinus surgery (FESS) versus balloon sinus dilation across multiple studies.

3. Congestion
   a. This can occur postoperatively resulting in facial pressure.
   b. First-line treatment would be oral decongestants.
   c. A short course of oral steroids (prednisone) can be given for 3 to 5 days.
4. Synechiae/stenosis of sinus openings
   a. These are less common with BSD than with FESS, due to reduced disruption of the mucosa.
   b. A true-cut forceps can be used to take these down, using a dissolvable middle meatal pack to separate opposing tissue.
   c. Repeat BSD may be necessary to enlarge a stenotic ostium.

Alternative Management Plans

1. Consider an endoscopic sinus surgery approach (FESS or hybrid).

   a. Significantly restricted anatomy (septal deviation, nasal polyps)

Discussion

Evidence-Based Medicine Question

Is BSD as effective as FESS for appropriate selected patients?

The gold standard for the management of medically refractory chronic rhinosinusitis is FESS. Any technique that seeks to add to or replace FESS has to demonstrate equivalent efficacy and safety, and BSD fits these requirements in properly selected patients.

There are many prospective, randomized controlled trials (RCTs) indicating that BSD is equally efficacious as FESS for like-sinus sufferers.[1-7] Consistently, BSD studies in patients with chronic maxillary sinusitis/limited anterior ethmoid disease have equivalent reductions in sinonasal outcome test (SNOT)-20 scores beyond 1 year after the procedure (Fig. 102.2). Additionally, revision rates in BSD are comparable or better than those of FESS patients in a variety of studies (Fig. 102.3).

Success of BSD is not only limited to the maxillary sinuses but also holds true for chronic frontal sinusitis. In the double-blind randomized controlled Plaza study in 2011,[6] patients with frontal sinus polyposis underwent BSD as a hybrid procedure with anterior ethmoidectomy compared to a Draf I frontal sinus procedure. After greater than 1 year follow-up, BSD patients experienced equivalent reductions in Lund McKay CT scores and equivalent patency while having lower revision rates.

Limited anterior ethmoid disease does not seem to preclude success in balloon dilation of the maxillary sinuses. Many studies have revealed up to 40% of patients with limited anterior ethmoid disease clear these sinuses after BSD of the maxillary sinus.[7]

Finally, the improvement in sinusitis among BSD appears to be long lasting. In a meta-analysis of six studies including 358 patients followed for at least 24 months, the improvements in SNOT-20 scores persist.[8]

Editorial Comment

BSD is increasingly used in the management of recurrent acute and chronic rhinosinusitis. By standard quality of life measures, such as the SNOT-22, BSD is effective in the management of select patients with chronic rhinosinusitis. Additionally, this intervention is increasingly used in an office-based setting, avoiding general anesthesia. The goal of these procedures is principally ventilation of the sinus with minimal mucosal disruption. In contrast, FESS can provide both ventilation as well as access to topical medications. The specific goals of the surgical intervention should be determined preoperatively to establish whether BSD is an appropriate intervention. As such, the indications for BSD continue to evolve and be refined with increasing experience and time.

Eric W. Wang

Access the review questions and additional source list online at http://www.expertconsult.com

Review Questions

1. Potential complications of BSD include:

   a. Bleeding

   b. Orbital injury

   c. CSF leak

   d. Stenosis of sinus openings

   e. **All of the above**

2. The most important anatomic relationship when performing frontal BSD is:

   a. To stay posterior to the posterior-most ethmoid cell

   b. **To stay anterior to the bulla ethmoidalis**

   c. To stay medial to the middle turbinate

   d. To stay anterior to the uncinate process

   e. To stay lateral to the inferior turbinate

3. Contraindications of BSD include all of the following, except

   a. Diffuse nasal polyposis

   b. Fungal sinus disease

   c. Severe septal deviation causing poor visualization

   d. **Limited anterior ethmoid disease**

   e. Need for excision of a sinus mass

4. Evidence-based medicine comparing BSD to FESS for properly selected patients with similar disease indicates:

   a. BSD is inferior to FESS in efficacy

   b. BSD results in higher revision rates than FESS

   c. **BSD shows equivalent efficacy to FESS**

   d. BSD results in higher complication rate than FESS

   e. BSD cannot be used in any cases with anterior ethmoid disease

5. Which of the following statements is *true* regarding BSD?

   a. Solitary polyps are a contraindication to BSD

   b. **Transillumination is necessary to confirm safe entry prior to BSD**

   c. A septal deviation prevents BSD

   d. Topical epinephrine 1:1000 should never be used in BSD

   e. Patients who have undergone BSD can blow their nose freely right after the procedure

Antral Lavage; Endoscopic Middle Meatal Antrostomy/Antrochoanal Polyp

Nicholas R. Rowan, Nivedita Sahu, and Barry Schaitkin

Introduction

Since the 1980s, the surgical approach to the maxillary sinuses has been revolutionized by the endoscopic endonasal approach. The goals of treatment of maxillary sinus disease are aeration and resumption of normal mucociliary flow. Additionally, there is an increasing number of surgeons who now operate with a goal of access for topical medications. Although often believed to be the one of the most straightforward steps of endoscopic sinus surgery, the surgical approach to the maxillary sinus is not without potential complications and controversy.

Many primary cases without nasal polyps can be managed with a minimally invasive approach that marsupializes the natural ostium into the nose using an uncinate window. For more complex cases or in the setting of more advanced disease, endoscopic middle meatal antrostomy can facilitate long-term management of patients with chronic maxillary sinusitis by allowing for easy in-office and home antral lavage. These antrostomies are also the treatment of choice for other middle meatal pathologies such as antrochoanal polyps and can serve as a corridor to the middle fossa in skull base surgery.

Antrochoanal polyps were first described by Killian in 1906.[1] The polyp originates within the maxillary sinus and eventually is extruded through the natural ostium into the nasal cavity, obstructs the choana, and is characterized by the symptoms of unilateral nasal obstruction, rhinorrhea, and postnasal drainage. It is more common in the pediatric age group and represents the most common nasal and sinus growth in

children. In the general population it is said to account for 4% to 6% of all nasal polyps, and in one study of 24 patients the mean age was 23 years (range, 11 to 40).[1]

The etiology of antrochoanal polyps remains controversial, and both allergic and infectious causes have been suggested.[2] Although medical treatment such as antibiotics, decongestants, and steroids may provide temporary relief, the treatment of choice for antrochoanal polyps is complete surgical excision. We prefer an endoscopic approach to these lesions, but in cases of recurrence or in those where the stalk of the polyp is not clearly visualized, the endoscopic approach may be combined with a canine fossa puncture or inferior meatal antrostomy for placement of an endoscope or instruments or a mini-Caldwell Luc.

Key Operative Learning Points

1. The natural ostium of the maxillary sinus is located in a parasagittal plane and is identifiable after an uncinectomy is performed.

2. In cases that require a maxillary antrostomy, the natural ostium of the maxillary sinus must be incorporated into the maxillary antrostomy to prevent recirculation.

3. The best results occur when operating with adequate vasoconstriction resulting in minimal bleeding, proper visualization, and minimal trauma to the mucosa.

4. Antrochoanal polyps are often found exiting an accessory os in the posterior fontanelle. Polyps exiting the natural os should raise suspicion for other pathologies including inverted papilloma.

Preoperative Period

History

1. History of present illness:

   a. What are the patient's presenting complaints?

      1) The four cardinal symptoms of sinusitis are nasal obstruction,

discolored nasal drainage, facial pain, or pressure and hyposmia.

2) Duration of symptoms should also be elicited.

3) Odontogenic infections that ascend into the maxillary sinus should also be considered and evaluated.

2. Past medical history:

a. Prior treatment:

1) Medical therapy: Has this patient previously been treated with oral antibiotics? Has he or she used intranasal or systemic corticosteroids? Have other nasal sprays or saline irrigations been tried?

2) Surgical history: Prior sinonasal surgery, including septoplasty and prior sinus surgery

3) Dental history: Prior infections, root canals, implants, or "sinus lifts"

b. Trauma history: Prior nasal bone fracture or trauma to the orbital rim, floor, lamina papyracea, or nasal septum

c. Medical illness:

1) Systemic illnesses that may have sinonasal manifestations such as sarcoidosis, granulomatosis with polyangiitis (formerly Wegener granulomatosis), or vasculitis

d. Family history of coagulopathy or anesthesia complications

e. Medications:

1) Antiplatelet medications or other blood thinners

2) Herbal products or supplements (e.g., vitamin E, ginseng, gingko biloba, garlic)

f. Social history:

1) Tobacco and alcohol history

2) Environmental exposures (e.g., woodworking and heavy metals)

Physical Examination

1. All patients evaluated by an otolaryngologist should undergo a comprehensive examination of the head and neck.

2. Nasal endoscopy

   a. The nose should be examined before and after being decongested with oxymetazoline and anesthetized with topical lidocaine to achieve an adequate examination while minimizing patient discomfort.

   b. What anatomic factors may be contributing to the patient's complaints or limit future surgical intervention?

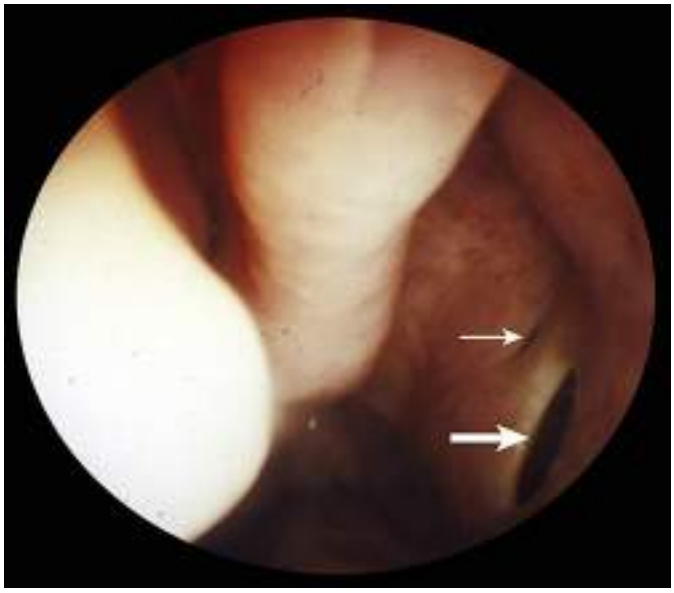

FIG. 103.1 Endoscopic view of accessory ostia *(arrows)* in the left posterior fontanelle.

   1) Is the nasal septum deviated? Is there a concha bullosa? Is there an accessory os and if so, is there evidence of recirculation?

      a) The natural ostium is the only functional ostium within the sinus, and the inferior meatus will be ignored by mucociliary activity. Patients who have a patent inferior meatal antrostomy can easily be examined in the office through that opening with 0- and 30-degree endoscopes, and not

infrequently, an obstructed natural ostium can be seen despite a surgically patent inferior meatal antrostomy (Fig. 103.1).

c. What is the health of the mucosal lining? Is there evidence of active infection?

1) This can only be appreciated if the patient has previous surgery or an accessory ostium.

2) Abnormal secretions can be sampled endoscopically for culture-directed therapy, and abnormalities that might impact surgical access to the ostiomeatal complex should be noted.

d. Detailed notes of the nasal endoscopy and, if possible, clinical photographs allow better preoperative surgical planning.

e. Are there signs of prior surgical intervention?

f. Diagnostic information about nasal tumors, as well as diseases of the mucous membranes such as Kartagener syndrome, cystic fibrosis, and granulomatosis with polyangiitis, can be gleaned from nasal endoscopy.

Imaging

1. When should imaging be completed?

a. Patients whose symptoms persist despite adequate medical therapy should undergo imaging. Fine-cut coronal computed tomography (CT) without contrast enhancement is the most informative. High-quality coronal scans effectively delineate the area of the maxillary sinus ostium or ostiomeatal complex and provide verification of anatomic abnormalities that may be contributing to the sinus obstruction. When using the standard window approach described in the 1980s, no mucosa should be apparent, so any amount of mucosal thickening seen within the boundaries of the maxillary sinuses is considered abnormal.

2. Correlation of endoscopic findings with those on CT allows further evaluation of the anatomy and function of these highly variable and important structures.

Indications

1. Chronic rhinosinusitis refractory to medical management

2. Recurrent acute sinusitis refractory to medical management

3. Nasal polyposis

4. Antrochoanal polyp

5. Maxillary sinus mucocele

6. Fungus ball

7. Benign or malignant tumors involving the maxillary sinus

8. Endoscopic endonasal access to the pterygopalatine fossa or infratemporal fossa

Contraindications

1. Inadequate trial of medical management of rhinosinusitis

2. Odontogenic etiology that will predictably resolve (>60% of the time) once the dental issue has been addressed

3. Asymptomatic maxillary opacification or mucus retention cyst

Preoperative Preparation

1. Coronal CT scans are mandatory for preoperative planning in patients who are expected to undergo endoscopic surgery. The surgeon should review the CT scans with particular emphasis on the important structures that lie adjacent to the sinus cavities. For the maxillary sinus, this primarily entails a thorough evaluation of the lamina papyracea and the floor of the orbit to look for anatomic anomalies or any areas of dehiscence. Additionally, intramaxillary ethmoid cells (Haller cells) should be identified preoperatively. Radiographic evaluation of an antrochoanal polyp reveals unilateral opacification of the maxillary sinus and antrum along with rarely associated opacification of the ethmoid sinuses (Fig. 103.2).

2. Discontinue blood thinning and antiplatelet agents if possible

3. Controversy continues regarding the optimal extent of surgery that should be performed in patients with chronic sinusitis, and surgical treatment of the maxillary sinus is no exception. Some surgeons recommend wide antrostomy to improve sinus drainage and access for topical medications. Others maintain that the goal of maxillary sinus surgery should be removal of a minimal amount of tissue necessary to restore patency of the outflow tract.[3] Practitioners of both schools continue to espouse their own philosophies, and these approaches appear to achieve comparable results. We believe that the extent of surgery should be dictated by, and individualized, for each patient's pathology. This should be carefully planned preoperatively.

Operative Period

Anesthesia

1. We prefer endotracheal intubation and general anesthesia for patient comfort and airway protection. This is mandatory in patients with reactive airway disease.

2. Total intravenous anesthesia (TIVA) and deliberate hypotension may improve visualization during surgery; however, this is a controversial topic.[4]

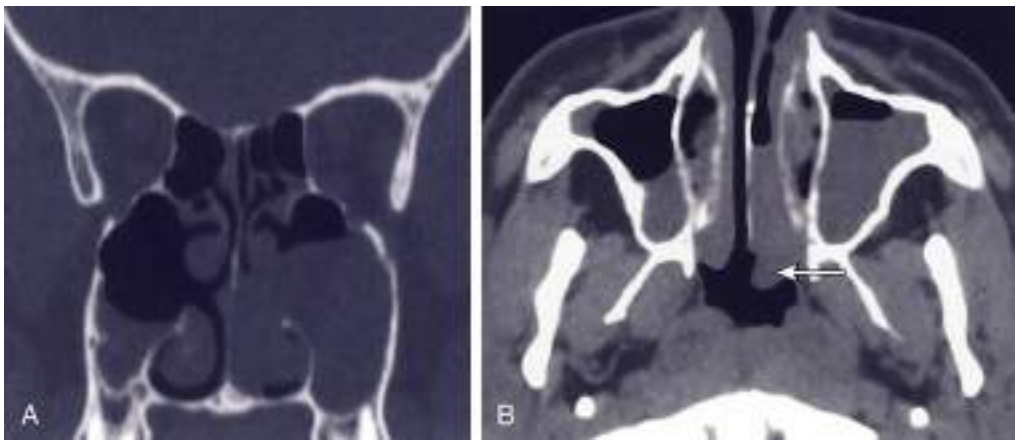

FIG. 103.2 CT scan demonstrating an antrochoanal polyp

from a left radiopaque antrum into the nose on the coronal image, **A**, and extending into the nasopharynx on an axial image, **B** *(arrow)*.

Positioning

1. The patient is placed supine on the operating table with the head rotated slightly toward the surgeon. The head remains midline when using the four-handed technique. Some surgeons prefer the reverse Trendelenburg position or the head rotated slightly toward the surgeon.

2. Careful attention should be paid to the ergonomic positioning of surgical monitors and image guidance systems if used.

3. The endotracheal tube should be secured to the lower lip to prevent loss of the airway during surgery.

Preoperative Antibiotic Prophylaxis

1. The sinonasal tract is considered a contaminated site. We typically use a single perioperative dose of first-generation cephalosporin.

   a. Consider a broader-spectrum antibiotic if the patient is currently infected and obtain intraoperative cultures.

   b. Clindamycin is an acceptable alternative if the patient has an allergy to cephalosporin.

   c. Antibiotic treatment may also be guided by preoperative cultures.

Monitoring

1. None required

2. In cases where more extensive surgery is required, image guidance systems may be used.

Instruments and Equipment to Have Available

1. Basic endoscopic sinus surgery set

   a. 0-, 30-, and 45-degree endoscopes are usually adequate to visualize the natural ostium and most aspects of the maxillary sinus, but a 70-degree scope maybe useful for complete visualization in the case of antrochoanal polyps and other maxillary sinus–occupying lesions (Fig. 103.3).

   b. Bipolar and suction monopolar cautery should be available.

Key Anatomic Landmarks

1. The maxillary sinus is typically a single air cell bounded by the orbit superiorly, the zygomatic process laterally, the hard palate inferiorly, the fontanelles and uncinate medially, and thin layers of bone anteriorly and posteriorly that separate the sinus from the soft tissue of the cheek and the pterygopalatine fossa, respectively. Normal mucociliary function from birth results in continuous removal of mucus against gravity through the natural ostium of the maxillary sinus. This ostium is bounded by the uncinate process and the ethmoid bulla, forming the hiatus semilunaris and draining into the infundibulum.

FIG. 103.3 Endoscopic view of the left nasal vault

demonstrating an antrochoanal polyp *(arrow)* exiting into the nose via an accessory ostium behind an intact uncinated process *(cross)*.

2. Haller cells: In some cases (Fig. 103.4), additional cells on the floor of the orbit known as Haller cells can also contribute to obstruction.

Prerequisite Skills

1. Basic nasal endoscopy and use of the two-handed surgical technique

Operative Risks

1. Epistaxis
   a. Minor bleeding can result from trauma to the nasal septum. However, significant bleeding is rare and occurs when the turbinate has been partially or totally resected or the sphenopalatine artery has been violated. See Chapter 98 for the sphenopalatine artery ligation technique.

FIG. 103.4 Haller cell *(asterisk)* on a coronal CT scan and natural ostium of the right maxillary sinus *(arrow)*.

2. Injury to the nasolacrimal duct
   a. Injury may occur when performing an uncinectomy and should be prevented by differentiating between the maxillary line and the

uncinate process.

3. Orbital injury

   a. We found that the orbit is entered most commonly during uncinectomy, primarily as a result of the tip of the sickle knife being driven through the lamina papyracea.

4. Injury to the infraorbital nerve

   a. This injury is rare but can occur while working within the maxillary sinus space, especially when there has been prior maxillofacial trauma involving the orbit.

Surgical Technique

1. The procedure begins in the holding area with the application of topical decongestants 30 minutes before the procedure, and repeat topical therapy is given at 15 minutes and on call in the operating room.

   a. If the surgeon prefers to use 1:1000 epinephrine intraoperatively for topical vasoconstriction, this step should be avoided because these decongestants compete for the same adrenergic receptor, thereby making the 1:1000 solution less effective.

2. Surgical preference will dictate the manner in which the operating room and Mayo stand are organized. A two-handed or four-handed technique is acceptable. We use a four-handed technique, which is particularly helpful for teaching and in patients with acute inflammation and bleeding.

3. There are many ways to clean the lens of the endoscope and prevent fogging. In the two-surgeon technique, the assistant instills saline into the nose via a 60-mL syringe with a blunt 18-gauge needle or a curved suction. Some soft tissue shavers irrigate the lens by squirting water from the tip of the dissecting instrument. An endoscopic scrubber or sleeve can be placed as a sheath over the endoscope to irrigate the tip. Antifog agents are also available from multiple manufacturers. Such agents are helpful but should not be used if an irrigating sleeve is on the endoscope because the film prevents irrigation of the tip of the scope. A clean endoscope and a dry field will enable surgical precision and decrease frustration and complications.

FIG. 103.5 Injection sites for maxillary sinus surgery ("+" represents superior attachment of middle turbinate, *black arrowhead* represents inferior aspect of uncinate process, and *white arrowhead* represents tail of middle turbinate).

4. To maintain a dry field, oxymetazoline or 1:1000 topical adrenaline is applied on ½- by 3-inch radiopaque neuro patties. Both are poured by the circulator into labeled basins. The adrenalin is dyed with a single drop of methylene blue to further decrease the risk of confusing it with local anesthetic and injecting it in the nose.

5. Many different systems of powered instrumentation, popularized by Reuben Setliff, are available. Optimal settings may vary, but in general, the device in oscillating mode is more effective at a slower speed, which allows a greater time for soft tissue to be entrained into the window of the device.

6. Local anesthesia is provided by injecting 1% lidocaine (Xylocaine) with 1:100,000 epinephrine as a vasoconstrictor before all procedures. The injection sites are the superior attachment of the middle turbinate, the inferior aspect of the uncinate process, and the tail of the middle turbinate (Fig. 103.5). The procedure is begun after 5 minutes has elapsed.

7. A right-handed surgeon stands on the right side of the patient. The scope is positioned in the superior aspect of the nasal vault so that

placement of surgical instruments is inferior and unencumbered.

8. The middle turbinate is gently medialized with attention paid to transmission of force to the lateral lamella of the cribriform plate. With a bulky, paradoxically curved turbinate, and certainly for the concha bullosa, access may be achieved by lateral reduction of the middle turbinate with a soft tissue shaver. Most patients do not require more than just gentle retraction of the middle turbinate. The narrowest part of the ethmoid labyrinth is located between the anterior portion of the middle turbinate and the uncinate and lacrimal processes. Care should be taken in this area to avoid damage to the mucosa and subsequent formation of synechia.

9. We espouse a retrograde dissection of the uncinate with a pediatric back-biting forceps as the safest approach to the infundibulum (Fig. 103.6).

10. After confirming the location of the free edge of the uncinate process, retrograde dissection is performed approximately one-third of the way from the attachment of the uncinate process to the ethmoidal process of the inferior turbinate. A powered instrument is then used to remove the uncinate process superior to the surgically created uncinated window up to the level of the agger nasi, or as dictated by the remainder of the procedure. The portion inferior to the uncinate window then consists of the nasal mucosa, the residual bone of the uncinate process, which inserts into the inferior turbinate, and the mucosa on the sinus side. The mucosa on the nasal side is gently removed with the microdébrider to expose the uncinate bone, which is dissected and elevated submucosally with a double-ball probe seeker (Fig. 103.7). This instrument is used to deliver the uncinate out of the mucosal pocket while leaving the maxillary ostium intact (Fig. 103.8). This allows the microdébrider to bring the mucosal flap to meet the nasal side. Removing the uncinate process in this submucosal fashion permits the natural ostium of the maxillary sinus to be enlarged without damage to the entire mucosal circumference of the ostium. The parasagittal orientation of the sinus opening is also maintained. Care is taken not to damage any of this mucosa, which could result in at least obstruction and edema with resultant infection and, at worst, stenosis of the maxillary ostium.

FIG. 103.6 Uncinate window created by retrograde dissection on the left side with pediatric back-biting forceps to reveal natural os *(arrow)*. The inferior portion consists of the remaining uncinate attached to the ethmoidal process of the inferior turbinate and the mucosa medially and laterally. (The x marks the middle turbinate.)

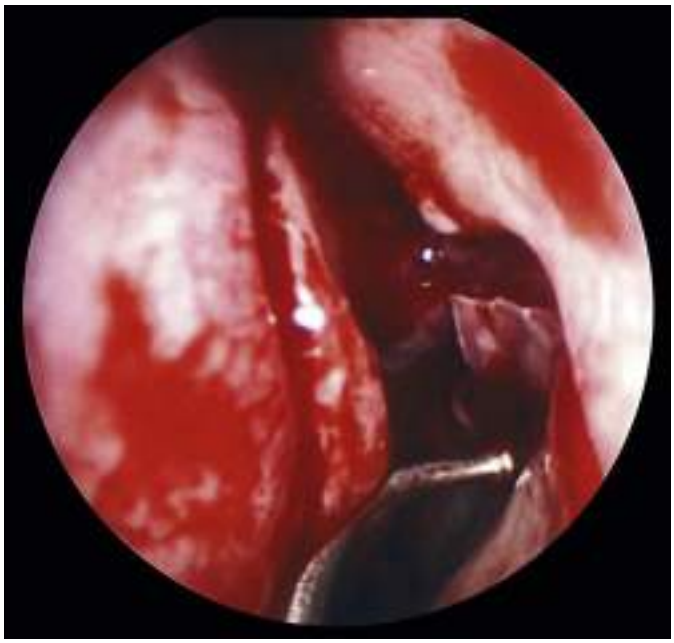

FIG. 103.7 Submucosal dissection of the uncinate process on the left side with a double-ball probe seeker.

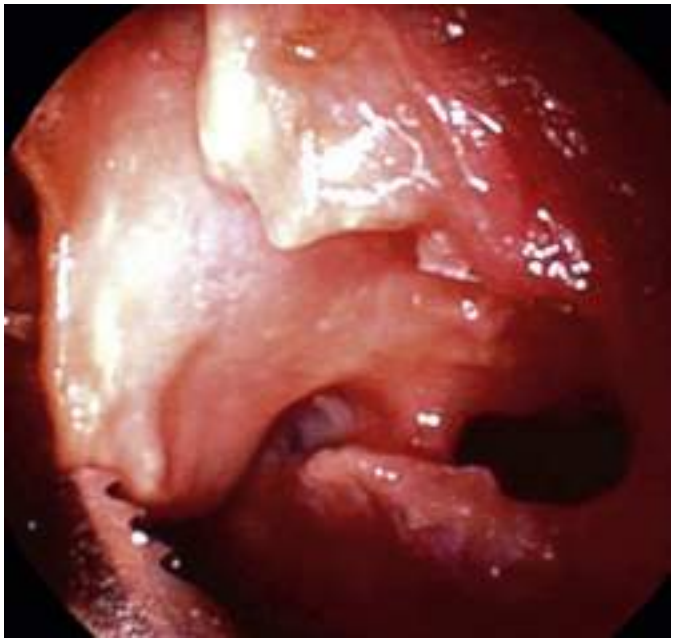

FIG. 103.8 Mucosal preservation of 360 degrees of the left natural ostium.

11. If antral lavage is required, it is performed by passing a small pediatric suction through the natural ostium in an atraumatic fashion for use as irrigation. Irrigation can also be performed through an accessory ostium if present or via an inferior meatal puncture. This technique is used for standard cases of recurrent acute sinusitis and chronic maxillary sinusitis (Video 103.1).

12. In cases in which a maxillary antrostomy is prudent, the verified natural ostium can be enlarged posteriorly into the posterior fontanelle while preserving the maxillary sinus mucosa 270 degrees anteriorly around the ostium. A ball probe seeker or curved suction can be used to accomplish this. Once the decision has been made to create an antrostomy, it should be a large one. A tear-shaped antrostomy may be ideal for the restoration of normal mucociliary clearance. Secretions can be managed by suctioning and lavage. Polypoid mucosa is not removed but can be reduced to allow for removal of trapped secretions. Care should be taken when dissecting posteriorly as injury to branches of the sphenopalatine artery or the descending palatine nerve can occur.

13. Depending on the pathology of the maxillary sinus, the degree of required access may differ. Studies have demonstrated that small-hole techniques severely limit the accessibility to the sinus. Similarly in our own study, we found that instruments with increasing curvatures

allowed for greater access to the sinus, but no single instrument could reach the entire maxillary sinus wall through an endoscopic antrostomy.[5]

Surgical Technique: Antrochoanal Polyps

1. Antrochoanal polyps must be completely excised to avoid recurrence. Endoscopically, this can sometimes be performed exclusively endonasally; however, even with 30- and 70-degree telescopes, it is often necessary to also approach the maxillary sinus component via an extended or external approach.

2. The nasal component can easily be removed endoscopically. A maximal maxillary antrostomy allows full view of the sinus component and usually the stalk, which has a variable location within the sinus but is most often found attached to the lateral wall of the sinus. The polyp often has a "neck," which can be grasped with a 90-degree ethmoid forceps to remove the bulk of the antrochoanal polyp. A standard curved 4-mm soft tissue shaver is used to eliminate the remainder of the polyp.

3. If the stalk is not readily accessible through the transnasal route, a canine fossa puncture is performed. A standard 4-mm soft tissue shaver can thus be placed with visualization of the sinus with an angled transnasal endoscope, or a 30-degree telescope can be introduced through the puncture and a curved instrument placed transnasally with a minimally invasive technique.

4. In some cases a double-barrel canine fossa puncture is performed to allow both the shaver and scope to be introduced, the scope through the trocar sleeve and the shaver directly through the front face of the maxilla. For the shaver, a standard canine fossa puncture is performed above the gingivobuccal sulcus superior to the canine tooth in the palpated fossa. An extended finger on the cheek prevents perforation of the posterior wall of the maxillary sinus after breeching the anterior wall. The nondominant hand may be kept on the orbital rim to prevent the trocar complex from sliding too superiorly on the front face of a dense maxilla and damaging the orbit.

   a. Once the trocar and sleeve are within the sinus, the trocar can be removed and a telescope placed for full exposure. Best results with the shaver occur with removal of both the sleeve and trocar and

placement of the device through the created surgical tract. A 30-degree scope is ideal for complete inspection of the maxillary sinus via the canine fossa. No packing or dressings are needed, and additional surgery on the ethmoid sinus is almost never required.

5. Though increasingly less common, external approaches using a Caldwell Luc operation may also be employed for antrochoanal polyp (see Chapter 104).

Common Errors in Technique

1. Mucus membrane stripping

   a. The hallmark of all endoscopic techniques is preservation of the mucosa. The excellent studies of Moriyama and colleagues from the 1990s demonstrated that once this lining is removed, the subsequent reparative lining is never organized in a ciliated pattern that can return to normal. Furthermore, stripping of the mucosal lining creates a favorable environment for osteitis and postoperative scarring. Thus, all current endoscopic sinus procedures are predicated on an improved ability to preserve the mucous membrane.

2. Failure to incorporate the natural ostium

   a. Patients may have multiple openings in their posterior fontanelle (accessory ostia). These openings will lie in the sagittal plane and appear as though the fontanelle had a punched-out area in its membrane (see Fig. 103.1). They will be round and lack the anterior elliptical extension that only the natural ostium provides. Patients are frequently symptomatic when there is circular movement of secretions between the natural ostium and an accessory ostia, known as recirculation. Such patients will complain of thick postnasal discharge, as well as symptoms of recurrent infection. Examination in the office with a 30-degree nasal endoscope pointed laterally will often demonstrate these secretions, which frequently contain bubbles moving between the two ostia. CT will demonstrate these bubbles on the floor of the maxillary sinus. When faced with an additional opening, obvious recirculation seen endoscopically, and bubbles on CT scan, the decision is usually made preoperatively to

enlarge the natural ostium into these accessory ostia.

Postoperative Period

1. Postoperative management

   a. Postoperative pain should be minimal and is typically managed with Tylenol or low-dose narcotics.

   b. Large-volume saline irrigations are started on postoperative day 0.

   c. Nasal steroid sprays and other intranasal medications are typically started 1 week after surgery or after the completion of systemic steroids if used.

   d. There is currently no strong evidence to support the routine use of postoperative antibiotics. Certainly, if infection is encountered, a culture should be taken, and the patient should be placed on empiric antibiotic therapy.

   e. Generally, the patient is cautioned against nose blowing and weight lifting is limited to less than 10 pounds postoperatively.

2. For the endoscopic approach, nasal saline irrigation usually serves as adequate postoperative care. Wide postoperative evaluation of the surgical site is afforded by the maxillary antrostomy. Thirty-degree telescopes and even flexible laryngoscopes allow wide surveillance. In cases of recurrence, performing a maximal maxillary antrostomy aids in irrigation, medication delivery, and postoperative surveillance.

3. Complications

   a. Failure to resolve facial pain. In many patients, the lack of a clear diagnosis and indication for surgery can result in unwarranted and unsuccessful surgery. It is difficult to know how to manage patients who have major symptoms and no objective endoscopic or CT evidence of sinus disease. This group creates a great deal of confusion diagnostically, and ideally they should undergo multiple nasal endoscopic examinations in an attempt to ascertain what is occurring in the nose when they are sick. The patients should be re-evaluated during exacerbation of symptoms so that a correct diagnosis can be made. Patients with facial pain in the absence of other symptoms are rarely offered surgery unless every other

avenue has been undertaken and the patient understands that no guarantee can be made.

b. Persistent disease. This can be continued infection, recurrence of polyposis, retained secretions, and a residual fungus ball or antrochoanal polyp.

c. Formation of synechia remains the main pitfall, and the use of powered instrumentation has minimized mucosal trauma and thus has avoided the vast majority of these problems. Powered instruments allow preservation of most or the entire mucosal ring of the natural ostium. If the mucosal preservation technique is used without a formal antrostomy, the middle turbinate will not obstruct the sinus even if it does lateralize (see Fig. 103.8). The sinus does not become obstructed because the natural os that remains in the anatomic parasagittal plane and its outflow tract are inaccessible to obstruction by the lateralized middle turbinate. This is not the case if a formal antrostomy is performed that converts the antrostomy into a true sagittal plane and lateralization of the turbinate can cause obstruction (Fig. 103.9). A lateralized middle turbinate may result in unilateral sinus obstruction (Fig. 103.10). Complications are minimal when an antrostomy is not performed.

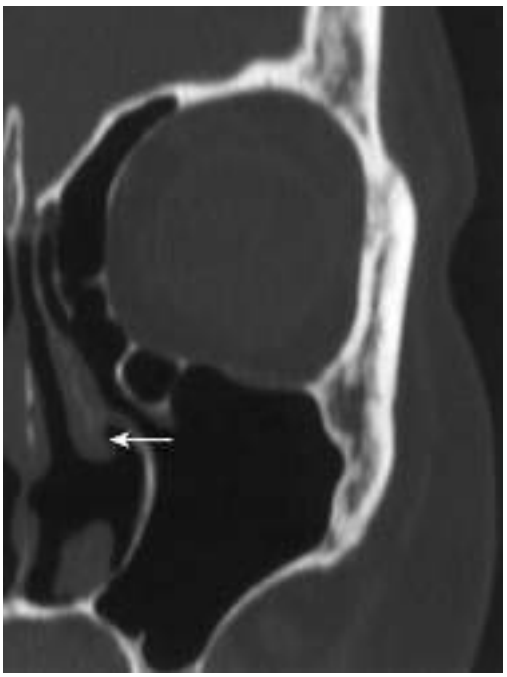

FIG. 103.9 The lateralized middle turbinate *(arrow)* on the left side

cannot obstruct the maxillary sinus because the undisturbed maxillary ostium is left in the parasagittal plane.

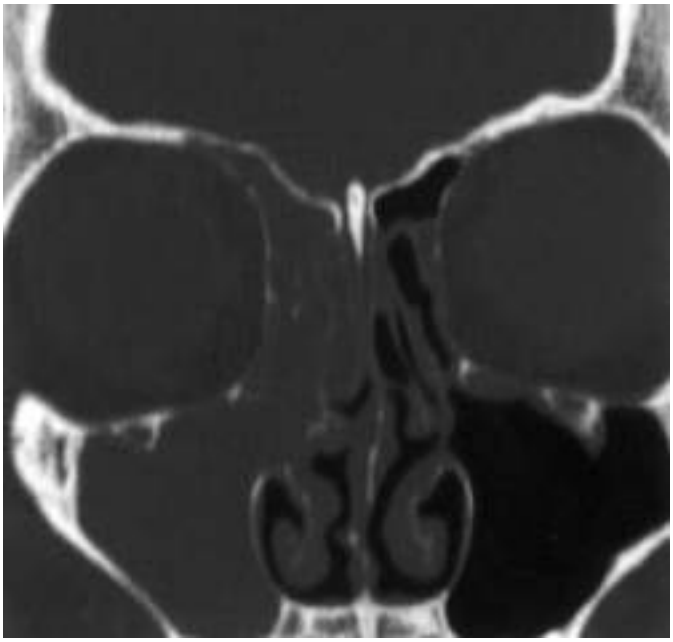

FIG. 103.10 Computed tomography shows a scarred lateralized middle turbinate causing right maxillary obstruction after antrostomy.

d. Stenosis of the ostium can occur if the surrounding mucosa is not preserved, subsequently leading to scar formation and an obstructed sinus.

e. Both injury to the lacrimal system and entry into the orbit are most commonly encountered during an uncinectomy and can be avoided with meticulous dissection in a dry operative field.

f. Recirculation of mucus as a result of failure to incorporate the natural ostium into a surgically created antrostomy

g. Bleeding is not usually a major problem with maxillary sinus surgery unless one violates the posterior limit of dissection with subsequent injury to the sphenopalatine artery or from some element of interior turbinate resection. Typical postoperative bleeding resolves with topical decongestants (e.g., oxymetazoline) or local pressure.

h. The pitfall in surgery for an antrochoanal polyp is recurrence, which

has been noted after limited surgical procedures such as polypectomy. Complete removal, most commonly via an endoscopic (or rarely through a Caldwell-Luc) approach, has been shown to minimize the likelihood of recurrence of the polyp in adults and children. The advantage of these techniques is that the polyp and involved antral mucosa are removed as a unit under direct visualization, thereby reducing the possibility of recurrence.

4. Alternative management plan
   a. Continued medical management
   b. Intranasal corticosteroids and other topical medications for chronic rhinosinusitis
   c. Given that this is a symptom-driven procedure and that there is no risk of malignant transformation, all surgical interventions should be as minimal as possible.

Discussion

Evidence-Based Medicine Question

What is the role of antibiotic usage following routine maxillary antrostomy?

The evidence for the use of routine postoperative antibiotics is poor. Several studies have shown no difference between control groups and those who were given amoxicillin or amoxicillin with clavulanic acid postoperatively. We advocate the use of nasal saline sprays and/or irrigations to clear clots and remove crusting.

Editorial Comment

Uncinectomy and middle meatal antrostomies are the standard surgical therapy used for patients with chronic rhinosinusitis unresponsive to medical management. Because it is increasingly understood that this represents an inflammatory rather than infectious disease, access for topical medications and ventilation have become the dual goal of this intervention in the management of chronic rhinosinusitis. The exception

to this paradigm is odontogenic sinusitis, an increasingly recognized cause in maxillary sinusitis. Although disease limited to the maxillary sinus can often resolve with treatment of the primary dental pathology, a wide middle meatal antrostomy is an effective option in more extensive or recalcitrant disease to alleviate the symptoms and aid in the treatment of these infections. In contrast, middle meatal antrostomies are generally ineffective in the presence of ciliary dysfunction such as cystic fibrosis. Because a middle meatal maxillary antrostomy is dependent upon mucociliary clearance, it is generally ineffective in these conditions with persistent pooling of thickened secretions in the inferior aspects of the maxillary sinus.

Review Questions

1. To prevent recirculation problems, which of the following must be accomplished during a maxillary antrostomy?

   a. Complete uncinectomy

   b. **Identifying the natural ostium**

   c. Entering the maxillary sinus through the posterior fontanelle

   d. Irrigating the maxillary sinus

2. A polyp stemming from an accessory os is most likely to be which of the following?

   a. **Antrochoanal polyp**

   b. Inverted papilloma

   c. Allergic fungal sinusitis

   d. Polyp associated with cystic fibrosis

3. Unilateral maxillary sinusitis is most likely due to which of the following causes?

   a. Immunodeficiency

   b. Allergy

c. Exposure to sick people

d. **Dental disease**

Anterior Antrostomy

The Caldwell-Luc Operation

Andrew C. Urquhart

Introduction

The Caldwell-Luc procedure was named after two surgeons, Caldwell and Luc. They both described a similar procedure, with Caldwell advocating an inferior meatal antrostomy and Luc advocating enlargement of the natural ostium in the middle meatus. Caldwell practiced in New York and published a report on anterior antrostomy in the *New York Medical Journal* in 1896. Luc was French, practiced in Paris, and independently reported his procedure in 1897.[1]

The Caldwell-Luc approach has been used extensively in the past with excellent exposure and classic anatomic landmarks. It was the standard surgical technique for chronic maxillary sinus disease and used gravitational drainage through the inferior meatus (Fig. 104.1). With the development of endoscopic sinus surgery for the treatment of chronic sinusitis as well as facilitating an approach for other conditions, including skull base surgery, most younger surgeons will have had a very limited exposure to this procedure.

Open approaches were also used in a number of situations, apart from chronic sinusitis, including a corridor for the transantral ligation of vessels in the pterygopalatine fossa for epistaxis; in Vidian neurectomy, for the repair of fracture of the floor of the orbit, the repair of oroantral fistulas, and the removal of antrochoanal polyps; and as part of the surgical approach in a maxillectomy. While needed less frequently today, it is certainly important to understand and be able to perform the procedure in cases that are not suitable for an endoscopic approach.

Key Operative Learning Points

1. The maxillary sinus is entered anteriorly through the thin bone of the canine fossa, which lies lateral to the canine tooth root.

2. The contents of the maxillary sinus can be viewed directly and removed with enlargement of the antrostomy.

3. The inferior meatal antrostomy (if required) is made below the inferior turbinate 1 to 2 cm behind the anterior tip of the inferior turbinate.

Preoperative Period

History

1. History of present illness
   a. Dependent on indications for surgery
   b. Chronic sinusitis with previous surgeries
   c. Immunosuppressed patient with invasive sinusitis, overall medical condition, and underlying coagulopathies
2. Past medical treatment
   a. Prior treatment and surgical approaches
   b. Medical illness: specifically a history of bleeding disorders and hypertension. Depending on indications for surgery, the patient may be neutropenic and coagulopathic if surgery is being performed for invasive fungal infection.
3. Surgery
   a. Specific details regarding previous sinus surgeries or dental surgery (i.e., odontogenic cysts, maxillary tooth extractions)
4. Family history
5. Medications
   a. Antiplatelet drugs
   b. Anticoagulation drugs

c. Herbal products

d. Alcohol

Physical Examination

1. Age and general appearance of patient

2. Oral cavity

Note whether edentulous or not; the condition of teeth, especially the upper incisors; the site and location of an oroantral fistula, if present. Examine the upper gingivobuccal sulcus.

3. Nasal

Examine the nasal cavity and perform an endoscopy; check the septum alignment; note the anatomic findings, if previous surgery; check the inferior turbinate location and the relationship to the lateral wall.

4. Orbit

Document the vision and extraocular movement. If surgery is indicated for a fracture of the orbital floor, document the findings and any muscle entrapment.

5. Trigeminal nerve

Examine and document the sensation of V2, particularly with regard to the infraorbital nerve.

Imaging

Computed tomography (CT) with contrast (maxillofacial). Images in both the coronal and axial planes define the size and extent of the sinus as well as its relationship to the surrounding structures.

Indications

1. Inflammatory disease: chronic maxillary sinusitis, fungal sinusitis, and antrochoanal polyp (Figs. 104.2 and 104.3)

2. Neoplastic disease: biopsy of maxillary sinus tumors, removal of

dental tumors, and staging of maxillary carcinoma

3. Access to pterygopalatine fossa

4. Initial step in medial maxillectomy

5. Access to orbital floor for orbital decompression and repair orbital floor fractures

6. Closure of oroantral fistula

Contraindications

1. Medical complications including uncontrolled hypertension and coagulopathy

2. Pediatric patients without secondary dentition

3. Initial approach to sinus disease (Functional endoscopic sinus surgery [FESS] should be the initial surgical treatment.)

4. Aplastic and hypoplastic maxillary sinus

FIG. 104.1 Mucociliary flow through the natural ostium. The Caldwell-Luc procedure uses an antrostomy through the inferior meatus, which is essentially drained by gravity.

FIG. 104.2 Coronal computed tomography scan in a patient with an antrochoanal polyp. Note the expansion of the natural ostium *(arrows)* by the polyp.

Preoperative Preparation

1. Preoperative medical clearance with optimum stability for elective procedure

2. Discontinue antiplatelets and anticoagulants.

3. If patient has invasive fungal disease and is immunosuppressed with coagulopathy, a transfusion as needed. Risks of surgery versus disease progression need to be weighed.

Operative Period

Anesthesia

General anesthesia is preferable for patient comfort and protection of the airway; however, the procedure can be done with local anesthesia and sedation. A nasotracheal or transoral endotracheal tube may be placed in the side opposite the operative site and secured to the surrounding soft tissue with adhesive tape.

FIG. 104.3 Coronal computed tomography scan in a patient with chronic sinusitis and calcified foreign body ("sinolith").

Positioning

- Supine: The patient is positioned in a neutral position with the head in the midline position or turned slightly toward the surgeon.

Perioperative Antibiotic Prophylaxis

While perioperative antibiotics can be given, there is no evidence that there is any benefit or decrease in postoperative infections.

Monitoring

The usual procedure for general anesthesia

Instruments and Equipment to Have Available

1. Headlight (surgeon)

2. Periosteal or elevator

3. Osteotome/mallet

4. Kerrison forceps

5. Blakesley forceps

6. Bone-cutting forceps

Key Anatomic Landmarks

1. Gingivobuccal sulcus: located at the upper reflection of the buccal and gingival mucosa, just lateral to the midline labial frenulum

2. Canine tooth roots: prominent bony protuberance covering the root of the canine tooth, next to the lateral incisor

3. Canine fossa: slight indentation just lateral to the canine tooth root, over the anterior face of the maxilla. The bone is thin and sometimes translucent in this area.

4. Infraorbital nerve: lies at the superior aspect of the surgical field, where it lies in the midline, just below the infraorbital rim

5. Inferior meatus: intranasal, lying below the inferior turbinate, with entry needed 1 to 2 cm behind the anterior end of the turbinate

6. The floor of the sinus is made up of the palatine and alveolar process of the maxilla; in adults, it extends approximately 4 to 5 mm inferior to the floor of the nasal cavity.[2]

Prerequisite Skills

1. Endoscopic sinus surgery (see Chapter 10)

Operative Risks

1. Injury to tooth roots

2. Injury to orbital floor with potential injury to the eye and blindness

3. Infraorbital nerve injury with numbness of the face, nasal ala, and upper lip

4. Injury to the nasolacrimal duct

5. Injury to the superior alveolar nerve with numbness of the maxillary teeth

6. Oroantral fistula

7. Ill-fitting dentures postoperatively

8. Persistent discomfort of the gingivobuccal sulcus

Surgical Technique

- The procedure is usually performed under general anesthesia, although local anesthesia is possible with blocking of the posterosuperior alveolar and greater palatine nerves.
- While transfusions are rarely necessary, immunocompromised and pancytopenic patients are at risk for bleeding, and any measures deemed necessary should be undertaken in these situations, which are usually life threatening.
- General anesthesia is obtained with the endotracheal tube taped off to the opposite corner of the mouth.
- Illumination using a headlight is important.
- Blood pressure should be kept normal or slightly lower than normal.
- The nose is packed with three cotton pledgets moistened in oxymetazoline (Afrin) or 0.25% phenylephrine (Neo-Synephrine).
- Using an assistant with two Army-Navy retractors, the sublabial region is exposed and injected with approximately 3 cc of 1% lidocaine with 1/100,000 adrenaline.
- With a needle-tip Bovie, the mucosa is incised horizontally along the alveolar bone for 2 to 3 cm, lateral to the midline above the tooth sockets (Fig. 104.4).
- The incision should be inferior to the gingivobuccal sulcus so that approximately 0.5 cm of mucosa is preserved for later closure. In

edentulous patients, the incision should be made over the attached gingiva to ensure proper fitting of dentures.

- The soft tissue is elevated off the bone of the maxilla using a broad periosteal elevator (Fig. 104.5). In the correct plane, this is easily performed and, using a sponge, can be gently swept superiorly over the anterior wall of the sinus.
- The canine fossa is a slight indentation just lateral to the tooth root, which is usually very prominent.
- Elevate the soft tissue superiorly enough to expose an area of approximately 2 × 2 cm^2 of the anterior wall of the maxilla. Be careful to avoid the terminal branches of the infraorbital nerve as it exits the canal, in the midline, just below the inferior orbital rim (Fig. 104.6).
- Using a small mallet and osteotome, create an opening over the canine fossa into the sinus (Fig. 104.7). Use a rongeur to remove the bone edges, further enlarging the opening and providing a good view into the sinus cavity.

FIG. 104.4 Incision is made in the buccogingival sulcus.

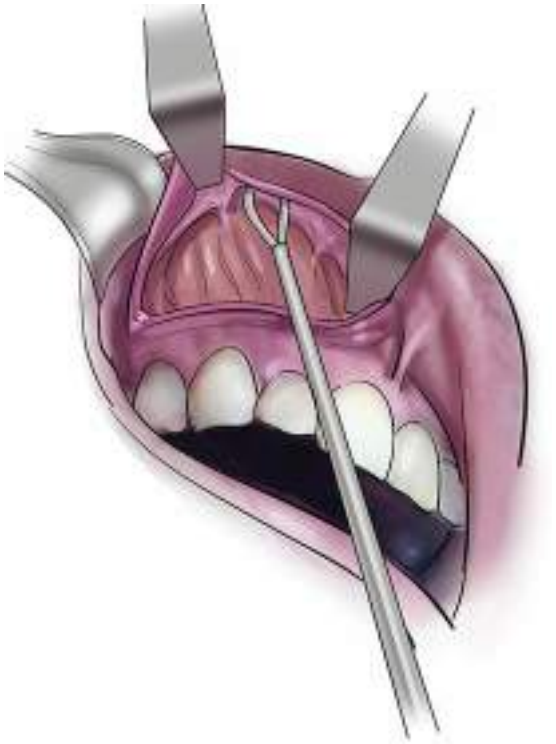

FIG. 104.5 Exposure of the canine fossa with elevation and blunt dissection of the overlying soft tissue.

- Depending on the indications for the procedure, the mucosa may be spared or removed in situations such as an antrochoanal polyp or severe chronic sinus disease (e.g., fungal sinusitis). When dealing with an antrochoanal polyp, the mucosa of the antrum is elevated and bluntly dissected toward the natural ostium, to facilitate its removal intact with the polypoid component, which is then grasped in the posterior choana through the nasopharynx. Using gentle traction, it is removed with the antral mucosa intact. Maximum hemostasis must be obtained using the needle-tip Bovie.

FIG. 104.6 The infraorbital nerve is identified and preserved at the point where it exits the infraorbital foramen.

FIG. 104.7 The sinus is carefully opened with an osteotome and widened with a Kerrison rongeur.

- If the Caldwell-Luc procedure is used to access the floor of the orbit, excellent visualization is obtained superiorly.
- If the posterior wall needs to be breached to gain access to the pterygopalatine fossa, this can be easily done with gentle fracturing of the bone, using a mallet and osteotome.
- Once incised, the periosteum behind this thin bone provides direct access to the contents of the pterygopalatine fossa.
- Creating an antrostomy is part of the original description of the procedure but may not be required in certain situations.

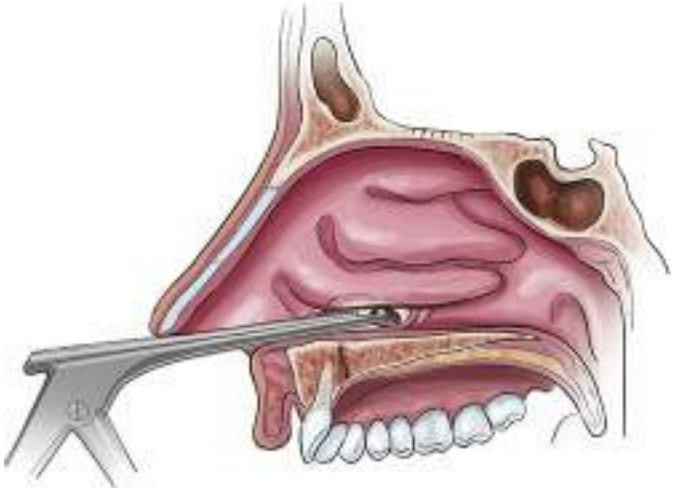

FIG. 104.8 The inferior meatal antrostomy is created inferior to the inferior turbinate after gentle medial mobilization of the turbinate.

- With visualization through the nose, the inferior turbinate is outfractured, gaining access to the inferior meatus. A small window of mucosa is incised with a needle-tip Bovie and reflected inferiorly with exposure of the underlying bone (medial wall of the sinus; Fig. 104.8).
- The sinus can be entered using a curved hemostat or elevator, with gentle pressure on the bone at the most superior point under the attachment of the inferior turbinate. Stay slightly more superior, where the bone is thinner, approximately 1 to 2 cm behind the anterior aspect of the inferior turbinate.
- This window can be widened with a Takahashi forceps or a curved

rasp creating a wide 2 × 1 cm^2 window with direct communication with the sinus. The inferior rim should be lowered as much as possible to facilitate gravitational drainage. An olive-tip curved suction can be introduced through the opening into the maxillary sinus.

- Depending on the indications for surgery, the sinus may need to be packed with ribbon gauze impregnated with Bacitracin. This is led out through the antrostomy into the nose. Make sure that the edges of the antrostomy are smooth and the packing is layered in the sinus cavity to avoid any difficulty with removal of the pack.
- If packing is required, another option is to place a Foley catheter through the nose and antrostomy site, into the sinus, and gently inflate the balloon with saline. This is very effective in tamponading any bleeding from the sinus cavity.
- The sublabial incision is closed with interrupted 3-0 Vicryl sutures.
- The packing or Foley catheter is removed 1 to 2 days postoperatively.
- Minor edema of the cheek will be noted postoperatively, which resolves in 4 to 5 days.

Common Errors in Technique

- Incorrect placement of the sublabial incision. Maintain 0.5 cm of mucosa to facilitate closure.
- Incorrect entry into the maxillary sinus. Stay lateral to the canine tooth root, entering into the soft bone forming the canine fossa.
- Avoid injury to the tooth roots by identifying landmarks and avoiding excessive removal of bone from the anterior wall.
- Avoid excessive elevation of soft tissue superiorly so that the infraorbital nerve is not injured, thereby avoiding associated numbness.
- Ensure adequate hemostasis using electrocautery and use packing to avoid bleeding.
- Inadequate intranasal antrostomy without smooth edges and prominent ledge hinders drainage and pack removal.

Postoperative Period

Postoperative Management

- Patients generally have moderate pain, and in the past they were kept overnight for observation.
- In the current health care environment, outpatient surgery is appropriate.
- Facial edema is treated with cold packs to the cheek.
- Liquid and a soft diet should be advised while the sublabial incision heals.
- If packing was inserted, it can be removed on the second or third postoperative day. This may be fairly uncomfortable for the patient, and care should be taken to avoid "catching" on bony fragments. If a Foley catheter is used, the balloon can be deflated and observed for any bleeding before removal.
- When the mucosa is removed, all bleeding points in the bone should be cauterized to prevent postoperative bleeding.
- The sublabial sutures usually dissolve in 7 to 10 days, but not infrequently a few remaining sutures may need to be removed.
- Avoid nose blowing for at least a week.
- Upper dentures should be replaced as soon as possible to avoid obliteration of the buccogingival sulcus.

Complications

- Bleeding: While this is usually controlled by initial packing, there is often fairly brisk bleeding after the pack is removed. This will usually stop spontaneously, but occasionally direct intervention with cautery and packing may need to be performed. Using a Foley catheter initially is very helpful in this situation, as the balloon can be deflated and the patient observed for any bleeding before removal of the catheter.
- Injury to tooth apices and their innervation: The teeth apices and their

innervation can be damaged, which can affect dental sensation and, rarely, devitalization and discoloration of the teeth.

- Numbness of the canine and premolar teeth: Some patients may experience numbness of their canine and premolar teeth due to injury to the superior alveolar nerve as it passes the inferior aspect of the anterior wall of the maxilla.
- Numbness and injury of the infraorbital nerve: This is typically secondary to dissection and traction of the infraorbital nerve during the initial exposure or rarely with direct injury to the nerve within the roof of the maxillary sinus.
- Orbital injury
- Damage to the nasolacrimal duct
- Oroantral fistula: Oroantral fistula, while rare, can occasionally occur and may require surgical intervention. Osteomyelitis of the maxillary bone is more of a historical complication and not something normally seen.
- Ill-fitting dentures can be avoided by correct placement of the incision.

Alternative Management Plan

1. Endoscopic technique if surgically feasible

Discussion

Evidence-Based Medicine Question

In the era of FESS, what are the common indications and uses for an external approach to the maxillary sinus?

- Since endoscopic sinus surgery was introduced, the indications for an external approach to the maxillary sinus have dramatically changed.[3]
- Most sinus procedures are safely and effectively managed endoscopically with the advantage of excellent illumination and relatively little tissue damage. The principle of mucociliary flow

through the natural ostea in the middle meatus is well accepted.

- The indications for this approach include removal of foreign bodies, closure of oroantral fistula, biopsy of suspected antral masses and malignancy, removal of dental cysts, as part of a medial maxillectomy, access to the orbital floor, removal of antrochoanal polyps, elevation and stabilization of the orbital floor in blowout fractures, and as part of the approach to the pterygomaxillary fissure and sphenopalatine fossa.[4]
- There still may be a role for the Caldwell-Luc procedure in chronic sinusitis after failed endoscopic approaches.[5]

Editorial Comment

In the latter part of the 19th century, transatlantic communication was slow, unlike today when a call to Europe is made in seconds using a smart phone. Dr. George Caldwell, an otolaryngologist in New York City, reported a new operation in 1896 that he called a maxillary antrostomy, which he used in the management of chronic maxillary sinusitis—a common problem in the preantibiotic era. Dr. Henri Luc, an otolaryngologist in Paris, reported a similar but not identical operation in 1897. When the news of these two similar operations eventually crossed the Atlantic, the names of the two surgeons were kindly applied to the operation, which became known as the Caldwell-Luc operation (procedure).

While the operation was originally designed to eliminate chronic maxillary sinusitis, it has been adapted by a series of imaginative surgeons to provide an entrance to the maxillary antrum to solve a variety of other problems. This remarkably versatile approach can be used to remove antrochoanal polyps intact, to reduce "blowout" fractures of the floor of the orbit, to retrieve foreign bodies, to close oroantral fistulae, to remove the floor of the orbit for decompression of thyroid exophthalmus, to remove mucoceles or small tumors, and to provide access for medial and total maxillectomy. The maxillary antrostomy also provides a corridor to the ethmoid to perform a transantral ethmoidectomy and to the pterygoid fossa for *sectioning* the Vidian nerve, for ligation of the internal maxillary artery and its branches, and for exposure of the skull base.

In the days before technology brought improvements in our management of certain problems—such as the introduction of the CT scan, the instruments for carrying out and monitoring FESS, interventional radiology with embolization in the treatment of epistaxis and juvenile angiofibroma of the nasopharynx (JNA)—the Caldwell-Luc operation provided a means of managing these problems. I used this approach to remove the posterior wall of the antrum and to ligate branches of the internal maxillary artery in the management of epistaxis. I also used this technique as a means of devascularizing the JNA as the first step in removing them. Fortunately, the interventional radiologists were able to make this step unnecessary by preoperative intra-arterial embolization.

The Caldwell-Luc procedure is still alive and well in parts of the world where modern technology is not available. The operation is also used in situations where the endoscopic approach has not yet solved the particular problem. Unfortunately, many otolaryngologists trained in the modern era have little or no experience with this operation, which should be part of the required curriculum in residency training programs.

Eugene N. Myers

Access the review questions online at http://www.expertconsult.com

Review Questions

1. The correct site to enter the maxillary sinus is

   a. Medial to the canine root

   b. Above the canine root

   c. **The canine fossa**

   d. Just below the orbital rim

2. Potential complications of the Caldwell-Luc procedure include all of the following, except

   a. Numbness of the cheek

   b. Injury to the nasolacrimal duct with tearing

   c. Blindness

   d. **Anosmia**

3. Correct statements regarding the inferior meatal antrostomy include all of the following, except

   a. **Placement 3 cm behind the anterior aspect of the inferior turbinate** (correct answer 1 to 2 cm behind the anterior aspect of the inferior turbinate)

   b. Below the inferior turbinate

   c. The inferior edge of the antrostomy should be as low as possible.

   d. The edges of the antrostomy should be as smooth as possible.

Oroantral Fistulas

Michael D. Chambers, and William Chung

Introduction

An oroantral communication occurs when there is an abnormal connection between the maxillary sinus and the oral cavity. The communication may be the result of trauma, osteomyelitis, pathologic lesions, or foreign bodies such as dental implants or endodontic material. However, the most common cause of an oroantral communication is the extraction of a posterior maxillary tooth. The root apices are in close proximity to the floor of the maxillary sinus and, in some cases, are only separated by a thin layer of lamellar bone or sinus mucosa. The teeth most commonly involved in communication are the maxillary molars.[1-3] If left untreated, this communication can result in unsuccessful healing of the Schneiderian membrane and progress to an epithelial-lined tract known as an *oroantral fistula,* which will not heal spontaneously.

Closure of the fistula is dependent on the size of the bony defect. Healing may occur spontaneously if the defect is less than 5 mm in diameter.[4] However, primary soft tissue closure at the time of the extraction and the use of a collagen plug stabilized with a figure-of-eight suture can promote clot formation and spontaneous healing of the defect. For defects greater than 5 mm, closure using various intraoral flaps in conjunction with functional endoscopic sinus surgery increases the chance for long-term success.

Key Operative Learning Points

1. Extraction of a posterior maxillary molar tooth is the most common cause of an oroantral fistula.

2. Long-term success in healing requires débridement of necrotic bone,

soft tissue, and the fistulous tract.

3. Crossing the buccal vestibule with a flap can obliterate the sulcus and interfere with denture use.

4. Fabrication of an acrylic splint can protect the flap and palate.

Preoperative Period

History

1. History of present illness
    a. Presence of a communication or fistula can be confirmed by asking the patient if regurgitation of fluid from the nose occurs after drinking liquids.
    b. Fetid odor/drainage due to oroantral communication
    c. Chronic pain from the defect
2. Past medical history
    a. History of chronic sinusitis
3. Past surgical history
    a. Previous attempts at closure of the oroantral fistula
4. Medications
    a. Antibiotics
    b. Antiplatelet agents
    c. Anticoagulant therapy
    d. Immune suppression
    e. Over-the-counter (OTC)/herbal medications
5. Allergies
6. Social history
    a. Alcohol use/abuse
    b. Cigarette smoking

c. Illicit drug use/abuse

Physical Examination

1. Oral and nasal examination may reveal erythema of the mucosa, intraoral or intranasal infection, oralantral fistula, or a compromised ostiomeatal complex (Fig. 105.5).

Imaging

1. Panorex (Fig. 105.1)
   a. First choice of radiograph, especially if the fistula occurred after dental extraction(s)
   b. Assess the size of the bony defect adjacent to the fistula.
   c. Assists in treatment planning and flap design, since there is no scatter from any existing maxillary dental restorations
2. Computed tomography (CT) scan (maxillofacial or sinuses; Fig. 105.2)

FIG. 105.1 Panorex radiograph depicts gutta percha point within oroantral bony defect associated with extraction site tooth #3 *(arrow)*. Radiograph courtesy Dr. Richard Bauer, University of Pittsburgh School of Dental Medicine.

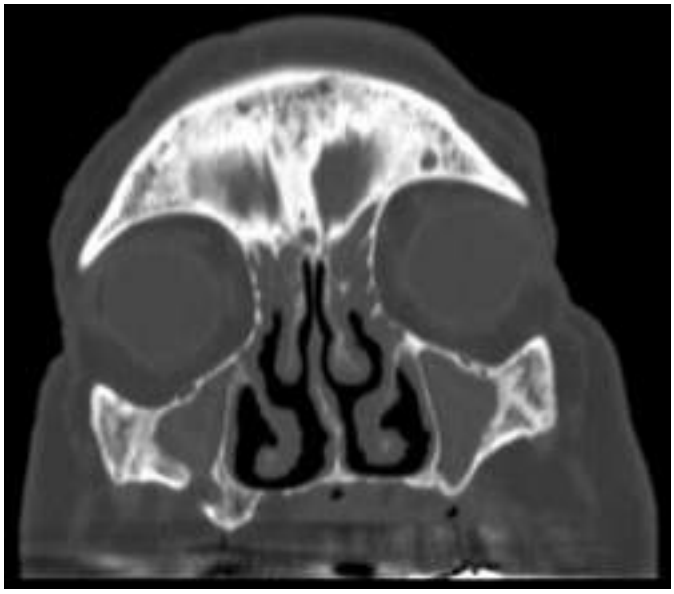

FIG. 105.2 Coronal computed tomography scan of patient from Fig. 105.1. Bony defect in right maxilla forms a communication between the maxillary sinus and the oral cavity.

a. Not necessary as a first-line choice of imaging

b. Recommended with larger defects (>1 cm) or cases of chronic fistula from repeated failure of fistula closure

c. Assess for mucosal thickening, maxillary opacification, and obstruction of the ostiomeatal complex.

d. Intrasinus injections or oral rinse with water-soluble contrast may further enhance the imaging by providing the surgeon with a better understanding of the oroantral fistula's path between the oral cavity and antrum.[5]

Indications

1. Nasal regurgitation of liquids through fistula

2. Foul odor or chronic purulent drainage from the fistula

3. Air leakage through the fistula

4. Chronic pain in the fistulous site

Contraindications

1. Acute oral infection or acute maxillary sinusitis

2. Medically unstable for anesthesia or surgery (immune compromised, severely malnourished)

3. Multiple failures with no further tissue options available to close the defect (patient may require prosthesis/obturator to cover the defect)

4. Patient is unable to consent or declines surgical repair

Preoperative Preparation

1. Preoperative management with antibiotics, antihistamines, nasal decongestants, and irrigation of the fistulous tract to reduce the risk of failure

2. Discontinue antiplatelet or anticoagulant therapies, if possible.

3. After flap design has been chosen, diagnostic impressions with alginate can be used to fabricate a clasp-retained acrylic partial denture. The denture protects the surgical site from oral trauma, improves patient comfort, and maintains adequate depth of the buccal vestibule during the healing phase.

Operative Period

Anesthesia

1. Request nasotracheal intubation with the endotracheal tube in the side of the nose opposite the fistula to allow for concurrent functional endoscopic sinus surgery (FESS).

2. If the endotracheal tube cannot be passed as desired, then place an oral Ring, Adair, and Elwyn (RAE) tube in the side opposite the oroantral fistula.

3. Paralysis is not necessary, unless the oral opening is limited due to the patient clenching teeth.

Positioning

1. Patient is placed supine with mid- and lower face appropriately prepped and draped

2. Oral prep with chlorhexidine rinse or clindamycin-infused normal saline

Perioperative Antibiotic Prophylaxis

1. Appropriate intravenous antibiotics with sinus coverage desired:
   a. Unasyn
   b. Clindamycin, if allergic to penicillin
   c. Ciprofloxacin, if there is a history of antibiotic-associated colitis with clindamycin and penicillin allergy
   d. Moxifloxacin, if there is a history of antibiotic-associated colitis with clindamycin and penicillin allergy

Monitoring

1. Routine

Instruments and Equipment to Have Available

1. Appropriate surgical retractor(s) of surgeon's preference (Minnesota, Seldon, Obwegesser, Wieder)

2. Periosteal elevator (no. 9)

3. No. 15 and 11 blades

4. Molt or double-ended dental curettes

5. Rongeurs, preferably fine-tipped

6. Bone file

7. Sutures:

a. 4.0 Vicryl

b. 4.0 chromic gut

8. FESS surgery set

9. Nasal endoscopes

Key Anatomic Landmarks

1. The location and size of the defect, presence of adjacent teeth, topography of surrounding bone, and potential plans for dental restoration once the fistula is removed must all be considered when developing a surgical plan.

2. The buccal adipose tissue pad is a large lobulated mass:

   a. Consists of a central body and four processes, including the buccal, pterygoid, pterygopalatine, and temporal extensions

   b. Derives its blood supply from the buccal and deep temporal branches of the maxillary artery, the transverse branch of the superficial temporal artery, and several branches of the facial artery

Prerequisite Skills

1. Familiarity of the relationship of maxillary teeth with maxillary sinus

2. Previous experience with creating, mobilizing, and advancing flap(s) in a tension-free manner

3. Familiarity with the location of the buccal adipose tissue pad

Surgical Technique

- Combined *intraoral and endoscopic* approaches increase the chances of long-term success of fistula closure.
- *Intraoral therapy* involves removal of the epithelialized fistulous tract and surrounding necrotic bone, followed by soft tissue closure using one of a variety of surgical flaps (Fig. 105.3).

  Flap design: Surgical closure of the fistula from the oral cavity is

typically accomplished with traditional soft tissue flaps such as the Rehrmann buccal advancement flap[6] or a palatal rotation flap. While numerous treatment modalities have been described in the literature (Fig. 105.4), Visscher et al. have found that the buccal and palatal flaps remain the primary treatment of choice due to both cost and the simplified approach of closure.[7]

1. Buccal advancement flap technique

- Simple and safe procedure with low postoperative morbidity (Figs. 105.6 and 105.7)
- Ideal for smaller defects; enhanced by including the pedicled buccal adipose tissue pad
- Two divergent vertical incisions, which extend from the extraction site to the buccal vestibule, allow for a broad base to ensure an adequate blood supply.
- Upon elevation, an additional incision of the periosteum at the base of the flap is created to allow for maximal advancement to cover the defect with a tension-free closure.

2. Buccal adipose tissue pad technique

- Small vertical incision in the reflected periosteum posterior to the zygomatic buttress, allowing adequate exposure of the buccal adipose tissue pad and advancement over the bony defect.

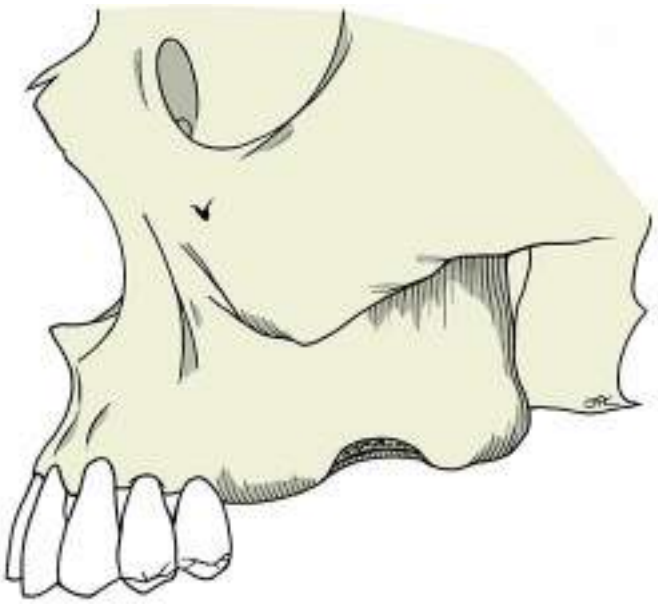

FIG. 105.3 The bone is recessed superiorly to ensure removal of all necrotic bone and epithelial elements of the fistulous tract. This, in turn, enhances primary closure of the fistula.

- The adipose tissue pad is secured to the palatal mucosa with absorbable sutures, followed by repositioning of the reflected oral mucosa.
- The mucosal flap does not need to be advanced over the adipose tissue pad covering the defect, preventing loss of vestibular depth.
- The rapid epithelialization of the uncovered adipose tissue with stratified squamous cells from adjacent soft tissue is a distinctive feature of the pedicled buccal adipose tissue pad flap.[8-10]

3. Palatal rotation (finger) flap

- Rotational, full-thickness mucoperiosteal palatal flap still widely used and ideal for larger defects (Figs. 105.8 and 105.9)
- The flap design should not include tissue from the median palatal raphe or be in close proximity to the gingival tissue, as this tissue is much thinner and friable.
- Once the flap has been mobilized, rotated into position, and secured, the exposed palatal bone will heal by secondary intention.
- Does not obliterate the buccal vestibule and uses keratinized tissue that is more resistant to trauma and dehiscence

4. Tongue flap

- Available when previously mentioned techniques have failed
- Endoscopic surgery includes removal of polypoid mucosa and any foreign bodies in the sinus, along with enlargement of the maxillary sinus ostium to ensure adequate sinus drainage.

Common Errors in Technique

1. Flap design insufficient in length

2. Flap closure under tension

3. Fistulous tract or residual necrotic tissue incompletely removed

4. Using buccal advancement flap for larger defects—more prone to dehiscence and recurrence of the oroantral fistula due to limited mobility and thin tissue

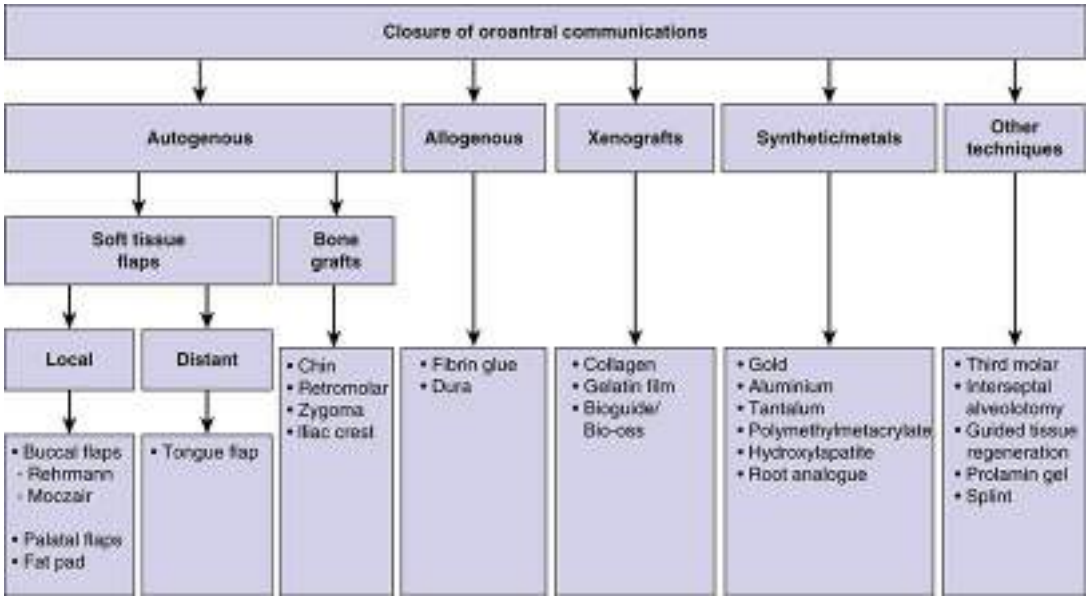

FIG. 105.4 Overview of the treatment modalities of oroantral communications. With permission from Visscher S, van Minnen B, Bos R. Closure of oroantral communications: a review of the literature. J Oral Maxillofac Surg 68:1384-1391, 2010.

FIG. 105.5 Clinical photo of the patient in Figs. 105.1 and 105.2. Purulent drainage from oroantral fistula noted in alveolar crest associated with tooth #3.

FIG. 105.6 Flap elevated, exposing bony defect associated with oroantral fistula.

5. The flap can also obliterate the depth of the buccal vestibule after advancement.

Postoperative Period

Postoperative Management

1. Oral antibiotics for *7 days*

   a. Augmentin

b. Clindamycin, if penicillin allergic

c. Avelox, if history of antibiotic-associated colitis to clindamycin and resistance to penicillins

d. Chlorhexidine (Peridex) oral rinses bid

2. Strict sinus precautions for *14 days*

a. No tobacco products

b. Avoid forcibly blowing of the nose or sneezing

c. No use of straws

3. Use of acrylic, clasp-retained postoperative splint, if fabricated, to protect the palatal tissues for *14 days*

4. Soft diet for *14 days*

5. Avoidance of wearing a pre-existing denture for *14 days,* since the denture may apply excess pressure on the surgical site

Complications

1. Hematoma

a. Drain to avoid pressure ischemia.

FIG. 105.7 Buccal advancement flap technique. Flap advanced over defect and closed with vicryl sutures.

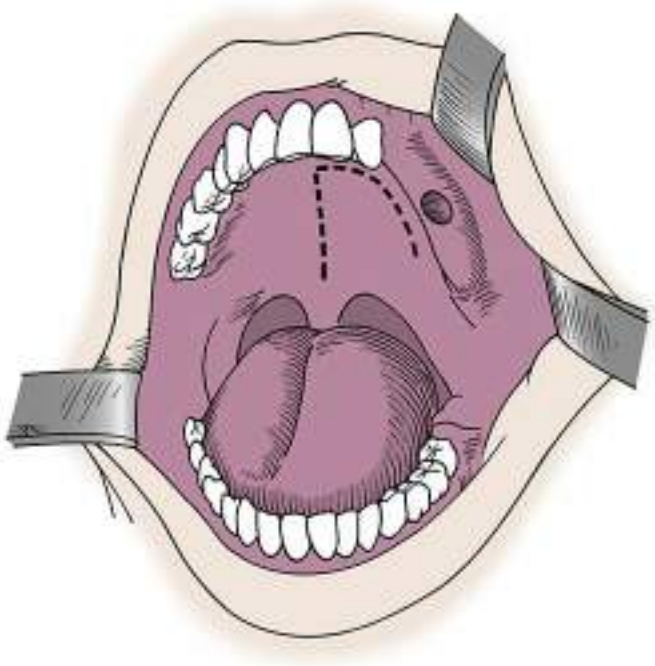

FIG. 105.8 Design of a posteriorly based palatal flap.

2. Dehiscence

   a. Gentle irrigation adjacent to opening with saline solution. If closure completely opens, plan for secondary closure with alternative flap design.

3. Infection

   a. Implement an appropriate antibiotic after incision and drainage, culture, and assessment of the sensitivity of purulence.

4. Obliteration of buccal vestibule/sulcus from flap

   a. Specific flap design can avoid/minimize this condition.

   b. Patient may require adjustment of existing denture or fabrication of new denture

Evidence-Based Medicine Question

Does concurrent FESS aid in the repair and successful closure of oroantral fistula?

Successful management of an oroantral fistula should address both the fistula and the chronic infectious process within the maxillary sinus (see

Fig. 105.9). The well-known Caldwell-Luc procedure, which was first described in the 1890s, includes a transoral approach via the canine fossa. While this operation is still used today, it is usually reserved for more complex cases or when FESS surgery is not available. As the physiologic drainage and anatomy of the maxillary sinus became clear, an intranasal approach to management of chronic sinusitis has become the standard of care through FESS. The use of endoscopic sinus surgery in the management of sinusitis caused by complications arising from oral surgical procedures is relatively new (Fig. 105.10).

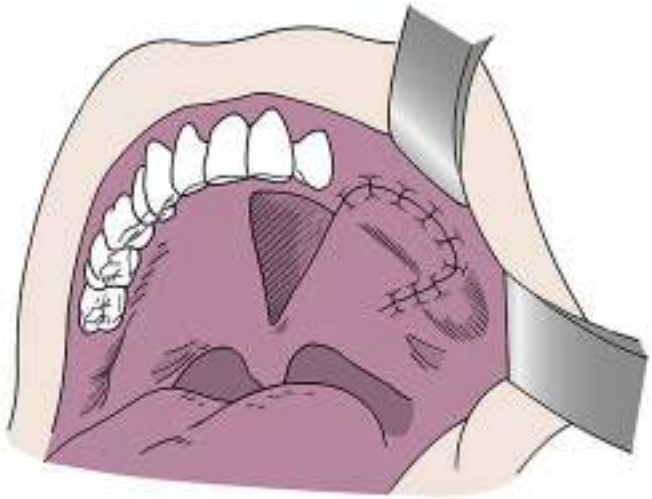

FIG. 105.9 Mobilization and rotation of the palatal flap to cover the fistula. The resulting mucosal defect in the palate is allowed to granulate and heal by secondary intention. An acrylic splint fabricated preoperatively can improve patient comfort over the palate, particularly during eating.

The FESS is a minimally invasive approach with relatively low morbidity and a high success rate, making it ideal for management of chronic sinusitis caused by an oroantral fistula.

The FESS involves dislocation of the middle turbinate toward the septum and a complete uncinectomy for visualization of the surgical field, followed by a maxillary antrostomy to reestablish drainage of the maxillary sinus. Additional evaluation of the anterior ethmoid cells is necessary to ensure removal of residual disease and to prevent recurrence. True inflammatory polyps and foreign bodies such as tooth

roots are subsequently removed from the maxillary sinus.

Editorial Comment

In larger oroantral fistula defects, vascularized tissue reconstruction is vital to long-term success. Similar to fistulas present in the upper aerodigestive tract and skull base, the use of vascularized reconstruction has increased the overall success rate of the procedure. This efficacy is balanced with donor site morbidity. In the case of a palatal rotational finger flap, the exposed hard palate will re-epithelialize quickly if the appropriate postoperative precautions are taken. The role of concurrent maxillary antrostomy is increasingly recognized in larger defects, as this allows for physiologic management of the sinus and prevents postoperative mucosal inflammation and secondary obstruction from hindering the repair.

Eric W. Wang

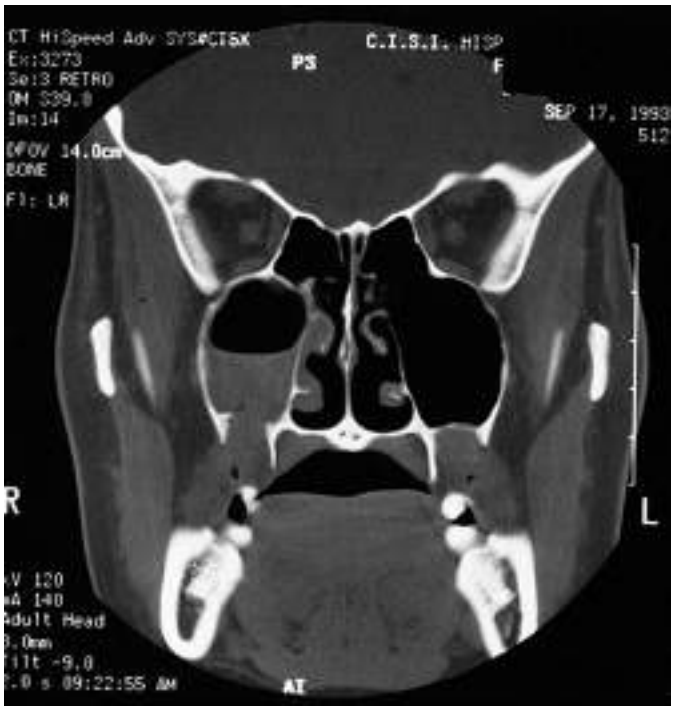

FIG. 105.10 Computed tomography scan demonstrating an oralantral fistula with obstruction of the maxillary sinus. Adequate intranasal drainage to either the middle meatus or the inferior meatus must be achieved to

ensure success when the fistula is closed.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Reasons for failure of oroantral fistula repair include each of the following, except

   a. Creation of a flap of insufficient length

   b. Incomplete removal of infected tissue or bone at the site of the defect

   c. A narrow flap base as a result of converging releasing incisions in the flap design

   d. **Scoring the periosteum to allow for advancement of the flap in a tension-free manner**

2. Each of the following postoperative instructions improves successful closure of the defect, **except**

   a. Avoidance of tobacco products

   b. Strict sinus precautions

   c. **Consumption of a regular diet**

   d. Use of an acrylic palatal splint

3. Each of the following can contribute to flap breakdown, **except**

   a. Not removing all epithelial remnants of the fistulous tract

   b. **Not reestablishing drainage of the sinus by widening the ostium in the middle meatus**

   c. Not removing all of the polypoid sinus tissue at the time of surgery

   d. Not removing all of the necrotic bone or mucosa adjacent to the fistula

4. Management of an oroantral fistula must take into consideration the degree of disease within the involved maxillary sinus. Concurrent FESS allows the surgeon which of the following advantages?

a. Removal of chronically inflamed sinus mucosa within the entire antrum

b. Exploration of the anterior ethmoid cells

c. Removal of any foreign bodies or tooth roots via an endoscopic approach

d. Create a new functional ostium to assist in drainage of the antrum

e. **All of the above**

Medial Maxillectomy

Ehab Hanna

Introduction

Medial maxillectomy is most commonly indicated for resection of tumors of the nasal cavity, lateral nasal wall, and medial maxillary sinus. The incision most commonly used for exposure is the lateral rhinotomy. This offers the best exposure for a medial maxillectomy and can be combined with a transcranial approach for an anterior craniofacial resection commonly used for removal of advanced tumors of the anterior skull base. Alternatively, a midfacial degloving procedure may be used. The midfacial degloving approach is most commonly used in the management of large benign lesions of the sinonasal region and skull base such as juvenile nasopharyngeal angiofibroma, for selected malignancy in this area, and to afford access to the nasopharynx and infratemporal fossa. The main advantage of the "degloving" approach is that an external facial incision is avoided. Another advantage is providing simultaneous exposure to the inferior and medial maxilla, bilaterally. This is particularly helpful when approaching tumors with bilateral involvement of the nasal cavity and maxillary sinus. A major disadvantage, however, is the limited superior and posterior exposure and the need for constant retraction of the soft tissue envelope for continued adequate exposure. Endonasal endoscopic medial maxillectomy and sphenoethmoidectomy may be also performed and provide excellent visualization for appropriately selected tumors. Regardless of the approach, medial maxillectomy includes removal of the lateral nasal wall and the medial aspect of the maxillary bone bounded laterally by the infraorbital nerve. In addition, a complete sphenoethmoidectomy is usually performed.

Key Operative Learning Points

- The lateral rhinotomy offers the best exposure for a medial maxillectomy.[1]
- The midfacial degloving is most suited for bilateral or midline lesions but provides limited superior and posterior exposure.
- The endoscopic approach may be used in selected cases, offers excellent visualization, and avoids a facial incision.[2]

Preoperative Period

History

- Small intranasal tumors are often completely asymptomatic or mimic more common benign conditions such as chronic sinusitis, allergy, or nasal polyposis.
- Common symptoms include nasal obstruction, "sinus pressure" or pain, nasal discharge that may be bloody, epistaxis, or anosmia.
- Failure of these symptoms to respond to adequate medical therapy or the presence of unilateral signs and symptoms should alert the physician to the possibility of malignancy and warrants further investigation by high-resolution imaging.
- Orbital symptoms such as tearing, double vision, or proptosis are a concern for malignancy with extension to the orbit.

Physical Examination

- Comprehensive examination of the nasal cavity should be done after topical decongestion and anesthesia using rigid or flexible endoscopy (Fig. 106.1). The presence of intranasal masses, ulcers, or areas of contact bleeding may suggest a malignant tumor. Although unilateral "polyps" may be inflammatory, they are more commonly neoplastic.
- Tumors may also present as a submucosal mass without changes in the mucosa.

- Any suspicious lesions should be biopsied, preferably after high-resolution imaging has been obtained, to avoid severe bleeding from highly vascular tumors and/or cerebrospinal fluid (CSF) leak in cases of intracranial extension.
- Extension of sinonasal tumors to adjacent structures renders the diagnosis obvious but is a late manifestation of the disease. Soft tissue swelling of the face may indicate tumor extension through the anterior bony confines of the nose and sinuses. Inferior extension toward the oral cavity may present with an ulcer or a submucosal mass in the palate or the alveolar ridge. Middle ear effusion may indicate tumor involvement of the nasopharynx, Eustachian tube, or tensor veli palatini muscle. Extension of the tumor to the skull base may lead to involvement of the cranial nerves producing anosmia, blurred vision, diplopia, or hypothesia along the branches of the trigeminal nerves.
- Orbital involvement is common in patients with cancer arising from the ethmoid, maxillary sinuses, or the nasal cavity. Epiphora usually indicates involvement of the nasolacrimal duct. Diplopia may result from compression or infiltration of ocular nerves or muscles. Proptosis may be the result of displacement or invasion of the globe. Visual loss secondary to optic nerve involvement is usually a late sign, although more subtle signs of optic nerve dysfunction, including afferent pupillary defect, loss of color vision, and visual field defects, are more frequently encountered. Finally, orbital involvement may be asymptomatic and is only discovered on computed tomography (CT) or magnetic resonance imaging (MRI) evaluation of patients with sinonasal complaints.

FIG. 106.1 Endoscopic view of a tumor arising from the floor of the right nasal cavity. Biopsy revealed squamous cell carcinoma.

- The presence of a mass in the neck usually represents metastatic cancer to the cervical lymph nodes.

Imaging

- Imaging is very helpful in obtaining pretreatment information regarding the location, size, and extent of the primary tumor, as well as the presence of regional and distant metastasis. Such information is critical in deciding on therapeutic options and for proper preoperative planning of the optimal surgical approach.
- Both CT and MRI might be needed for optimum radiologic assessment of sinonasal malignancy, particularly in assessing the cranial base, orbit and pterygopalatine, and infratemporal fossae. Coronal images best delineate involvement of the orbital walls and invasion of the skull base, particularly the cribriform plate. Axial images are particularly helpful in demonstrating tumor extension through the posterior wall of the maxillary sinus into the pterygopalatine fossa and infratemporal fossae. Sagittal images are particularly helpful in evaluating extension along the cribriform plate, planum sphenoidale, and clivus.
- The main advantage of CT scans is in delineating the architecture of the bones, especially in "bone windows." The addition of contrast

enhancement increases tumor definition from adjacent soft tissue, especially intracranially. Bone destruction and invasion of soft tissue suggest an aggressive lesion, usually a malignant neoplasm. Widening or sclerosis of the foramina of the infraorbital, Vidian, mandibular, or maxillary nerves may indicate perineural spread.

- MRI with its superior soft tissue contrast and multiplanar capability is superior to CT in pretreatment evaluation of primary malignant tumors of the sinonasal cavity.[3] MRI is unsurpassed in delineating soft tissue detail, both intra- and extracranially. Obliteration of adipose tissue planes in the pterygopalatine fossa, infratemporal fossa, and nasopharynx usually indicates tumor transgression along these boundaries. Dural thickening or enhancement is usually an indication of tumor involvement, and evaluation of critical structures such as the brain and carotid artery is best delineated by MRI. Similarly, enhancement or thickening of cranial nerves suggests perineural spread, which is better detected on MRI than CT.[4] Perhaps one of the most significant advantages of MRI is the ability to distinguish tumor from retained secretions secondary to obstruction of sinus drainage (Fig. 106.2).
- *Angiography* is not indicated in the routine assessment of patients with neoplasms of the nose and paranasal sinuses. In certain selected cases, however, angiography may be necessary. These cases include vascular neoplasms of the sinonasal region such as juvenile angiofibroma, where angiography will not only delineate the tumor extent and the blood supply but also permit the use of selective embolization of the vascular supply to the tumor. This reduces intraoperative blood loss, facilitating surgical resection.

Indications

1. Medial maxillectomy is indicated for resection of tumors of the lateral nasal wall, nasal cavity, nasal septum, or the medial wall of the maxillary sinus.[1]

2. Medial maxillectomy may also be used for exposure of and access to the pterygopalatine fossa, pterygoid plates, nasopharynx, sphenoid sinus, clivus, and the medial infratemporal fossa.[5]

3. Medial maxillectomy can be combined with resection of the floor of the nose, palate, or upper gingiva (inferior maxillectomy).

4. Medial maxillectomy may also be combined with a transcranial approach for resection of the anterior skull base.

Contraindications

Medial maxillectomy is not adequate if the tumor extends laterally to the infraorbital nerve, palate, or facial soft tissue.

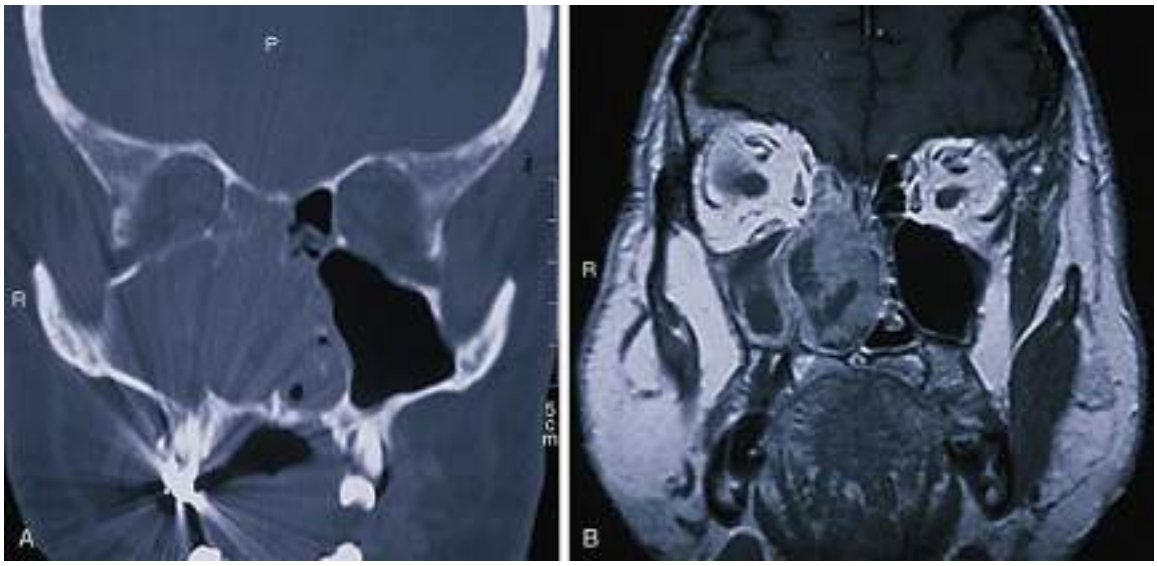

FIG. 106.2 **A**, Coronal computed tomography scan demonstrating opacification of the right nasal cavity, the maxillary and ethmoid sinuses. There appears to be destruction of the lateral nasal wall and the nasal septum. The lesion is abutting the orbital floor and the cribriform plate, but it is unclear whether or not these structures are involved. **B,** Coronal T1-weighted magnetic resonance imaging with gadolinium of the same patient revealing that the lesion is limited to the nasal cavity and ethmoid sinuses and that the changes in the maxillary sinuses are due to retained secretions secondary to obstruction of the ostium, rather than soft tissue involvement. It also demonstrates that the lesion does not invade the orbit or the cranial base.

Preoperative Preparation

- A thorough preoperative assessment should determine the candidacy of a patient for surgical management of his or her neoplasm. This involves a careful "mapping" of the tumor extent, as well as the patient's general medical condition and functional status.
- This is usually accomplished by a detailed history and a comprehensive examination of the head and neck region including sinonasal endoscopy.
- Examination of the cranial nerves as well as ophthalmologic evaluation should be done to evaluate the cranial base and orbital extension, respectively.
- Evaluation by a maxillofacial prosthodontist is required in most patients to obtain preoperative dental impressions and to design surgical obturators or splints for maintenance of proper dental occlusion and oral rehabilitation.
- Consultations with medical and radiation oncology colleagues should be done to consider incorporation of chemotherapy or radiation in the treatment plan. Radiation and/or chemotherapy may be used preoperatively as induction (neoadjuvant) or postoperatively as adjuvant therapy. Such decisions are best discussed in the format of a multidisciplinary tumor board.
- If surgery is chosen as a treatment modality, the plan for the surgical approach, the extent of resection, and reconstructive options should then be formulated.
- Careful assessment of the patient's general medical condition should be carried out prior to surgery. Preoperative chest radiograph, blood counts, liver and renal function tests, blood sugar, electrolytes, coagulation studies, and an electrocardiogram (ECG) should be performed routinely. Appropriate consultations from internal medical colleagues should be obtained in order to optimize the patient's medical status before surgery and help in the postoperative management.
- Finally, the surgical team should discuss with the patient and the family the nature of the disease, the evaluation, and the indications,

risks, possible complications, sequelae, and any alternative plans of management. The expected postoperative course including length of stay in the hospital, feeding, rehabilitation, and the need for adjuvant therapy should be described. This ongoing communication should be maintained in a clear, honest, and sympathetic fashion throughout the course of the patient's care.

Operative Period

Anesthesia

1. General endotracheal anesthesia is needed to provide monitored, controlled, deep anesthesia needed for soft tissue dissection and bone removal during medial maxillectomy.

2. Orotracheal intubation with a reinforced endotracheal tube taped and secured to the contralateral oral commissure offers the best working area for a medial maxillectomy.

Positioning

1. Supine with a shoulder roll to extend the neck

2. The head of bed should be elevated about 30 degrees. This reduces blood loss and allows better visualization of the surgical field.

Perioperative Antibiotic Prophylaxis

Prophylactic antibiotics should be given approximately 30 minutes prior to making the incision and for 24 hours after surgery. Antibiotics should be broad spectrum covering the aerobic and anaerobic bacterial flora of the nasal and oral cavities. Intraoperative topical antibiotic irrigation of the surgical field greatly reduces postoperative infections.

Monitoring

Routine monitored anesthesia control is usually all that is needed.

Instruments and Equipment to Have Available

1. Soft tissue dissection set

2. Bone resection set including various size rongeurs and both cutting and diamond high-speed irrigating drills

3. Sinus instrument set including optional endoscopic set

Key Anatomic Landmarks

1. Infraorbital nerve

2. Nasolacrimal duct

3. Anterior and posterior ethmoid arteries

4. Cribriform plate

5. Fovea ethmoidalis

6. Opticocarotid recess in the sphenoid sinus

Prerequisite Skills

1. Meticulous soft tissue technique

2. Familiarity with bone resection including facial osteotomies and drilling techniques

3. Expert knowledge of sinonasal and skull base anatomy

Operative Risks

1. Inadvertent corneal injury. This should be avoided by performing a temporary tarsorrhaphy to protect the eye during the procedure. Alternatively, a corneal shield may be used.

2. Injury to the infraorbital nerve during soft tissue elevation and dissection or during bone drilling or osteotomies. Excessive retraction of the infraorbital nerve may cause temporary neuropraxia of the nerve

resulting in hypoesthesia of the cheek and/or the teeth.

3. Injury to the nasolacrimal duct leading to postoperative epiphora. If the nasolacrimal duct is sacrificed, a wide marsupialization of the lacrimal sac into the nasal cavity should be done.

4. Inadvertent skull base entry leading to CSF leak. The most common site of injury is the cribriform plate and the point of insertion of the middle turbinate. This can be avoided by studying the details of the patient's skull base anatomy on preoperative imaging. The middle turbinate insertion to the skull base should not be fractured or pulled by force but rather sharply incised with scissors or other cutting forceps.

5. Injury to the orbita due to inadvertent entry through the periorbita. Peri- or intraorbital hemorrhage may result from inadequate control of the anterior or posterior ethmoid arteries that should be coagulated using bipolar cautery or clipped prior to their division.

6. Injury to the optic nerve or carotid artery in the sphenoid sinus. Careful assessment of the anatomy of the sphenoid sinus, its septal insertions, and the opticocarotid recess should be noted on the preoperative imaging. Bony dehiscence of the carotid or optic canals should be noted. Sphenoid sinus septa frequently insert into the opticocarotid recess and should not be fractured.

FIG. 106.3 Lateral rhinotomy incision *(1,2,3)* and its extensions (*4* and *5*). A temporary tarsorrhaphy protects the ipsilateral globe. The basic lateral rhinotomy incision

is outlined by connecting three surface points. The first point *(1)* is marked halfway between the nasion *(A)* and the medial canthus *(B)*. The second point *(2)* is where the alar crease begins, and the third point *(3)* is at the base of the columella. The basic incision provides adequate exposure for a medial maxillectomy. The basic incision may be extended to include a lip splitting extension *(4)* or a "Lynch" type extension *(5)* if further exposure is necessary. The extended incision provides adequate exposure for a total maxillectomy.

Surgical Technique

1. Soft tissue approaches

   a. Lateral rhinotomy

   - The *lateral rhinotomy* is the standard incision for performing a medial maxillectomy (Fig. 106.3).
   - Elevation of the soft tissues of the cheek is done in a subperiosteal plane over the maxilla and around the inferior orbital nerve (Fig. 106.4A).[6]
   - The attachment of the medial canthal tendon to the nasal bone is released.
   - The periorbita is elevated over the medial orbital wall exposing the lacrimal crest, the lamina papyracea, and the frontoethmoidal suture. This suture serves as a landmark for the position of the floor of the anterior cranial fossa and, when followed posteriorly, leads to the anterior and posterior ethmoidal foramina.
   - The anterior and posterior ethmoidal arteries are cauterized with the bipolar electrocautery, clipped or ligated, and transected (see Fig. 106.4B).
   - The optic nerve is located 4 to 5 mm posterior to the posterior ethmoidal artery.
   - The orbital floor should be dissected as far laterally as the inferior orbital fissure.
   - The lacrimal sac is identified in its fossa between the anterior and

posterior lacrimal crests.

- If the lacrimal duct is transected, the lacrimal sac should be marsupialized into the nasal cavity to provide adequate drainage of the lacrimal system and to prevent stenosis and postoperative epiphora (see Fig. 106.4C).

b. Midfacial degloving

- The midfacial degloving approach requires a basic level of proficiency and understanding of closed rhinoplasty incisions.
- It involves a complete transfixion incision of the membranous septum.
- This is joined endonasally with a bilateral intercartilaginous incision, with soft tissue elevation over the nasal dorsum as far superior as the nasal root. A gingivobuccal incision extends bilaterally across the midline to both maxillary tuberosities laterally.
- The nasal skeleton is therefore "degloved" from overlying soft tissues as far laterally as the pyriform aperture.
- Subperiosteal dissection is continued cephalad over the anterior wall of both maxillae to the level of the inferior orbital rims.
- The dissection joins the nasal degloving using sharp dissection over the pyriform aperture attachments.

c. Osteotomies and resection

- *Osteotomies* are done as shown in Fig. 106.4D, and the anterior wall of the maxillary sinus above the level of tooth roots and medial to the infraorbital nerve is removed. Lateral to the infraorbital foramen, the anterior wall antrostomy may be enlarged to expose the zygomatic recess of the antrum. Resection of the lateral nasal wall begins with an inferior osteotomy along the floor of the nose below the attachment of the inferior turbinate, starting at the pyriform aperture, and carried posteriorly to the posterior maxillary wall.
- With the orbital contents retracted laterally and protected with a malleable brain retractor, the lamina papyracea is identified and, if necessary, resected.

- A complete sphenoethmoidectomy is done, staying below the level of the frontoethmoidal suture to avoid injury to the floor of the anterior cranial fossa.
- The superior attachment of the middle turbinate is then transected along the roof of the nose.
- Posteriorly, the lateral nasal wall osteotomies are connected with right-angled scissors behind the turbinates. The specimen is thus delivered and examined for adequacy of the margins using frozen section control.
- If the tumor involves the nasal septum, it should be included in the resection specimen by adding appropriate septal cuts to allow for tumor-free margins.

d. Closure

- Closure is begun by reattachment of the medial canthal tendon to the nasal bone in its anatomic position.
- Meticulous multilayered closure of the lateral rhinotomy is performed and usually results in excellent healing and acceptable postoperative appearance (see Fig. 106.4E).
- If a sublabial approach is done, the mucosal incisions are closed with absorbable suture.
- Adequate nonadherent nasal packing may be left in place for 1 to 2 days.

Common Errors in Technique

- Failure to properly drain the lacrimal sac after transecting the nasolacrimal duct
- Failure to properly reattach the medial canthal ligament
- Excessive traction on the infraorbital nerve leading to numbness of the cheek
- Failure to properly execute a complete sphenoethmoidectomy with adequate drainage and ventilation to avoid recurrent sinusitis

Postoperative Period

Postoperative Management

- Overnight recovery to observe for bleeding, CSF leak, or orbital complications
- Pain management

FIG. 106.4 Medial Maxillectomy. **A,** Elevation of the soft tissues of the cheek is done in a subperiosteal plane over the maxilla and around the inferior orbital nerve *(ION)*. The periorbita is elevated over the anterior lacrimal crest *(ACL)* to expose the lacrimal sac *(LS)*. **B,** Dissection of the medial periorbita over the lamina papyracea reveals the anterior ethmoid artery *(arrow)* at the level of the frontoethmoid suture line, which marks

the level of the anterior cranial floor. The artery is coagulated by bipolar electrocautery, clipped or ligated, then transected. **C,** After the lacrimal sac is transected, it is marsupialized into the surgical cavity as a dacryocystorhinostomy. Silicone stents are placed through the upper and lower canaliculi and brought into the nasal cavity to prevent postoperative epiphora. These stents are removed in about 3 to 6 months. **D,** Osteotomies: *(A)* vertically medial to the infraorbital foramen *(arrowhead)*, *(B)* horizontally above the level of tooth roots and into the pyriform aperture, and *(C)* obliquely along the nasomaxillary suture line. If the lateral nasal wall is to be resected, the lacrimal sac *(arrow)* is transected and marsupialized into the nasal cavity. **E,** Postoperative appearance of a patient who had lateral rhinotomy incision.

- Elevate the head of bed 30 degrees to reduce postoperative swelling and bleeding.
- Patient to avoid strenuous activity
- Broad-spectrum antibiotics for 24 hours
- Nasal pack (if placed) to be removed within 24 to 48 hours
- Liberal saline nasal irrigation to minimize postoperative crusting

Complications (See Section on Operative Risk for Prevention)

- Postoperative bleeding
- Cheek or dental numbness from injury to the infraorbital nerve
- Orbital complications may include
  - Corneal injury during the procedure
  - Epiphora due to nasolacrimal duct injury or stenosis
  - Telecanthus from failure to reattach the medial canthal tendon in its anatomic location if detached

- Orbital hematoma from the anterior or posterior ethmoidal arteries
- Extra-ocular muscle swelling or injury may cause postoperative diplopia.
- Optic nerve injury

- Skull base injury with CSF leak and risk of meningitis

Alternative Management Plan

Alternative management plan for patients who are not good surgical candidates will depend on the pathology. Benign and asymptomatic lesions may be observed for some time. Vascular lesions with repeated epistaxis may be managed with palliative embolization, coiling, or other endovascular interventional techniques. Malignant tumors can be managed with palliative radiation or chemotherapy.

Evidence-Based Medicine Question

Medial maxillectomy can be performed through an entirely endonasal endoscopic approach in well-selected cases with good outcomes: True or False

Answer: True

The lateral rhinotomy has been shown to be the gold standard for performing an adequate and safe resection of sinonasal tumors involving the nasal cavity, nasal septum, lateral nasal wall, and paranasal sinuses with significantly lower recurrence rates compared to other more limited approaches. (1) There has been an ongoing debate about the efficacy of endonasal endoscopic techniques in management of sinonasal tumors, particularly those that are malignant. Evidence suggests, however, that in carefully selected cases that predominantly involve the medial maxillary wall, the oncologic outcomes are equal to a similar procedure performed through a lateral rhinotomy (2).

Editorial Comment

Whether visualization is accomplished through a lateral rhinotomy or

endoscopically using an endonasal corridor, the principals of the procedure are the same. As clearly outlined in this well-written chapter, removal of the medial maxillary wall, inferior turbinate, and the lateral nasal wall in carefully selected patients is associated with excellent oncologic outcomes with modest aesthetic impact. Additionally, this approach can be combined with both endoscopic and open craniofacial approaches to achieve an oncologically sound resection.

Beyond its use in oncology, increasing the endoscopic medial maxillectomy is used in the treatment of benign tumors and inflammatory conditions. Classically described for inverted papilloma of the medial maxillary wall, an endoscopic medial maxillectomy can provide both access for the complete removal of the soft tissue component of this tumor as well as remove the bony attachment site. Based upon the success of this procedure for this pathology, it is now used in a variety of benign tumors of the maxillary sinus and access to the pterygopalatine and infratemporal fossa.

An endoscopic medial maxillectomy is also used in recalcitrant maxillary sinusitis, typically when there is a significant disruption of mucociliary clearance. Because of its superior location in relation to the remainder of the maxillary sinus, a middle meatal antrostomy is dependent upon mucociliary clearance to clear secretions and to be effective. In conditions such as cystic fibrosis and primary ciliary dyskinesia where cilia are ineffective, a standard middle meatal maxillary antrostomy has limited effectiveness. In contrast, an endoscopic medial maxillectomy minimizes pooling of secretions and inflammatory debris in the floor of the maxillary sinus, allowing for clearance by nasal saline irrigations. When used for inflammatory pathology, maintaining the anterior one-third of the inferior turbinate is advocated to prevent empty nose syndrome.

The medial maxillectomy is an increasingly versatile surgical intervention for a variety of pathology. Understanding the anatomy and surgical techniques of this procedure is critical for head and neck oncologic surgeons, rhinologists, and skull base surgeons.

Review Questions

1. Medial maxillectomy is indicated in resection of the following

   a. Tumors of the lateral nasal wall

   b. Tumors of the nasal septum

   c. Tumors of the medial maxillary sinus

   d. **All of the above**

2. Medial maxillectomy can be achieved through which of the following approaches?

   a. Lateral rhinotomy

   b. Facial degloving

   c. Endoscopic endonasal

   d. **All of the above**

Complete Maxillectomy

Adam Zanation

Introduction

Both benign and malignant tumors may originate within or around the maxillary sinus and hard palate. These tumors may arise from the epithelial surfaces of the oral cavity (hard palate or alveolar ridge) or the sinonasal mucosa (within the maxillary sinus or lateral nasal wall). Tumors that involve the maxillary sinus can also arise from adjacent structures such as the skin, orbit, lacrimal system, infratemporal fossa, ethmoid sinuses, and anterior skull base. Squamous cell carcinoma is the most common malignant histology encountered in the maxillary sinus.[1] The second most common malignant pathology is a variety of adenocarcinomas.[1]

The primary treatment paradigm for all tumors of the maxillary sinus involves surgical resection, once appropriate clinical evaluation and staging have been completed. The exceptions to this management plan are lymphomas or plasmacytomas, which are very radiosensitive tumors and do not require surgery. In addition, symptomatic or rapidly growing benign tumors may often need surgery but do not require obtaining wide margins or having radical resection as a surgical goal. Regarding surgical planning, complete removal of the tumor with negative margins is the goal, but one must also consider concurrent reconstructive planning. Reconstruction depends on the extent of the defect, but the mainstays of reconstructive techniques include palatal obturator or vascular tissue reconstruction. After primary surgery, malignant tumors of the maxillary sinus often undergo postoperative radiation or chemoradiation.

Key Operative Learning Points

1. Surgical goals depend on the tumor histology and tumor location.

2. Types of maxillectomy include:

   a. Infrastructure (mainly used in the treatment of tumors of the oral cavity that involve the maxillary sinus)

   b. Superstructure (mainly used to treat tumors of the anterior facial skin without palate involvement or rarely tumors from the lacrimal system/orbit)

   c. Medial (mainly used to treat tumors from the nasal cavity that come from or extend to the lateral nasal wall such as inverted papillomas)

   d. Complete (primarily used to treat tumors that originate within and fill the maxillary sinus). This chapter will focus on a complete maxillectomy with obturator placement.

   e. Complete with orbital exenteration

   f. Extended (complete that also includes significant adjacent structures such as facial skin, anterior skull base, and/or infratemporal fossa)

3. Accurate preoperative assessment of the extent of disease is important, and the complementary information provided by computed tomography (CT) and magnetic resonance imaging (MRI) should not be underestimated.

Preoperative Period

History

May present with primary symptoms including but not limited to nasal congestion, lesion of the palate or alveolar ridge, epistaxis, facial numbness, abnormal tearing diplopia, or loss of vision. Patients may present with nodal metastasis (<10% of time), although the metastasis rate for squamous cell carcinoma of the alveolar ridge and hard palate may be as high as 35%. Symptoms of advanced disease include trismus, airway compromise, complete loss of vision or ophthalmoplegia, and lower cranial nerve palsies.

Physical Examination

1. A complete examination of the head and neck must be carried out. Special attention should be paid to:

a. Examination of the oral cavity including the dentition, hard palate, buccal mucosa, and soft palate mobility. Loss of sensation of the palate is an important finding, since it would suggest either perineural spread into the palatine canals or involvement of the pterygopalatine fossa. Trismus is associated with invasion of the infratemporal fossa.

b. Cranial nerve examination: Special attention should be paid to cranial nerves III, IV, V, and VI, with a focus on testing extraocular motion and infraorbital nerve function.

c. Eye examination: Hyperglobus may represent lesion expansion and not necessarily invasion; however, severe extra ocular muscle restriction and loss of visual acuity are almost always due to direct intraconal invasion. Abnormal tearing can be due to invasion of the lacrimal system or invasion of the pterygopalatine fossa by disruption of Vidian nerve supply.

d. Examination of the neck: The rate of metastasis to the cervical lymph nodes is generally low for squamous cell carcinoma (10% to 35%) but can be present. Usually levels 1 or 2 and facial nodes are the levels most commonly involved.

e. Facial skin changes: Invasion through the anterior wall of the maxillary sinus represents advanced cancer and is important for postsurgical reconstructive considerations.

2. Nasal endoscopy is also warranted to examine the floor of the nose (nasal side of the hard palate) and the lateral nasal wall. Additionally, involvement of the ethmoid can be identified in the middle meatus. If there is a tumor present in the nasal cavity, endonasal biopsy may be warranted.

Imaging

Accurate preoperative assessment of the extent of disease is important, and the complementary information provided by CT and MRI should not be underestimated. This will drive the extent of any planned surgery and should be reviewed with the patient so he or she understands the extent

of the operation, as well as any functional consequences that should be expected, such as oral competency, eye involvement, potential for vision loss, or hypoglobus.

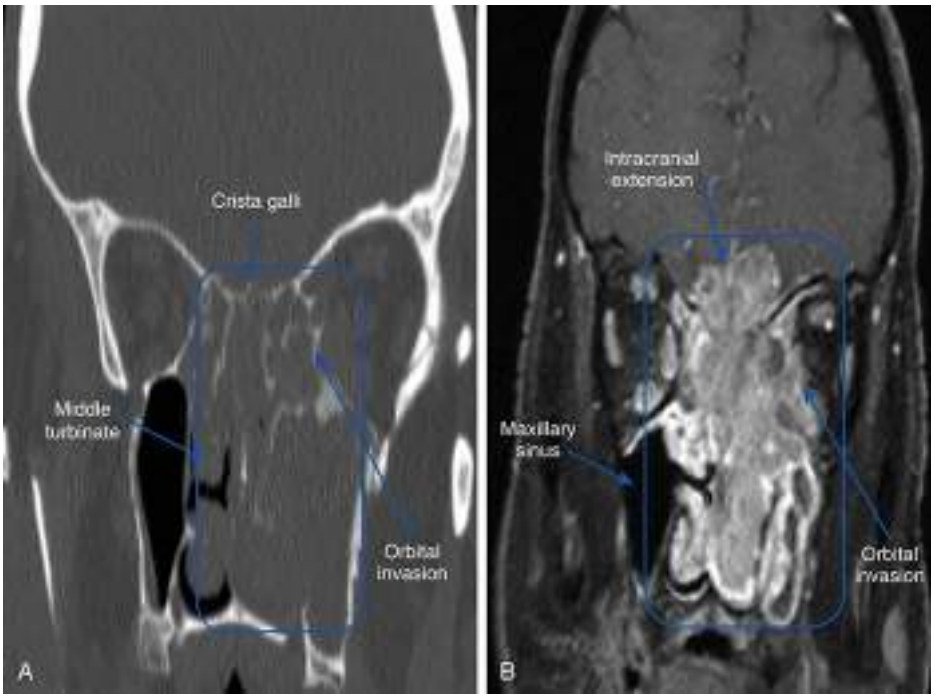

FIG. 107.1 Radiographic imaging of a maxillary sinus and skull base neoplasm.

A, Coronal computed tomography demonstrating bone destruction of the medial maxillary wall and ethmoid cavities. Note the limited information obtained on intraorbital or intracranial extent of disease. **B,** Coronal magnetic resonance imaging of the same patient, showing much better soft tissue differentiation, where the full extent of the spread of the cancer into the orbit and intracranial cavity can be appreciated.

1. CT (Fig. 107.1A): Defines the bony boundaries as well as bone invasion of the palate and posterior wall of the maxillary sinus or orbital floor

   a. Ohngren's line (Fig. 107.2): An imaginary line drawn from the medial canthus of the eye to the angle of the mandible. It divides the maxillary sinus into an anterior/inferior portion and a posterior/superior portion. This line helps give relative prognostic

value (with anterior/inferior being better) as well an idea of adjacent structures at risk for potential spread.

2. MRI (see Fig. 107.1): Delineates affected soft tissue and provides information on perineural spread, characteristic of some malignant neoplasms. This study provides the best information regarding the orbit, skull base, intracranial extension, and anterior facial skin.

3. Regional and distant staging: Usually completed with either contrasted CTs of the neck and chest or positron emission tomography (PET) CT.

4. Angiography: Rarely indicated—only needed when there is a presumed vascular malformation or if the tumor has invaded the carotid artery on the primary site imaging

Indications for Surgery

1. Malignant tumors

2. Benign tumors that are either symptomatic or growing

3. Symptom relief

Contraindications to Surgery

1. Patient factors: Inability to undergo general anesthesia or have major blood loss

2. Unresectable tumors (unless palliative surgery indicated)

3. Diffuse distant metastasis

4. Lymphomas, plasmacytomas, or other tumors that are highly radiation or chemotherapy sensitive

Preoperative Preparation

1. Full staging evaluation (see "Imaging" section)

2. Presentation to a multidisciplinary tumor board

3. Reconstructive considerations

a. Preoperative consultation with prosthodontist (obturator fitting)

b. Head and neck microvascular surgeon for consideration of reconstruction using a free flap

4. Full informed consent: In particular, a full discussion of risks and postoperative expectations should be had with the patient. Importantly, hypothetical, intraoperative possibilities need to be discussed with the patient and appropriately added to the informed consent including but not limited to: more involvement of the eye than what is seen in imaging, involvement of the anterior facial skin, or potentially positive lymph nodes when performing neck exposure for microvascular anastomosis requiring a neck dissection. If the patient's wishes in these situations are well documented and known prior to the operation, intraoperative decisions including more or less extensive surgical dissection can be made much more swiftly if such situations are encountered.

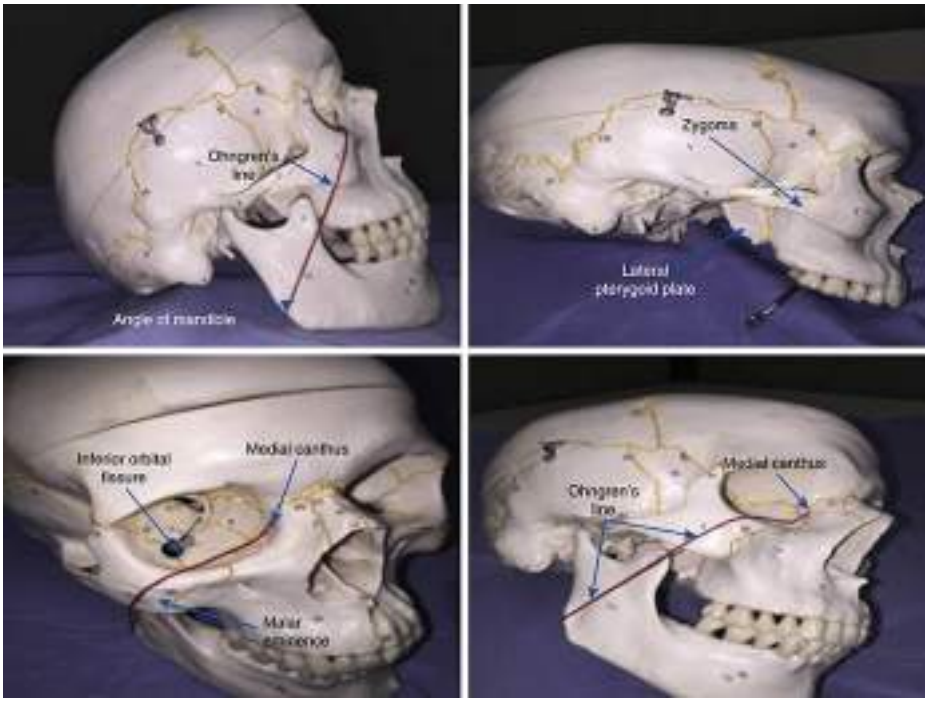

FIG. 107.2 Ohngren's line.

A line defined from the medial canthus of the eye to the angle of the mandible. It divides the maxillary sinus into an anterior/inferior portion (better prognosis) and a posterior/superior portion (worse prognosis).

5. Preoperative laboratory evaluation: Complete blood count (CBC), coagulation markers (PTT and PT/INR), complete metabolic panel (CMP). Although large volume blood loss is rare in these cases, all patients are typed and screened for this possibility.

6. Plan for airway management and, if complex, a preoperative discussion with the patient and the anesthesia team about options and an intraoperative action plan should an emergent situation arise. For most maxillary tumor surgery, the patient can be managed with an oral intubation and extubation. Exceptions to this rule may include patients with severe trismus, patients who require large pharyngeal or soft palate resections, and patients that will need free flap reconstructions of the palate defect. These patients may require an awake or elective tracheostomy for safe airway management.

7. Need for preoperative embolization is rare but would be necessary for vascular tumors such as arteriovenous malformations (AVMs) or juvenile nasopharyngeal angiofibromas (JNAs) that involve the maxillary sinus. The internal maxillary artery is the primary blood supply in this area; however, the inferolateral trunk of the carotid artery can also provide blood supply into the infratemporal fossa. Balloon test occlusion for carotid sacrifice is very rarely indicated, and there is virtually no role for carotid resection in the setting of high-grade epithelial malignancy.

Operative Period

Anesthesia

See the previous section on airway planning. General anesthesia is standard. Paralysis is generally acceptable unless a parotidectomy or neck dissection is needed with the maxillectomy, in which case it would be contraindicated. We try to maintain the patient with normal blood pressures, as there is no need for planned hypotension. We also try to be thoughtful about the fluid intake over the course of these operations, since they can be lengthy. If the operation is being done with an ET tube only, then the tube is taped to the side opposite the lesion.

Positioning and Intraoperative Setup

1. Either 180 degrees rotation (our preferred) or a little past 90 degrees to the side of the proposed maxillectomy. This removes the anesthesia team from the head and allows the surgical team to be on all sides of the head, allowing for better sight lines and retraction.

2. Tarsorrhapy sutures are generally placed to protect the eyes.

3. The neck is always prepped into the field in case proximal vessel control or neck dissection is needed. The thigh is prepped for taking a skin graft.

4. Sterile preparation of the surgical field is always done with betadine, since we are prepping around the eyes. Minimize exposure of betadine solution to the eyes, and at the end of the case, the eyes must be washed out with balanced salt solution.

5. Incisions are marked with the natural skin creases in mind, along with the planned needs for exposure.

6. Perioperative antibiotic prophylaxis: Standard first- or second-generation cephalosporin or penicillin-based antibiotics are given 30 minutes before the incision. They are continued for 24 hours after the operation. If the patient is allergic to penicillin, clindamycin is generally used.

7. Monitoring: Usual general anesthesia monitoring

Instruments and Equipment to Have Available

- Soft tissue and neck dissection set
- Small bone saws
- Side cutting pencil drill
- Bone chisels
- Dental extraction set
- Oral retractors
- Monopolar and bipolar cautery

- Endoscopic equipment: 0- and 30-degree Hopkins-rod nasal endoscopes and endoscopic tower should be available

Key Anatomic Landmarks

En bloc resection and achieving negative margins remain a steadfast principles in oncologic surgery and are often the key to the best patient outcomes. However, achieving this goal can be difficult within the orbit and along the periorbita, if the cancer has extended either intraconally or posteriorly into the infratemporal fossa. As outlined later in this chapter, a keen understanding and awareness of crucial landmarks in the maxillectomy approach allow for an easier dissection when working with advanced tumors.

Prerequisite Skills

Head and neck oncologic and/or skull base training

Operative Risks

Blood loss, inherent risk with general anesthesia, ocular risks (including possible vision loss or diploplia), facial numbness (other than in the V2 distribution that is often expected), and parapharyngeal carotid injury are risks but rare.

Surgical Technique

1. The facial incisions are carried down to bone with the assistance of electrocautery (if there is no anterior soft tissue invasion present).

Incision types include:

a. Sublabial incision only

b. Sublabial incision with partial or full degloving incision

c. Lateral rhinotomy incision. It is the preference of the senior author to make our nasal incision between the dorsal nasal subunit and the lateral nasal wall (Fig. 107.3).

d. Extended lateral rhinotomy incisions (see Fig. 107.3)

2. Fully expose the anterior bony surface of the midface, inferior and lateral orbit, and buccal space. Dissect out V2 and obtain neural margins.

3. Make an incision along the piriform aperture into the intranasal cavity, and retract the nose to the opposite side.

4. Make palatal incisions and obtain intraoral margins. If the soft palate is being salvaged, then dissect it free from the hard palate so there is full access into the nasopharynx. Control bleeding from palatine vessels with bipolar electrocautery.

5. Dissect the periorbita away from the orbital rim and from the orbital floor. Closely examine the orbital floor and periorbita to ensure that the cancer has not invaded into these structures.

6. Using a 1-mm side cutting pencil grip drill and copious irrigation, the anterior and periorbital osteotomies can be made. These osteotomies usually extend from the superior piriform aperture through the orbital rim for a complete maxillectomy. A metal retractor is used to protect the eye during dissection. At the same time as the globe is retracted superiorly, a thin, sharp osteotome is used to connect the medial and lateral orbital rim osteotomies extending posteriorly into the orbit freeing the floor of the orbit.

7. Using the same pencil drill, an osteotomy is made from the lateral orbit, through the rim, and extending across the malar process or occasionally through the zygomatic arch. This osteotomy extends posteriorly toward the pterygoid plates and all the way through the lateral buttress.

8. Using a thin reciprocating saw, the palatal osteotomy is made in a posterior to anterior direction and subsequently extended into the anterior nasal cavity.

9. At this point, the last bony attachment is at the pterygoid plates. The standard way to remove the plates is by using a curved osteotome placed behind the plates and angled up into the infratemporal fossa. This technique has two limitations, including lack of proximal control of the internal maxillary artery and inadvertent fracture at the level of the pterygopalatine fossa instead of behind the plates. Given these limitations, it is generally recommended that the osteotomy should be

made from the lateral position. In this approach, the mandible is initially retracted inferiorly and posteriorly. Using blunt dissection, the pterygoid plates and muscles can be identified, and often the internal maxillary artery can be palpated and directly controlled with a hemostat if necessary. The junction of the fused portion of the pterygoid plates can be palpated at the base of the middle cranial fossa. Using a sharp straight osteotome, this fused portion can be fractured from the underside of the sphenoid bone, and the entire maxilla can be rocked medially and inferiorly.

10. The infratemporal fossa is now exposed so that the internal maxillary artery can be fully controlled and the pterygoid muscles can be dissected from the bone with bipolar electrocautery, which allows for freeing of the entire maxilla and pterygoid plates from the infratemporal fossa. V3 can often be identified, and, if needed, neural margins can be taken from the skull base.

11. Using large curved scissors, the remainder of the medial maxillary wall is cut posteriorly from the medial orbital osteotomy, across the duct and inferiorly toward the torus tubarius, and the entire specimen is removed.

12. Intraoperative soft tissue margins are then sent for frozen section examination, and bleeding is subsequently controlled.

13. A medium-thickness split thickness skin graft is taken from the thigh, placed over the exposed buccal contents, and draped posteriorly into the infratemporal fossa defect.

14. Gauze packing is placed and the temporary obturator (Fig. 107.4) is placed and secured with wires and screws. The facial incisions are then closed in several layers, with care taken to reapproximate the orbicularis oris and oculi.

Common Errors in Technique

- Obtaining insufficient and superficial bony margins (which should extend at least 1 to 1.5 cm from involved tumor)
- Incomplete removal of the posterior wall and ptyergoid plates is a common error in dissection.

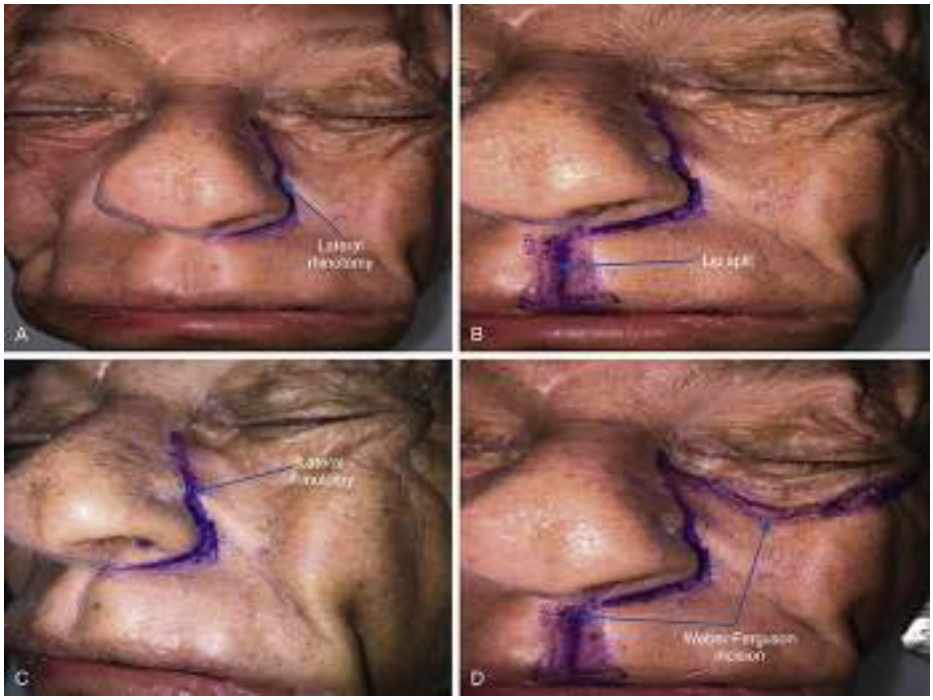

FIG. 107.3 Facial incisions for complete maxillectomy.

A and **C,** Lateral rhinotomy incision, **B,** lateral rhinotomy with lip split incision and **D,** modified Weber-Ferguson incision. Several modifications of the incisions can be made: **B** is a lip-splitting extension with dart, and the dart provides some potential benefits for lip notching. **A** and **C** are the senior authors' preferred lateral rhinotomy incisions, where instead of being in the nasolabial crease (purple marking), the incision is carried up onto the nose at the junction of the dorsum and the lateral nasal wall *(dashed blue line).* This has potential cosmetic benefits, in addition to placing the incision over the nasal bones, an area that will have less contact with the intranasal air containing spaces. **D** is the periocular extension (a Weber-Ferguson incision) that allows for lateral and orbital access. In the elderly, such as in this cadaveric specimen, the author makes this incision at the inferior orbital rim; however, in a younger patient, a subciliary or transconjunctival incision is preferred *(dashed blue line).*

- Underestimating the difficulty in dissecting and clearing tumor margins if the lesion has periorbital or ethmoid sinus invasion

- If microvascular free flap reconstruction with bony palatal repair is indicated, then the coronoid process is routinely removed to prevent bony fixation of the mandible to the repaired palate.

Postoperative Period

Postoperative Management

Fastidious wound and eye care, dietary restrictions including either a clear liquid diet or strict NPO with a nasogastric tube if a free flap used for reconstruction, and early ambulation toward normalization take precedence. DVT prophylaxis is routinely used during the postoperative hospital course, given increased risk for venous thromboembolism secondary to relative immobilization. Lastly, beginning trismus therapy early in the postoperative period is important, since the muscles of mastication can scar during the healing period.

Complications

1. Wound complications from facial incisions
2. Free flap failure
3. Corneal ulceration
4. Bleeding or hematoma formation
5. Vision loss and/or diplopia

This requires emergent ophthalmology consultation to evaluate for elevated pressures or optic neural loss. Full visual field testing with an evaluation of extraocular muscles is required. If orbital pressures are more than 30 and the patient has loss of visual acuity, an emergent canthotomy and cantholysis may be warranted. Additionally, imaging may be required to evaluate for a retrobulbar hematoma and plan for any needed decompressive operations.

Discussion

Evidence-Based Medicine Question

What effect do surgical margins have on outcomes following resection of sinonasal malignancy?

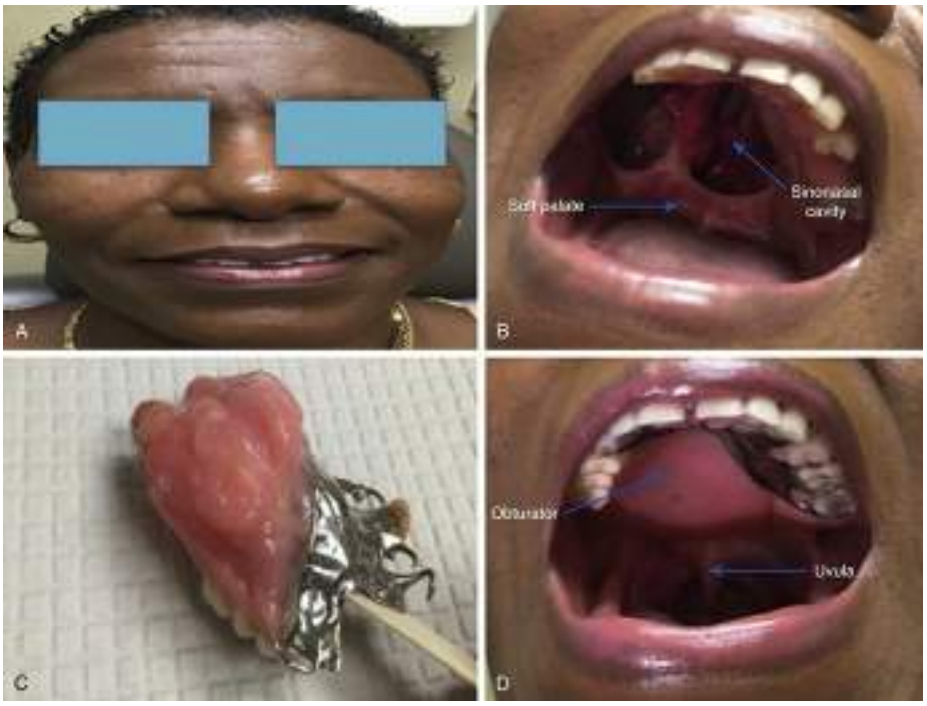

FIG. 107.4 Healed complete maxillectomy defect with obturator reconstruction.

A, Healed frontal view of a patient 5 years after a Weber-Ferguson incision and complete maxillectomy. Note the good alignment of the nose and lip and the dental rehabilitation that the final obturator gives. **B,** Intraoral view of complete maxillectomy defect with obturator removed. **C,** View of the actual obturator. **D,** Intraoral view of the same patient with the obturator in place.

One of the central principles of oncologic surgery is that tumor resection must be complete at both the microscopic and macroscopic level, which is generally achieved intraoperatively via obtaining frozen sections to confirm negative surgical margins. With regard to sinonasal and anterior skull base malignancies, obtaining surgical margins can be technically challenging and sometimes may not be feasible given the

proximity of critical neurovascular structures. Subsequently, it has been shown that in 30% and 24% of sinonasal neoplasms resected via open and endoscopic approaches, respectively, residual microscopic disease has been left due to the proximity to such structures as the internal carotid artery and optic nerve.[2] However, in these situations, it is important to understand the effect of surgical margins on prognosis and outcome following the resection of a sinonasal malignancy, including those requiring a maxillectomy approach.

Although the literature is generally consistent on the concept that leaving residual gross cancer during resection will result in local recurrence and increase overall mortality rate, findings regarding the role between positive microscopic margins and decreased survival rates historically remain fairly equivocal.[3,4] Recently, in a large, multiinstitutional retrospective review from the International Collaborative Study Group, it was found that the status of the surgical margins was a critical predictor for overall, recurrence-free, and disease-specific survival. Specifically, a statistically significant decrease in 5-year survival was observed in the studied population, when comparing patients with negative margins with those with positive surgical margins on histology. In another retrospective review from a single institution, Manjunath et al. showed that regional and distant recurrences were increased and disease-free survival was significantly decreased in patients with positive surgical margins compared with negative margins following resection of their sinonasal or anterior skull base malignancy.[5]

Conclusively, this central, oncologic tenet in head and neck surgery is crucial when approaching tumors requiring complete maxillectomy. Often requiring dissection of the face, sinonasal cavity, orbit, and anterior and middle cranial fossa, the complete maxillectomy is a technically challenging surgical approach, in which obtaining surgical margins can be equally difficult. Although we have delineated the significance of obtaining negative margins given its importance in patient outcomes, safe dissection and taking of circumferential margins in the complete maxillectomy approach may often not be feasible, given vital adjacent structures such as the optic nerve, globe, and internal carotid artery. Thus this element of the operation must be discussed at length with the patient, where the benefits and risks of obtaining surgical margins must be highlighted when discussing the procedure. With regard to the surgical technique in a complete maxillectomy, surgical margins must be

obtained in a three-dimensional space, which often involves taking margins from varying forms of tissue. Lastly, as surgical margins often dictate long-term outcomes for these patients, its importance cannot be understated.

Editorial Comment

Preoperative imaging using both CT and MRI is invaluable in evaluating the patient for a total maxillectomy. As outlined by the authors, achieving negative surgical margins is critical for oncologic control and can be challenging in this anatomic site. Additionally, the surgery often results in a significant change in the patient's function in regard to oral competence and the potential for hypoglobus if the orbit is preserved. Accurate preoperative assessment of the extent of disease is important, and the complementary information provided by CT and MRI should not be underestimated.

Review Questions

1. What is the most common malignancy encountered in the maxillary sinus?

   a. Adenocarcinoma

   b. Inverted papilloma

   c. **Squamous cell carcinoma**

   d. Esthesioneuroblastoma

e. Mucosal melanoma

2. Which artery represents the primary arterial supply to the posterior maxilla?

   a. Ethmoidal artery

   b. Facial artery

   c. **Internal maxillary artery**

   d. Internal carotid artery

   e. Occipital artery

3. What is Ohngren's line?

   a. An imaginary line drawn from the nasion to the angle of the mandible

   b. An imaginary line drawn from the lateral canthus of the eye to the angle of the mandible

   c. An imaginary line drawn from the medial canthus of the eye to the body of the mandible

   d. **An imaginary line drawn from the medial canthus of the eye to the angle of the mandible**

Endoscopic Ethmoidectomy

Garret Choby, and Stella E. Lee

Introduction

The decision to proceed with ethmoidectomy in the context of endoscopic sinus surgery (ESS) should be based on the patient's pathology, degree of symptoms, and response or lack of response to appropriate medical therapy. The goal is to eliminate chronic disease and restore function to the ethmoid sinuses and frequently to the frontal and maxillary sinuses, which can be secondarily infected or diseased because of obstruction in the anterior ethmoid air cells. Knowledge of the ethmoid sinus and its relationship to the orbit, skull base, anterior/posterior ethmoid arteries, and the frontal outflow tract is crucial to prevent complications. For patients with pansinusitis due to chronic rhinosinusitis (CRS), the endoscopic sinus surgeon should perform a complete ethmoidectomy by removing all ethmoid partitions in a mucosal sparing fashion. This allows for appropriate access for topical therapy and surveillance. A landmark-based approach is discussed in this chapter to perform endoscopic ethmoidectomy in a safe and effective manner.

Key Operative Learning Points

1. Removal of the ethmoid bulla allows for identification of the lamina papyracea (medial orbital wall), which should be clearly identified in order to prevent injury to the orbit.

2. The basal lamella should be traversed in an inferior-medial fashion with the goal of identifying the superior turbinate and the skull base.

3. The junction of the skull base, medial orbital wall, and the anterior face of the sphenoid is the superior/lateral "corner" from which the dissection

proceeds anteriorly along the skull base.

4. Careful study of the maxillofacial computed tomography (CT) scan should precede any surgical intervention. The key anatomic structures that should be identified include the following:

a. Ethmoid bulla and relationship to the medial orbital wall

b. The superior turbinate and relationship of the posterior ethmoid sinus to the skull base

c. Identification of the anterior and posterior ethmoid arteries

d. Height of the ethmoid sinus in relationship to the maxillary sinus to understand the slope and proximity of the skull base when performing ESS

e. Anatomic variations such as Onodi cells and suprabullar cells

Preoperative Period

History

1. History of present illness

a. Primary symptoms most bothersome to the patient

1) Identification of these symptoms allows for effective counseling of what surgery can and cannot achieve, thus framing patient expectations.

b. Duration of symptoms

c. Specific symptoms

1) Nasal obstruction

2) Hyposmia

3) Facial pressure/pain

4) Nasal discharge/postnasal drip

d. Previous attempts at treatment including systemic antibiotic and steroid therapies, topical therapies, and surgery

2. Past medical history

a. Prior management: Medical and surgical

b. Medical illness

1) Comorbidities

2) Allergies

3) Asthma/reactive airway disease

a) Patients with reactive airway disease or asthma frequently have concomitant sinonasal disease. Surgery should be postponed until asthma is under good control and consultation with a pulmonologist is completed.

4) Cystic fibrosis

a) Similarly, planning for ESS in cystic fibrosis patients should be completed in consultation with a qualified pulmonologist comfortable managing the pre- and postoperative care of these patients.

b) Perioperative antibiotics are usually necessary to prevent infectious complications in this patient group.

5) Aspirin/nonsteroidal anti-inflammatory drug (NSAID) sensitivity

c. Medications

1) Anticoagulants/aspirin/NSAIDs

2) Supplements that can increase the risk of bleeding

Physical Examination

1. Nasal endoscopy is completed in an office setting using a topical anesthetic and decongestant. Documentation should be made of any polyps, mucopurulent exudate, anatomic abnormalities including septal deviation, and any sinonasal masses. Use of 0-degree and 30-degree endoscopes can help fully visualize the sinonasal cavity. The classic endoscopic evaluation involves three "passes" of the endoscope.

a. The first pass is along the floor of the nose with special attention paid to the inferior turbinate, inferior meatus, nasolacrimal duct, and nasopharynx (fossa of Rosenmuller and eustachian tube orifice).

b. The second pass is toward the middle turbinate (MT), examining the middle meatus, ethmoid bulla, uncinate, lateral nasal wall, sphenoethmoidal recess, superior turbinate, and sphenoid os.

c. The third pass is made (often with a 30-degree endoscope) to visualize superiorly toward the olfactory cleft.

Imaging

1. Maxillofacial CT scan

a. A dedicated maxillofacial CT scan is a prerequisite for ESS. At our institution the scans are performed under a navigation protocol with at least 1-mm slice thickness and corresponding coronal and sagittal reformatting. These images can then be linked to conceptualize the sinus anatomy in three dimensions. Specific anatomic landmarks should be identified to prevent complications of cerebrospinal fluid (CSF) leak and orbital or vascular injury during endoscopic ethmoidectomy. Thus particular attention should be paid to these areas in preoperative CT evaluation and intraoperative dissection.

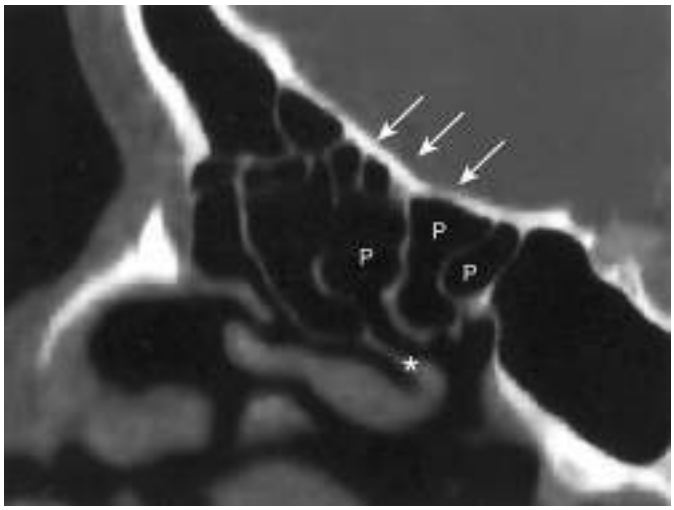

FIG. 108.1 This sagittal view of a CT scan demonstrates the slope of the skull base. Posterior ethmoid cells are marked with *P*. The basal lamella of the middle turbinate is marked with an *asterisk*.

1) The skull base should be assessed for its height, thickness, and

slope (Fig. 108.1). The roof of the ethmoid cavity tends to be thicker laterally and becomes thin medially near the lateral lamella of the cribriform plate. The Keros classification has divided the anatomic arrangement of the skull base based on the depth of the olfactory sulcus into type I (1 to 3 mm), type II (4 to 7 mm), and type III (8 to 16 mm), with increased depth representative of increased risk of skull base injury and subsequent CSF leak (Fig. 108.2).[1]

2) The anterior and posterior ethmoid arteries should be carefully inspected on CT for relative position to the skull base. Those that course in a mesentery inferior to the skull base are at greater risk of injury than those contained within the bony skull base (Fig. 108.3: anterior/posterior ethmoid arteries). The anterior ethmoid artery can be reliably identified on CT scan on coronal images just posterior to the globe (Fig. 108.4: CT anterior ethmoid artery).[1]

3) The medial orbital wall should also be closely examined for erosion or previous trauma that may pose a risk to the orbital contents. Frequently, there is posterior/superior pneumatization of a posterior ethmoid cell over the sphenoid (an Onodi cell), bringing this ethmoid cell close to the optic nerve and cavernous sinus/carotid.

2. In cases of skull base tumors or sinonasal malignancies, a skull base magnetic resonance imaging (MRI) with and without contrast may be indicated.

a. MRI with contrast can help differentiate tumors from surrounding inflamed mucosa and inspissated secretions.

b. This imaging modality also helps determine perineural spread of disease toward the skull base in malignancies such as adenoid cystic carcinoma.

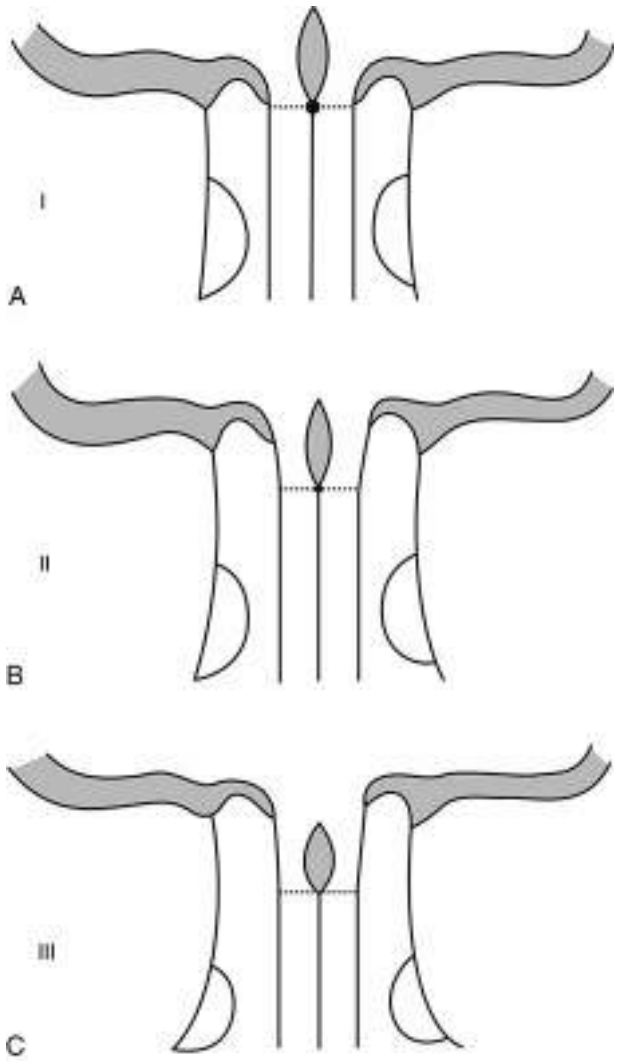

FIG. 108.2 Keros classification of the depth of the olfactory fossa.

A, Keros type I—olfactory fossa is 1 to 3 mm in depth. **B,** Keros type II—olfactory fossa is 4 to 7 mm in depth. **C,** Keros type III—olfactory fossa is 8 to 16 mm in depth. Modified from Stammberger H: Functional endoscopic sinus surgery: the Messerklinger technique. Philadelphia, PA, BC Decker, St Louis, 1991, p 75.

Indications

1. Patients selected for functional ethmoidectomy should demonstrate symptomatic and significant mucosal disease, causing anatomic obstruction. Other indications for endoscopic ethmoidectomy include mucocele formation or access to the other sinuses. Ethmoid mucoceles, which can cause erosion of the lamina papyracea and produce orbital

symptoms such as proptosis and diplopia, are usually secondary to scarring from prior surgery or associated with hyperplastic mucosal diseases such as allergic fungal rhinosinusitis. Access to the sphenoid sinus may be gained via an anterior and posterior ethmoidectomy, but this is not always required. Approaching the sphenoid via the posterior ethmoid cavity preserves the vertical stability of the MT, which may be lost if the MT is lateralized to approach the natural ostium of the sphenoid, which usually lies medial to the middle and superior turbinate.

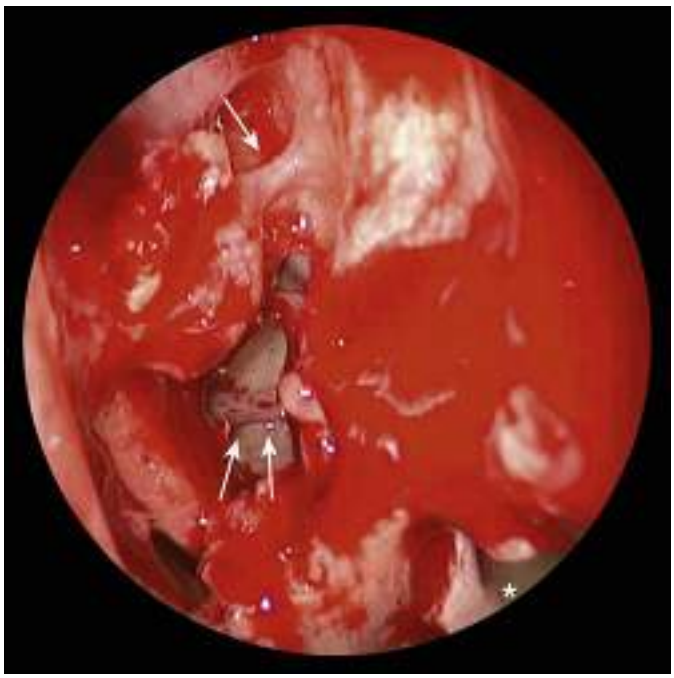

FIG. 108.3 Endoscopic view of anterior *(single arrow)* and posterior *(double arrows)* ethmoid arteries. Left maxillary antrostomy is marked with an *asterisk*.

FIG. 108.4 Coronal CT scan showing left anterior ethmoid artery just posterior to the globe *(white arrow)*.

2. Ethmoidectomy is often performed for access to the frontal sinuses with removal of the agger nasi and associated suprabullar cells, which will be discussed further in Chapter 112, "Endoscopic Approach to the Frontal Sinus."

Contraindications

1. Medical comorbidities that would prevent the patient from safely undergoing general anesthesia. Patients should be appropriately screened for potential risks that outweigh the benefits of an elective surgery.

2. Uncontrolled asthma or reactive airway disease should be adequately controlled prior to ESS.

Preoperative Preparation

1. Dedicated maxillofacial CT scan should be obtained and carefully reviewed prior to surgery as discussed in the "Imaging" section.

2. Patients should stop taking aspirin, nonsteroidal anti-inflammatories, or other anticoagulants and supplements at least 7 days preoperatively. If there is a history of bleeding with prior surgery or trauma, then a coagulation profile is obtained. Profuse intraoperative bleeding precludes safe endoscopic visualization and is a contraindication to continuation of an endoscopic dissection.

3. Preoperatively, patients are counseled regarding the procedure, risks, and complications. This informed consent should be detailed and include the following risks: loss of smell, worsening of symptoms, bleeding, infection, CSF leak, and orbital injury, including diplopia and loss of vision.

4 Imaging studies and pathology slides from previous surgery done elsewhere should be obtained and reviewed by in-house experts.

Operative Period

Anesthesia

1. Close communication with the anesthesiologist in the perioperative period is critical to ensure that blood loss is minimized and that surgery can be performed with optimal visualization.

2. In most cases, it is recommended that ethmoidectomy be performed under general anesthesia if possible in order to achieve the best surgical outcome in a safe manner due to close dissection near the orbit as well as the skull base.

3. Total IV anesthesia (TIVA) can potentially limit bleeding, especially in cases of severe nasal polyposis.

   a. A prospective randomized controlled trial suggests that TIVA results in better surgical field visualization compared with inhalation anesthesia.[2]

4. The anesthesiologist and the sinus surgeon must also be aware of the potential dangers of using beta-blockers concurrently with the use of topical alpha agonists (oxymetazoline, phenylephrine) due to the risk of potential unopposed alpha stimulation and cardiogenic shock.

Positioning

1. The surgeon, the patient, and the screens from which the surgeon is operating (image guidance and endoscopic view) should form a common axis for optimal ability of instrumentation in the nasal cavities and visualization (Fig. 108.5: room setup).

2. The head of the bed is elevated to 20 to 30 degrees to reduce venous congestion and tilted 15 degrees to the surgeon's side.

3. In patients who require extensive frontal dissection, a shoulder roll can be helpful for slight extension of the patient's head for access to this region.

Perioperative Medications

1. Patients undergoing endoscopic sinus surgery often have been treated with antibiotics and oral and topical steroids without significant benefit. If a culture is available, it is ideal to use the appropriate antibiotic to cover culture positive organisms.

   a. This is critical in the patient who has cystic fibrosis to prevent perioperative infectious complications.

2. If cultures have been negative and patients do not present with an infectious component to their sinus disease, cefazolin 1 g is administered preoperatively and can be dosed upwards to 2 g, depending on the patient's weight.

FIG. 108.5 Patient positioning.

The surgeon stands to the right of the patient. The navigation system is placed just above the patient's head *(black arrow)*. The endoscopic projection screen is placed coaxial to the surgeon across from the patient's

head *(asterisk)*. The anesthesia setup is to the left of the patient. Notice the patient's head is elevated 20 to 30 degrees and tilted 15 degrees toward the surgeon.

3. Treatment with systemic steroids in patients with eosinophilic polyposis can significantly improve inflammation prior to surgery, therefore minimizing blood loss. Patients should be counseled regarding the risks of antibiotic and steroid therapy, including *Clostridium difficile* infection and avascular necrosis of the hip, respectively.

Monitoring

1. Standard hemodynamic monitoring is required by anesthesia during surgery.

2. Although exceptions may be made due to a particular patient's cardiovascular status and medical history, maintaining an otherwise healthy patient's heart rate to 60 beats per minute and mean arterial pressure to 60 beats per minute is felt to be safe and effective at reducing bleeding in the operative field.[3]

Instruments and Equipment to Have Available

1. Key instruments necessary to perform a successful ethmoidectomy include through-cutting straight and 45-degree upturned mucosal-sparing forceps. The senior author prefers fine flat jaws in comparison to the pointed Blakesley shape when removing partitions from the skull base. The smaller caliber through-cutting instruments, which are 1 mm in size, can be easier to maneuver in a narrow ethmoid cavity, compared with the standard size.

2. A double-ended "J" curette with curved oval tips can be helpful to remove anterior ethmoid partitions and the ethmoid bulla.

3. Kerrison rongeurs or a sphenoid punch can be helpful in removing partitions along the lamina papyracea, which are often oriented in the coronal plan.

4. Computer-assisted navigational technology

   a. Computer-assisted navigational technology does not replace a thorough knowledge of anatomy and is not required in the majority of ESS cases. However, this technology may be helpful in revision ESS in which landmarks are distorted or absent, in extensive nasal polyposis, and for disease abutting the skull base, optic nerve, or carotid artery (as in an Onodi cell).

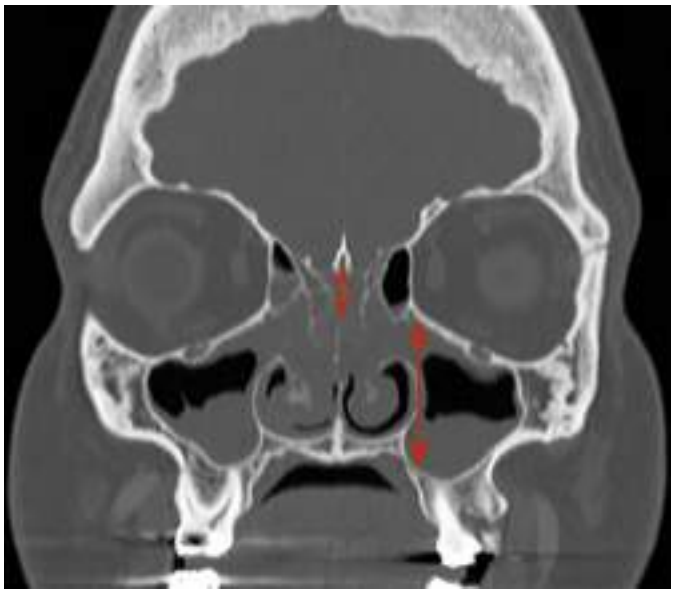

FIG. 108.6 Relative ethmoid height.

This coronal CT scan demonstrates a case where the relative short height of the ethmoid cavity *(short red arrow)* compared with the height of the well-pneumatized maxillary sinus *(long red arrow)* makes the skull base "closer than it may appear."

Key Anatomic Landmarks

1. The key to performing safe and effective ethmoidectomy is understanding the ethmoid cavity anatomy and identifying critical landmarks in a stepwise fashion. The maxillofacial sinus CT scan should be carefully studied prior to the procedure to understand the anatomy and variations that could pose hazards during surgery, including the anterior/posterior ethmoid arteries, Onodi cells, dehiscences, and the

surrounding borders, including the orbit and skull base.

a. Although the Keros classification is commonly described and is important for understanding the location of the lateral lamella of the cribriform plate, the most useful relationship in a practical sense is the relative height of the maxillary sinus to the height of the ethmoid cavity. The patient with a short ethmoid height due to a largely pneumatized maxillary sinus will require increased awareness that the skull base is closer than it may appear (Fig. 108.6: relative ethmoid height).

2. The initial step is to identify the ethmoid bulla. Once removed, the lamina papyracea or medial orbital wall is the first landmark that should be identified and further dissected and preserved.

3. The basal lamella is the second important landmark, which is the lateral attachment of the MT and serves as the divider between the anterior and posterior ethmoid cavities.

4. Once the vertical basal lamella has been traversed, the third important landmark is the superior turbinate.

5. Once the superior turbinate is identified, the fourth landmark is the skull base in the posterior ethmoid sinus. The "corner" is a useful term to describe the junction of the face of the sphenoid, the skull base, and the orbit. If this point is reached, then the surgeon can be confident that a complete ethmoidectomy can be performed in a safe manner.

Prerequisite Skills

1. Endoscopic sinus surgeons should be knowledgeable of medical therapy that precedes the decision to move forward with surgery.

a. Patients should be appropriately counseled that surgery for diseases that involve chronic inflammation and infection including polyposis and cystic fibrosis is only an adjunct for a broader strategy to provide effective medical therapy to the sinuses in a topical fashion and facilitate the use of nasal saline irrigations as well as débridements if necessary. At this time there is no known cure for CRS with polyposis or cystic fibrosis, and therefore it is crucial that patients are advised of the importance of continued medical therapy

and postoperative follow-up.

2. The endoscopic sinus surgeon must also have a good working knowledge of the sinonasal anatomy and be skilled in the use of not only 0-degree Hopkins telescopes but also angled telescopes to facilitate dissection of the sinuses.

3. Mucosal preservation is crucial in performing a "functional" surgery, since the functioning component of the sinuses is the ciliated lining that allows for mucous clearance and innate immune regulation. Therefore the ability to accurately use through-cutting instruments is important in removing ethmoid partitions without stripping the lining. Meticulous technique by removing partitions, avoiding stripping, and making distinct cuts through mucosa-bone-mucosa limits bleeding and scarring.

Operative Risks

1. CSF leak

2. Orbital injury either at the lamina or at the orbital apex

3. Vascular injury to anterior/posterior ethmoid arteries, resulting in orbital hematoma

4. Hyposmia

5. Bleeding

6. Infection

Surgical Technique

1. Perform endoscopic injections with 1% lidocaine with epinephrine 1:100,000 (Fig. 108.7: preoperative injections).

   a. Region of the sphenopalatine artery (approximately 1 cm from the posterior edge of the MT along the lateral nasal wall)

   b. Axilla of the MT

   c. Uncinate process

   d. Medial aspect of the MT

2. The mucosa should be anesthetized and decongested with pledgets soaked in a 50/50 mixture of 0.05% oxymetazoline for vasoconstriction and 4% lidocaine for topical anesthesia. Alternatively, some surgeons prefer pledgets soaked in 1:1,000 topical epinephrine.

   a. These pledgets should be left in place for at least 10 minutes to maximize topical decongestion.

   b. One of the pledgets should specifically be placed between the MT and lateral nasal wall to gently medialize the MT and decongest the region of the ethmoid bulla.

3. Identify the ethmoid bulla and maneuver the J-curette posterior to the bulla with the 90-degree side upward, removing the entirety of the bulla using an anterior motion (Fig. 108.8: dissection of ethmoid bulla). It is important to maneuver the curette in only the anterior plane to prevent entry into the skull base (superior) or orbit (lateral).

4. Alternatively a sickle knife can be used to enter the bulla with the point facing inferiorly, and through-cutting forceps are used to dissect the bulla from the lamina papyracea.

5. Remove residual partitions along the lamina papyracea with a sphenoid punch or Kerrison rongeurs.

   a. As one dissects from anterior to posterior, care should always be made to enter cells inferiorly and medially, thus avoiding inadvertent injury to the skull base or orbit.

6. Identify the basal lamella as well as the roof of the maxillary sinus to determine the trajectory for entering the posterior ethmoid sinus. The straight portion of the J-curette or a sickle knife is used to traverse the basal lamella and dissect out the bony portion of this structure.

   a. The horizontal basal lamella should be preserved to allow continued stability to the MT. A destabilized MT may have a tendency to lateralize postoperatively, thus obstructing the osteomeatal complex and frontal outflow tract.

7. The superior turbinate should be identified through the basal lamella. Using a microdébrider, the remaining soft tissue of the basal lamella is removed to further define the anterior head of the superior turbinate. This can be accomplished by using the microdébrider in a controlled

sweeping motion from a 6 to 9 o'clock fashion on the patient's left side and 3 to 6 o'clock on the right side.

8. Remove the ethmoid partitions with 45-degree upturned through-cutting forceps, taking care to identify the skull base in the most posterior ethmoid sinus. Partitions that are oriented axially or sagittally can be removed with a straight through-cutting forceps.

9. Identify the junction of the skull base, anterior face of the sphenoid sinus, and the medial orbital wall.

10. At this juncture, it is safest to use an angled telescope, either at 30 or 45 degrees, to help remove the remaining ethmoid partitions along the skull base, taking care to identify the anterior and posterior ethmoid arteries if they are exposed in a mesentery (see Fig. 108.3: figure anterior/posterior ethmoid arteries and Fig. 108.9: removal of ethmoid partitions).

a. Once the skull base is clearly identified at the "corner" of the orbit and sphenoid, it is safest to remove these remaining partitions in a posterior to anterior fashion, following the slope of the skull base.

Common Errors in Technique

1. Incomplete removal of the ethmoid bulla and residual partitions left along the lamina papyracea. This will limit access to the posterior ethmoid sinuses.

2. Failure to identify the superior turbinate completely by inadequately removing the medial portion of the basal lamella as described

3. Overly aggressive removal of the basal lamella causing MT instability and potential lateralization

4. Failure to fully identify the posterior ethmoid sinuses and the skull base leading to incomplete ethmoidectomy

5. Incomplete removal of ethmoid partitions secondary to prior steps not being performed correctly

6. Pointing the open portion of the microdébrider toward the orbit or skull base when a bony dehiscence is present

Postoperative Period

Postoperative Management

1. Counsel the patient to avoid nose blowing and, if sneezing, to keep the mouth open to prevent increased pressure in the sinus cavities.

2. Start nasal saline irrigations three times daily, preferably the day of or the day after surgery.

    a. We prefer a "high volume, low pressure" irrigation (total of 240 mL of saline split between each nostril).

3. Antibiotics at the discretion of the surgeon

4. Corticosteroids if patients have CRS with polyposis

    a. Patients with nasal polyposis at our institution are treated postoperatively with methylprednisolone 32 mg daily for 7 days and then a ~3-week taper (32 mg every other day for 3 doses, 24 mg every other day for 3 doses, 16 mg every other day for 3 doses, and off).

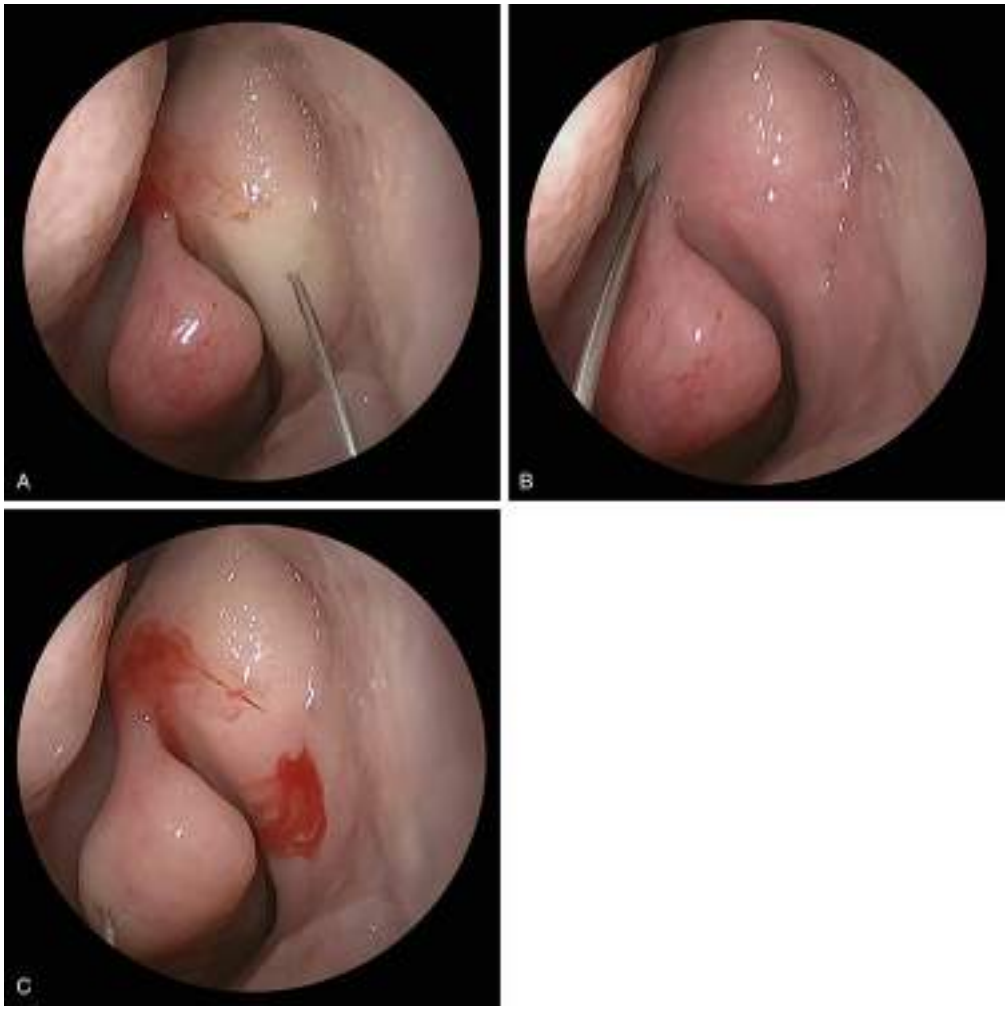

FIG. 108.7 Preoperative injections of the left **A,** lateral nasal wall, **B,** MT axilla, **C,** medial aspect of MT.

FIG. 108.8 Dissection of the left ethmoid bulla with a J-curette.

FIG. 108.9 Removal of ethmoid partitions along the skull base with a through-cutting instrument.

5. Follow up within 1 week to perform débridement and assess healing.

6. Provide short-term and long-term medication strategies depending on the patient's pathology.

Complications

1. Orbital injury
    a. This most often occurs from failure to identify the lamina papyracea at the onset of surgery as well as with obstructive nasal polyposis and bleeding.
2. CSF leak
    a. May occur from failure to identify skull base landmarks, improper use of through-cutting instruments or curettes in areas of significant osteitis, aggressive "rocking" of the MT, obstructing polyps, or significant bleeding
3. MT instability and lateralization from causing mucosal trauma during dissection or from removing a significant portion of the basal lamella, thus destabilizing the MT

Alternative Management Plan

1. Medical management
    a. Surgery is generally only offered after failure of attempted appropriate medical management, as discussed previously.
    b. Symptomatic patients should undergo directed medical therapy prior to surgical consideration. At a minimum, this usually includes culture-directed antibiotics given for as long as patients are steadily improving (often 3 to 4 weeks), nasal steroid sprays, a short course of systemic steroids, and occasionally topical antimicrobials.[4]
    c. Medical treatment efforts should be directed at the particular patient's pattern of disease with consideration of mitigating factors, including presence of polyps and previous treatment efforts.[4]
    d. Patients whose conditions warrant exception from a preoperative trial of medical therapy include those with impending orbital complications, those with mucocele, and those with unilateral disease in which a diagnosis is required to evaluate for diseases other than chronic nonspecific sinus inflammation.
        1) In patients with unilateral maxillary disease, a dental origin

should always be considered (i.e., periapical abscess with secondary involvement of the sinus).

Discussion

Evidence-Based Medicine Question

What is the evidence supporting or refuting MT resection in patients with nasal polyposis?

The MT is an important anatomic and physiologic structure that is often carefully preserved in ESS. In general, the MT should be preserved if it is not affected by disease, because it serves as a useful landmark and provides underlying physiologic function. However, there may be a role for MT resection in cases of MT destabilization, polypoid degeneration, or obstruction. A recent systematic review examined the role of MT resection in cases such as this. It suggested no difference in quality of life outcomes, nasal airway resistance, or rates of postoperative frontal sinusitis in patients undergoing MT resection during ESS when compared with MT preservation. Postoperative olfaction scores were generally better in the MT resection group. In regard to postoperative endoscopic examinations, some studies note greater improvement in the MT resection group compared with MT preservation, while others were equivalent.[5] This topic remains an active area of debate.

Editorial Comment

Endoscopic ethmoidectomy, primary and revision, remains a source of complications and medicolegal issues for the otolaryngologist. Stankiewicz drew early attention to this problem (Stankiewicz JA: Complications of intranasal ethmoidectomy. *Laryngoscope* 97(11):1270-1273, 1987), and it remains the most common cause of litigation for the specialty (Tolisano AM, Justin GA, Ruhl DS, et al.: Rhinology and medical malpractice: an update of the medicolegal landscape of the last ten years. *Laryngoscope* (1):14-19, 2016). The authors' thorough review of the indications and contraindications allow the reader to arrive at good surgical decision making, and the technique outlined documents a safe surgical approach to avoid complications.

External Ethmoidectomy

Carl H. Snyderman

Introduction

In many countries, external ethmoidectomy is rarely performed due to the widespread adoption of endoscopic techniques. However, in some clinics where endoscopic equipment is not available, the external ethmoidectomy approach is still an important technique used in the management of ethmoid disease. It also still has value for the management of sinonasal tumors, epistaxis, orbital infection, and trauma in special circumstances. It may be used in combination with other approaches (transnasal and transcranial) to provide additional exposure. An open approach may be preferred for some highly vascular tumors.

Key Operative Learning Points

- The incision should be placed at the junction of aesthetic units, midway between the nasal dorsum and medial canthus.
- The frontoethmoidal suture line defines the level of the skull base (roof of the ethmoid sinus).
- The anterior and posterior ethmoidal arteries are at the level of the frontoethmoidal suture line. Injury to these arteries can result in a retrobulbar hematoma.
- The posterior lacrimal crest is the anterior limit of the ethmoid sinus and defines the lacrimal fossa. Avoidance of trauma to the nasolacrimal duct will avoid postoperative epiphora.
- The cribriform plate is medial to the middle turbinate and may be at a lower level than the frontoethmoidal suture line. Violation of the lateral lamella can result in a cerebrospinal fluid (CSF) leak.

- The optic nerve is in close proximity to the posterior ethmoidal artery.

Preoperative Period

History

- Orbital swelling
- Diplopia
- Epiphora
- Nasal obstruction
- Sinus pain/pressure
- Epistaxis

Physical Examination

- Widening of the nasal bones
- Orbital swelling or proptosis
- Nasal mass
- Purulent nasal discharge

Imaging

- Computed tomography (CT) with or without contrast

  Contrast is indicated for neoplastic conditions. An image-guidance protocol is used in anticipation of surgery with navigation

Indications

- Subperiosteal orbital abscess

  An external ethmoidectomy approach is a suitable approach for a subperiosteal abscess that is located medially or superiorly.

- Osseous tumor of ethmoid region with obstruction of the frontal sinus (osteoma)
- Neoplasm in the ethmoid sinus
- Vascular tumor
- Skull base trauma with CSF leak from the roof of the ethmoid, cribriform plate, or frontal sinus
- Meningoencephalocele of the anterior cranial base or frontal sinus

Contraindications

- Biopsy of malignant tumors

  Sinonasal neoplasms should be biopsied intranasally if possible to avoid tumor seeding of the external soft tissues. If there is tumor involvement of the skin, an external incision is optional.
- Bilateral disease

Preoperative Preparation

- Cessation of antiplatelet drugs according to guidelines
- Antibiotic therapy for concomitant sinus infection

Operative Period

Anesthesia

- Local anesthesia with intravenous sedation may be considered for biopsy or drainage of an abscess.
- General anesthesia is preferred for most cases.

Positioning

- Supine

Perioperative Antibiotic Prophylaxis

- Second-generation cephalosporin or penicillin
- Third-generation cephalosporin with CSF penetration if there is an intraoperative CSF leak

Monitoring

- None

Instruments and Equipment to Have Available

- Image-based navigation (optional)
- Needle-tip electrocautery
- Periosteal elevator (Cottle)
- Sinus surgery set
- Kerrison rongeurs
- Drill with 4-mm coarse diamond bit

FIG. 109.1 The incision is equidistant between the nasal

dorsum and the medial canthus. A Z-plasty can be incorporated into the incision at closure to prevent scar contracture.

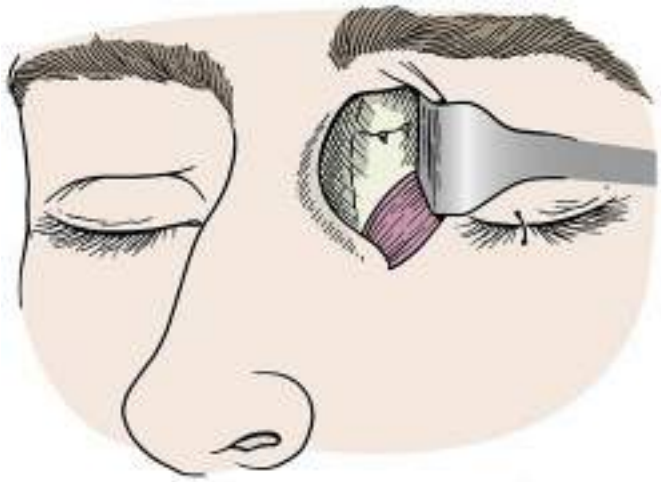

FIG. 109.2 The periosteum is elevated from the lamina papyracea, and the ethmoidal arteries are identified along the frontoethmoidal suture line.

- Bipolar electrocautery
- Nasal tampons (Merocel)

Key Anatomic Landmarks[1]

- Frontoethmoidal suture line
- Posterior lacrimal crest
- Anterior ethmoidal artery
- Posterior ethmoidal artery
- Lamina papyracea
- Middle turbinate

Prerequisite Skills

- Familiarity with Caldwell-Luc and other sinonasal procedures

Operative Risks

- Orbital injury

The medial rectus muscle is at greatest risk of injury if there is violation of the periorbita

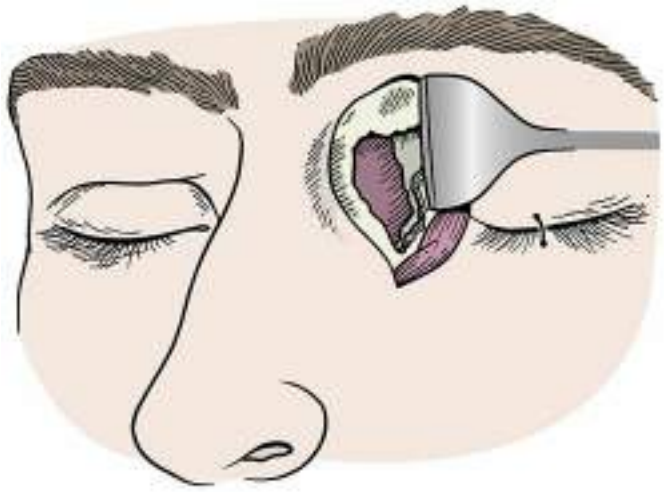

FIG. 109.3 The bone of the lamina papyracea is removed with bone rongeurs to the frontoethmoidal suture line superiorly and to the posterior lacrimal crest anteriorly. The posterior ethmoidal artery is a landmark for the optic canal.

- Hematoma of the orbit

Orbital hematoma is usually associated with violation of the periorbita. Failure to adequately cauterize the anterior ethmoidal artery can allow it to retract into the orbital tissues and cause a retrobulbar hematoma.

- CSF leak

A CSF leak may result from removal of bone superior to the frontoethmoidal suture line or disruption of the attachment of the middle turbinate to the skull base.

Surgical Technique

- A temporary tarsorrhaphy suture is placed to protect the eye during surgery. Alternatively, a protective lens with lubrication can be placed.
- The incision site is injected with 1% lidocaine with 1:200,000 epinephrine solution.
- The skin is prepped with ophthalmic Betadine solution.
- A linear incision is made equidistant between the nasal dorsum and medial canthus and extends for approximately 1 cm above and below the level of the medial canthus (Figure 109.1).[1]
- Superficial vessels (angular artery branch of facial artery) are best controlled with bipolar electrocautery.
- The periosteum is elevated from the underlying bone using a Cottle elevator, and the frontoethmoidal suture line is identified and followed posteriorly to the anterior ethmoidal artery (Figure 109.2).[2]
- Inferiorly, the periosteum is elevated to the superior aspect of the lacrimal fossa and the attachment of the medial canthal ligament.
- The orbital contents are retracted with a narrow malleable ribbon retractor, and the anterior ethmoidal artery is identified and cauterized with bipolar electrocautery. This is more secure than clipping the vessel. The artery is then transected to allow further subperiosteal dissection posteriorly. Dissection is not carried out beyond the posterior ethmoidal artery due to proximity to the optic nerve.
- If there is violation of periorbita with herniation of orbital adipose tissue, it can be gently cauterized with bipolar electrocautery to shrink the adipose tissue.
- The lamina papyracea is easily fractured with a Cottle elevator, and the ethmoid air cells are opened.[3] The opening is enlarged with Kerrison rongeurs to the level of the frontoethmoidal suture line superiorly and to the posterior lacrimal crest anteriorly (Fig. 109.3).
- The contents of the ethmoid sinus are removed with standard sinus instruments in a medial and inferior direction until there is communication with the nasal cavity. The middle turbinate is the medial limit of dissection for inflammatory disease and care is taken to avoid injury to its attachment at the skull base (lateral lamella of the

cribriform).

- Removal of ethmoidal air cells continues posteriorly to the basal lamella or anterior wall of the sphenoid sinus. The dissection may be carried to the posterior ethmoid cells to expose the anterior wall of the sphenoid sinus (see Chapter 110). Visualization is limited without endoscopy, and the plane of the skull base must be carefully followed as it slopes inferiorly.
- If exposure of the frontal sinus is necessary, the nasofrontal recess can be followed superiorly with a Kerrison rongeur. Drilling of thick bone may be necessary, depending on the degree of exposure needed. Excessive bone removal may result in obstruction of the outflow tract from herniation of orbital tissue.
- Following removal of pathology, it is imperative to confirm adequate hemostasis. The superficial tissues are approximated in two layers using absorbable suture. A Z-plasty may be incorporated into the incision to minimize scar contracture. Steri-Strip dressings are applied longitudinally along the incision. Nasal packing with a Merocel tampon may be used if there is mild bleeding.

Common Errors in Technique

- Incision too high (above frontoethmoidal suture line)
- Avulsion of anterior ethmoidal artery without hemostatic control
- Violation of periorbita
- CSF Leak

Postoperative Period

Postoperative Management

- Careful observation of the eye in the minutes to hours following surgery is necessary to detect orbital hematoma.
- Nasal packing can be removed in the recovery room if there is no bleeding.

- The patient is discharged on a regimen of saline spray and is instructed to avoid nose blowing or excessive exertion for at least 1 week.

Complications

- Orbital hematoma

  If there is bleeding from the anterior ethmoidal artery intraoperatively, it needs to be thoroughly cauterized using bipolar electrocautery. If proptosis from a retrobulbar hematoma is discovered intraoperatively or postoperatively, gentle massage of the closed orbit may halt the bleeding. Nasal packing should be removed immediately. Ophthalmology should be consulted emergently for measurement of ocular pressures and further management. The surgeon should be prepared to perform a lateral canthotomy if there is progression of proptosis, deterioration of vision, or absent afferent pupillary reflex.

- CSF leak

  Whenever there is an unanticipated intraoperative CSF leak, it is important to confirm that there is no associated intracranial vascular injury. Additional removal of bone with visualization of dural margins is necessary. Surrounding mucosa should be removed, and the defect can be repaired with fascia or adipose tissue grafts. Neurosurgery should be consulted postoperatively for further management, and a CT scan of the head should be obtained to rule out an intracranial complication (hemorrhage or tension pneumocephalus).

- Injury to the orbit

  Injury to the extraocular muscles can result in diplopia. Consultation with an ophthalmologist is necessary.

- Medial canthal tendon

  Detachment of the medial canthal tendon is usually not a problem unless the underlying bone is removed or mobilized. Failure of the tendon to reattach can result in "rounding" of the medial canthus.

- Injury to the nasolacrimal sac

  Dissection anterior to the posterior lacrimal crest can injure the lacrimal sac. Postoperative scarring can result in epiphora. If there is

intraoperative injury, Silastic nasolacrimal stents can be left in place for several weeks to prevent stenosis.

- Scar contracture

  A long linear incision can form a cicatrix with healing. This can be avoided by using a minimal incision or placing a small Z-plasty in the center of the incision.

Alternative Management Plan

- Endoscopic sinus surgery is preferred for most ethmoid pathology.
- Subperiosteal orbital abscesses can be drained endoscopically if favorably located or through a transorbital (eyelid crease or transcaruncular) approach.

Discussion

Evidence-Based Medicine Question

What is the best approach for drainage of a subperiosteal orbital abscess?

Most subperiosteal orbital abscesses occur in children as a complication of sinusitis. Although most surgeons have adopted endoscopic techniques for drainage of abscesses that are favorably located (medial), there is sparse literature comparing endoscopic and external approaches.

In a retrospective review of 38 children treated surgically for subperiosteal abscess associated with acute ethmoid sinus infection, Rubin et al.[2] compared the outcomes based on surgical approach: 12 endoscopic (32%), 21 external (55%), and 5 combined (13%). There were no surgical complications in any of the groups, but the percentage of surgical failures requiring additional drainage was almost twice as high after endoscopic surgery (failure rate: 25%) than after an external approach (failure rate: 14.3%); this difference was not significant.

This review and other literature[3] demonstrate the continued need for

external ethmoidectomy, especially if a first attempt with endoscopic drainage fails.

Editorial Comment

Many years ago while training as a resident, I never saw or was exposed in any way to surgery of the ethmoid sinuses. Once in practice as chief of the department in an academic referral center, otolaryngologists in the community referred patients whom they could not manage. These included orbital to me abscess secondary to acute ethmoiditis and massive nasal polyposis causing proptosis as well as sinonasal neoplasms. So what to do? Well, I recalled that during my fellowship in head and oncologic surgery, I did have a brief introduction to the lateral rhinotomy and medial maxillectomy procedure for tumors of the lateral nasal wall and ethmoid sinuses. That memory, aided by a glimpse into *Gray's Anatomy,* was my segue into performing external ethmoidectomy.

Using the modified lateral rhinotomy incision rather than the classical semicircular incision eliminated the unsightly scar which sometimes developed. Using a headlight, a #15 blade, ribbon retractors, a Cottle elevator, and a Takashi forceps, I was able to identify the landmarks and thoroughly remove polyps and tumors—usually inverted papillomas—and drain orbital abscesses. With a bit of experience I added transantral sphenoidotomy and transethmoidal hypophsectomy (used in cases of metastatic breast cancer for pain control) to my repertoire.

Of course all of this took place before Professor Messerklinger, of Graz, Austria, introduced functional endoscopic sinus surgery (FESS) and in collaboration with industry developed advanced endoscopes and improved instrumentation. This has resulted in most of the external techniques being replaced by endonasal endoscopic surgery. The endonasal endoscopic method of skull base surgery, developed by Dr. Carl H. Snyderman, uses various surgical corridors to approach a variety of neoplasms arising at the skull base. This technique replaced the transfacial-craniotomy approach that we had used for several decades.

Endoscopic endonasal surgery has largely replaced external ethmoidectomy in many areas in the world. However, there are still

hospitals that do not have the financial resources to purchase the necessary equipment, or there are government restrictions in place for the surgeons' training even if the equipment could be purchased. In these areas, external ethmoidectomy remains a versatile procedure that can be incorporated into the training of young surgeons for the benefit of their patients.

Eugene N. Myers

Review Questions

1. Which of the following statements about the anterior ethmoidal artery is false?

   a. **It is situated 4 to 7 mm anterior to the optic canal.**

   b. It is found along the frontoethmoidal suture line.

   c. Injury can result in a retrobulbar hematoma.

   d. Sacrifice of the artery provides greater access to the medial orbit.

2. Indications for an external ethmoidectomy include all of the following, except

   a. Subperiosteal orbital abscess

   b. Cerebrospinal fluid (CSF) leak from cribriform plate

   c. Osteoma of ethmoid sinus

   d. **Inverted papilloma of maxillary sinus**

3. Which of the following statements is false?

   a. The posterior lacrimal crest is the anterior limit of an external ethmoidectomy.

   b. **The cribriform plate is superior to the frontoethmoidal suture line.**

   c. The middle turbinate separates the ethmoid roof from the cribriform plate.

   d. The posterior limit of an external ethmoidectomy is the posterior

ethmoidal artery.

Endoscopic Sphenoidotomy

Evan S. Walgama, and Jayakar Nayak

Introduction

The paired sphenoid sinuses are the most posteriorly positioned of the paranasal sinuses. Due to this location, endoscopic approaches to the sphenoid sinus are preferred to address most pathology that may arise in this location. The pathology may be isolated within the sphenoid sinus or may be part of inflammatory sinonasal disease involving the ethmoid or other paranasal sinuses. The sphenoid sinus is also the gateway to many extended endonasal procedures, including approaches to pituitary lesions, other sellar and parasellar lesions, and petroclival lesions amenable to an endonasal approach.

The two main endoscopic pathways to the sphenoid sinus are the transseptal and transethmoid approaches. Both require identification of the natural sphenoid ostium medial to the superior turbinate (ST) and enlargement of this ostium for endoscopic access. These approaches may be combined with a posterior septectomy for simultaneous access to both sphenoid sinuses, most commonly indicated for extended endonasal approaches (Figs 110.1 and 110.2).

The transseptal approach proceeds through the sphenoethmoidal recess, in the geometrically narrow airspace between the nasal septum medially and the middle turbinate laterally. This corridor rarely requires ethmoid dissection or resection of the ST and thus has the advantage of a simpler dissection with preservation of olfactory fibers. This is the most direct endoscopic approach and is most commonly used for isolated sphenoid pathology and for access to the sphenoid sinus for extended endoscopic approaches in the sagittal plane.

The transethmoid approach to the sphenoid sinus proceeds lateral to the middle turbinate and requires dissection of the uncinate process,

anterior and posterior ethmoid sinus labyrinths, and typically resection of the inferior one-fifth to one-third of the ST. The approach affords a larger corridor for improved endoscopic visualization and instrumentation and provides for early identification of the skull base and lamina papyracea landmarks prior to enlarging the sphenoid ostium and taking down the rostrum. This approach is most commonly used as part of functional sinus surgery in the management of chronic sinusitis.

In some patients, the sphenoid sinus may have pneumatization of a lateral recess between the vidian and trigeminal nerves, and selected lesions in this part of the sphenoid, such as a meningoencephalocele, may be approached endoscopically with the addition of a transpterygoid dissection. The latter approach requires a transethmoid corridor to the sphenoid sinus, combined with a wide maxillary antrostomy with posterior maxillary wall/pterygopalatine fossa dissection to allow unobstructed endoscopic access to the lateral recess of the sphenoid sinus.

Key Operative Learning Points

1. The two main endoscopic approaches to the sphenoid sinus are transnasal and transethmoid.

2. The preferred point of entry to the sphenoid sinus is through the natural ostium, always located medial to the ST and just lateral to the articulation of the nasal septum into the face of the sphenoid sinus/sphenoid rostrum.

3. The sphenoid sinus is in close proximity to critical structures, including the internal carotid artery, optic nerve, orbital apex and intraconal musculature, posterior ethmoid artery, pituitary gland, and skull base, any of which may be injured during endoscopic surgery.

History

1. History of present illness

   a. The nature, severity, and duration of symptoms related to sphenoid pathology should be obtained. In chronic rhinosinusitis, this may include cardinal symptoms of nasal obstruction, postnasal drip or

chronic drainage, loss of the sense of smell, or facial pain. Sphenoid sinusitis classically, though not reliably, produces headaches felt at the scalp vertex and/or deep-seated retro-orbital pain.

b. Determine if there are associated symptoms, especially if noninflammatory disease is suspected. This may include ophthalmologic deficits such as visual loss, decreased color vision, diplopia, or xerophthalmia. Look for signs of orbital apex syndrome (decreased vision, ophthalmoplegia, proptosis) or superior orbital fissure syndrome (ophthalmoplegia, proptosis). Evaluate any neurologic complaints, including changes in mental status, facial numbness, and severe headache.

c. For chronic sinusitis, the history should include recent requirements for antibiotic or oral steroid therapy, current use of topical nasal medications including saline lavage, clinical response to these medications, previous medications trialed for control of symptoms, and any associated asthma, allergies, aspirin sensitivity, or immunodeficiency.

d. Additional questions may be tailored to the suspected pathology. For example, for sphenoid sinus meningocele, whether there is any antecedent history of unilateral rhinorrhea, or history of meningitis, assess for risk factors for chronic invasive fungal sinusitis, including immunocompromise, history of diabetes, and country of origin.

2. Past medical history

a. Determine the patient's current level of general health, including the history of major systemic disease, history of cardiopulmonary disease, and fitness for general anesthesia.

b. Survey for systemic disease that may present with sinonasal complaints. These include granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis), sarcoidosis, Churg-Strauss disease, aspirin-exacerbated respiratory disease (Samter's triad), and/or cystic fibrosis.

c. Elicit any history of previous sinus, nasal, or skull base procedures, and whether there were any associated complications with these procedures. Revision endoscopic surgery often proceeds through distorted anatomy which increases the complexity of the procedure.

d. Family history: History of coagulopathy or atopy

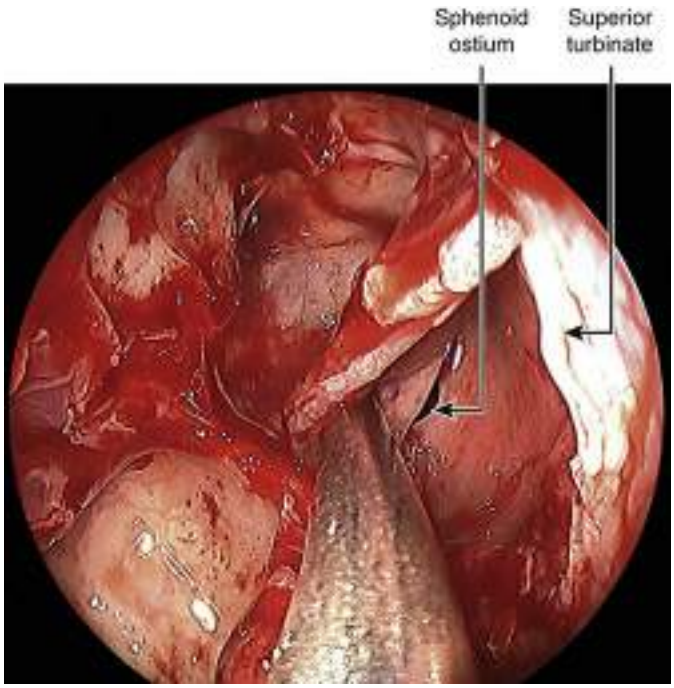

FIG. 110.1 Endoscopic view of right sphenoid ostium medial to superior turbinate (retracted laterally in this image). Previous total ethmoidectomy and maxillary antrostomy have been performed.

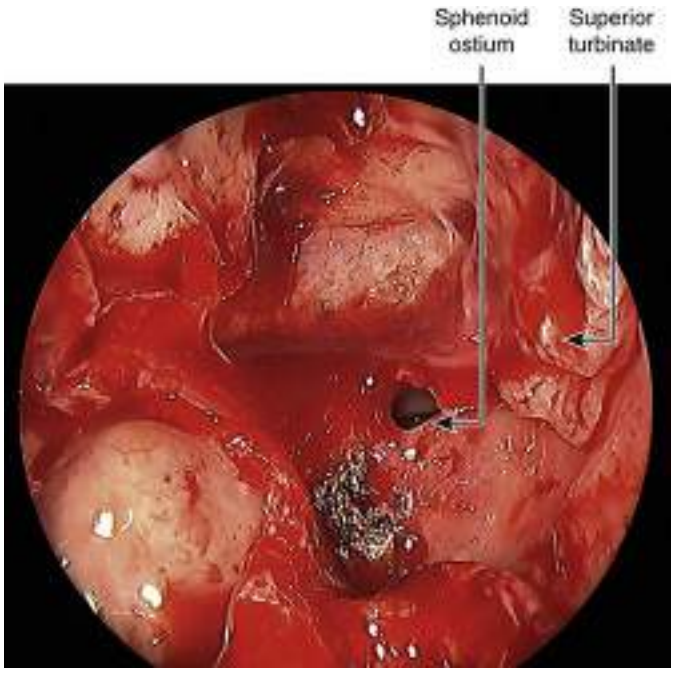

FIG. 110.2 Right sphenoid ostium is visible following resection of the inferior one-third of the superior turbinate.

e. Medications:

1) Antiplatelet drugs

2) Herbal products such as garlic, ginseng, and gingko

Physical Examination

1. A complete examination of the head and neck should be performed on all patients.

2. Preoperative, diagnostic nasal endoscopy should be performed on all patients undergoing endoscopic sphenoidotomy. The nose should be prepared with topical anesthetic with decongestant. Endoscopic visualization of the sphenoethmoid recess in the unoperated nose is best tolerated with a 30-degree endoscope angled superiorly and passed posterior along the floor of the nose, following the course of the inferior turbinate. In the setting of ongoing inflammation, is sometimes not possible to visualize the sphenoid ostium without manipulation of the turbinates. A trail of purulence arising from the sphenoid sinus and/or posterior ethmoid complex can sometimes be seen in this recess.

Imaging

Computed Tomography Imaging

Computed tomography imaging (CT) best defines the pneumatization and bony confines of the sphenoid sinus, including the presence of dehiscent bone of the optic nerve canal, internal carotid artery canal, and/or skull base. A deviated septum, ethmoid disease, and the lateral recess that may be encountered during an endonasal approach may be identified preoperatively. CT may be paired with a computer-assisted intraoperative navigation system for assistance in endoscopic identification of landmarks, including the natural ostium. The sphenoid sinus should be evaluated on axial, coronal, and sagittal views, preferably with cuts of less than 1 mm. Bone windowing is useful, and, in the case of opacification, soft tissue-windowing should be studied to

evaluate the contents of the sinus. Heterogeneous opacification of the sphenoid sinus could signal the presence of a fungal ball, eosinophilic mucin, or a sinonasal tumor.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is indicated in select cases to further characterize the internal contents of the opacified sphenoid sinus or soft tissue lesions found in this cavity or to identify extrasinus extension of disease. This includes suspected neoplasm, encephalocele or meningocele, and complicated rhinosinusitis.

Indications

1. Chronic, symptomatic sphenoid sinusitis after failure of a trial/several trials of maximal medical therapy

2. Neoplasm involving the sphenoid sinus, for biopsy and/or definitive management

3. Cerebrospinal fluid leak, with or without associated meningoencephalocele, for endoscopic repair of the skull base

4. Access for expanded endonasal approaches to the cranial base or orbit

Contraindications

1. Not medically fit for surgery

2. Largely dehiscent carotid artery (relative)

Preoperative Preparation

1. A course of oral steroids and antibiotics may be considered for 3 to 5 days prior to surgery to reduce inflammation and bleeding and to improve endoscopic visualization.

2. Preoperative medical clearance, if necessary

3. Reverse/manage anticoagulation, if necessary

4. Obtain consent for surgery, including discussion of possible risks, benefits, and alternatives to surgery.

Operative Period

Anesthesia

General

The use of total intravenous anesthesia (TIVA) may reduce intraoperative blood loss and improve endoscopic visualization. Blood pressure and heart rate should be controlled in the lower range of what is tolerated by the patient, to reduce mucosal bleeding and improve endoscopic visualization. However, in endoscopic skull base surgery where there is pre-existing compromise of the optic nerve, mean arterial pressures should be maintained in the normal range.

Local

Topical anesthesia may be used in the office for the revision endoscopic sphenoidotomy that shows restenosis from synechiae formation.

Positioning

Supine

The operating table should be placed in reverse Trendelenburg position to about 20 degrees from the floor to improve endoscopic visualization. The patient's head should be turned slightly toward the surgeon.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Second-generation cephalosporin

Clindamycin if allergic to penicillin

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Basic endoscopic sinus set including Cottle elevator, J curette, mushroom punches, Kerrison punches, straight through-cutting forceps, image navigation probe

2. Zero-degree, 4-mm endoscope

3. Powered shaver/microdébrider

4. Computer-assisted, intraoperative system

5. Topical 1:1000 epinephrine with cotton pledgets

Key Anatomic Landmarks

1. ST. The anterior pole is identified by lateralization of the middle turbinate during the transnasal approach or in the superior meatus just posterior and medial to basal lamella of middle turbinate during transethmoid approach. The sphenoid ostium is universally located medial to the ST.

2. Planum sphenoidale. The roof of the sphenoid sinus just anterior to the thickened tuberculum sellae bone of the skull base. The sphenoid ostium is on average 11 mm inferior to the skull base[1] and is approximately halfway between the floor of the sphenoid sinus and planum sphenoidale. It can be closer to the skull base in sinuses that are poorly pneumatized.

3. Optic nerve and lamina papyracea. The face of the sphenoid inserts laterally on one or both of these structures. The optic nerve may be dehiscent in an Onodi cell, which is a posterior ethmoid air cell with pneumatization posterior to the coronal plane of the face of the sphenoid sinus.

4. Posterior septal branch of the sphenopalatine artery. This artery serves as the vascular pedicle for nasoseptal reconstructive flaps. The vessel runs 2 to 6 mm inferior to the sphenoid ostium, within the mucosa superior to the choana. Unfortunately this vessel can be encountered during enlargement of the sphenoid ostium in an inferior direction toward the nasal floor.

5. Sphenoid face/rostrum. The face of the sphenoid may appear convex by comparison to the ethmoid skull base in the unopened sphenoid sinus. The ostium is located in the medial and inferior quadrant of the rostrum.

6. Choanal arch. The sphenoid ostium is typically found 2 cm superior to the arch of the choana, at the nasopharyngeal inlet.

Prerequisite Skills

For transethmoid approach, see the chapter on endoscopic ethmoidectomy (Chapter 108).

Operative Risks

1. Cerebrospinal fluid (CSF) leak

2. Orbital or optic nerve injury

This may occur due to imprecise lateral dissection of the face of the sphenoid, an unrecognized Onodi cell containing the optic nerve, or improper entry into the sphenoid sinus at a site distinct from the natural sphenoid ostium. This is a devastating complication and is difficult to manage and/or correct but should lead to an immediate ophthalmology referral for an evaluation of the patient's vision.

3. Arterial hemorrhage

Care should be taken upon widening of the sphenoid ostium inferiorly, as the posterior septal branch of the sphenopalatine artery may be encountered. The involved mucosa over the sphenoid face/superior choana should be cauterized if this issue is encountered.

4. Internal carotid artery injury

The artery may be dehiscent within the sphenoid sinus in up to 22% of patients. The sphenoid intersinus septum may insert on the face of the carotid artery in 16% of patients and should be reduced or removed with sharp through-cutting instruments and with great caution.

Endoscopic Transnasal Surgical Technique

- Review of CT scan

  Prior to taking the patient to the operating room, a CT scan with thin cuts (preferably <1.25 mm) is reviewed in all three planes. It may be calibrated to the patient with an intraoperative computer-assisted navigation platform once the patient is intubated.

- Topical nasal preparation

  Placement of decongestant-soaked pledgets (e.g., 1:1000 epinephrine) on the mucosa medial to the middle turbinates to chemically vasoconstrict and reduce the caliber of the nasal mucosal blood vessels and reduce sites of intraoperative bleeding.

- Lateralization of the middle turbinate is carefully performed with a Freer elevator placed onto the inferior aspect of the turbinate head. Pressure is sequentially applied posteriorly until the basal lamella of the middle turbinate is displaced laterally, exposing the anterior pole of the ST.

- Lateralization of the ST with identification of the sphenoid ostium. This may be performed via direct endoscopic visualization and gentle turbinate adjustment using a straight navigation probe or with the Cottle elevator.

- Removal of the most-inferior one-fifth to one-third of the ST that may lie inferior to the sphenoid ostium and obstruct its drainage. A limited posterior ethmoidectomy may be performed by removing cells within the superior meatus to create additional exposure for sphenoidotomy or to help in early identification of landmarks, including the lamina papyracea and ethmoid skull base.

- Blunt dissection to enter the sphenoid ostium and enlarge it

- Widening of the ostium laterally toward the lamina papyracea and

superiorly toward planum sphenoidale to ensure long-term patency

Endoscopic Transethmoid Surgical Technique

- Review of CT scan

  Prior to taking the patient to the operating room, a CT scan with thin cuts (preferably <1.25 mm) is reviewed in all three planes. Special attention is given to findings in the ethmoid cavity, the position of the anterior and posterior ethmoid arteries, and the integrity and shape of the orbit and skull base. It may be calibrated to the patient with an intraoperative computer-assisted navigation platform once the patient is intubated.

- Topical nasal preparation

  Placement of decongestant-soaked pledgets (e.g., 1:1000 epinephrine) on the nasal mucosa to chemically vasoconstrict the nasal mucosa and reduce sites of intraoperative bleeding.

- Total ethmoidectomy (see Chapter 108)

  Of note, the basal lamella of the middle turbinate is lowered to allow visualization of the inferior aspect of the ST. The posterior ethmoid cells in the superior meatus are removed to allow manipulation and resection of the ST and identification of the sphenoid ostium.

- Lateralization of the ST with identification of the sphenoid ostium. This may be performed via direct endoscopic visualization and gentle turbinate adjustment using a straight navigation probe or with the Cottle elevator. If a maxillary antrostomy has been performed, the floor of the orbit can be used as the superior limit when searching for the sphenoid ostium, as the sphenoid ostium lies below the level of the floor of the orbit.

- Removal of the most-inferior one-fifth to one-third of the ST that may lie inferior to the sphenoid ostium and obstruct its drainage. This may be accomplished with a straight through-cutting or powered instrument.

- Blunt dissection to enter the sphenoid ostium and enlarge it using J-

curette or Cottle elevator

- Widening of the ostium laterally toward the lamina papyracea and superiorly toward planum sphenoidale to ensure long-term patency

Common Errors in Technique

1. Failure to identify the true natural ostium of the sphenoid sinus

2. Dissection inferiorly, through the posterior septal branch of sphenopalatine artery

3. Inadequate blunt dissection of the ostium, leading to difficulty passing the Kerrison or mushroom punch into the ostium

4. Contact with the posterior wall of the sphenoid sinus during ostial identification or dissection may lead to inadvertent injury to the carotid artery or optic nerve.

5. Limited mucosal preservation technique (except in tumor surgery), which can lead to scarring and restenosis of the sinus

6. Insufficient sphenoid ostial enlargement, which may also risk postoperative restenosis

7. Confusion of an Onodi cell/posterior ethmoid air cell for the sphenoid sinus

8. During sphenoidotomy, stripping of the mucosa of the anterior face of the sphenoid away from the rostrum bone, with displacement into the sphenoid sinus proper. This surgical maneuver can lead to loss of landmarks and significant bleeding within the sinus cavity.

Postoperative Period

Postoperative Management

1. Standard postsinus surgery instructions should be given.

2. Start saline irrigations on postoperative day 1.

3. In-office débridement and clearance of material from within the sinus

cavity (usually performed on postoperative day 7 to 14)

4. Typical medications include antistaphylococcal antibiotics, oral prednisone, and a short course of analgesic medications.

5. In-office endoscopic surveillance for evidence of ongoing inflammation and/or restenosis as indicated

Complications

1. Synechiae

Postoperative initial follow-up typically helps limit the extent of synechiae formation. If it occurs and also becomes symptomatic, cicatricial scar can often be resected in the office with through-cutting and powered instruments. If circumferential stenosis develops, this can sometimes be enlarged in office under local anesthesia with an elevator and mushroom punch.

2. Loss of olfaction. May result from overresection of ST containing olfactory filiae

Alternative Management Plan

1. Balloon sinuplasty. This procedure allows gentle widening of the ostium through the action of balloon-based dilation of the sphenoid ostium. Sinuplasty has the advantage of performance under local anesthesia in the office as an initial procedure or also in the operating room when combined with other sinonasal interventions. In-office/intraoperative image guidance platforms are available to confirm entry and placement of the balloon tip within the sinus airspace. This procedure may be indicated in patients suffering from chronic sinusitis without nasal polyps or diagnosed with recurrent acute sinusitis.

2. Ongoing medical therapy/observation. In most patients with inflammatory disease of the sphenoid sinus, continued medical therapy is an alternative.

Discussion

Evidence-Based Medicine Question

What is the risk of loss of olfaction with routine endoscopic sphenoidotomy?

Many rhinologic surgeons resect the inferior portion (one-fifth to one-third) of the ST to provide improved access to the sphenoid ostium. The ST has been shown to contain olfactory filae that are responsible for detection of odorants. Loss of olfaction has been associated with a decrease in quality of life.[2] Furthermore, it may result in practical dangers such as failing to detect spoiled food, smoke, natural gas, or other harmful substances.

Olfactory fibers emanate from perforations in the cribriform plate and innervate the olfactory epithelium located in the olfactory region of the nasal cavity, which includes the superior portions of the nasal septum and the medial surfaces of the superior and middle turbinates. A postmortem analysis of tissue from the superior and middle turbinates has shown the greatest concentration of olfactory neuroepithelium to be present in the posterior portion of the ST.[3] Previous authors have expressed concern that overzealous resection of the ST may lead to postoperative hyposmia or anosmia, but nonetheless these authors advocated partial inferior resection of the ST for improved, unobstructed access to the sphenoid ostium.[4]

In perhaps the most directed study on this question to date, histologic analysis of the olfactory neuroepithelium was performed on the inferior portion of the ST taken during endoscopic sinus surgery.[5] Olfactory fibers were detectable in only 16% of specimens. Twelve percent of patients in this cohort had complaints of olfactory loss after surgery, but none of the latter patients had olfactory neurons detectable on histology.

Much is still unknown about the effects on olfaction of endoscopic sinus surgery, including endoscopic sphenoidotomy. At present the available data suggest that resection of the inferior portion of the ST during sphenoidotomy provides a low risk for adverse olfactory outcomes (Fig. 110.3).

Editorial Comment

A third option for opening the sphenoid sinus is to approach in the midline. The posterior septum is disarticulated from the sphenoid rostrum with a Cottle instrument, and the rostral bone is removed with rongeurs or a drill to open both sides of the sphenoid sinus. The opening into the sphenoid sinus is then maximized with Kerrison rongeurs. This approach is advantageous when bilateral access is needed (skull base surgery) or when the natural sphenoid ostium is not visible due to mucosal edema or polypoid tissue. The anterior face of the sphenoid sinus can be safely punctured with a Frazier suction inferomedial to the sphenoid ostium where the bone is thinnest in most cases.

In patients with chronic inflammatory disease and osteitis of the bone, circumferential stenosis of the sphenoidotomy is common postoperatively. A wide sphenoidotomy that extends to the floor of the sinus or crosses the rostrum and intersinus septum will help prevent circumferential scarring and stenosis.

Carl H. Snyderman

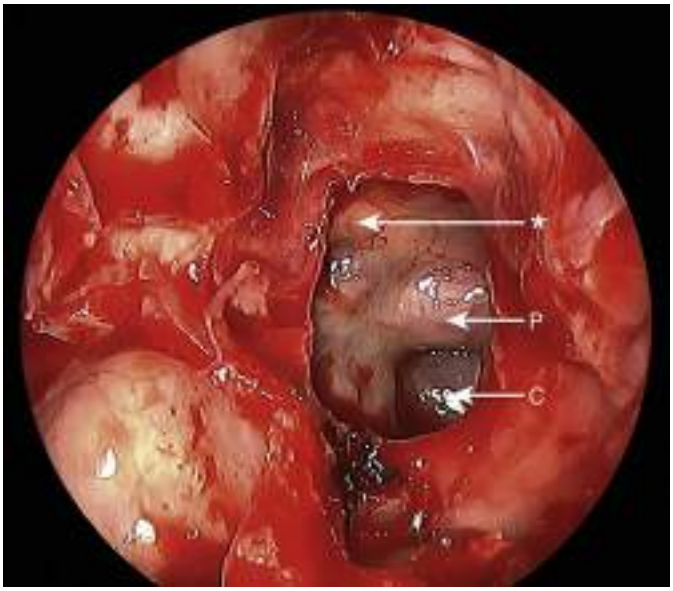

FIG. 110.3 Endoscopic view of right sphenoid sinus after completion of endoscopic sphenoidotomy procedure. The clival recess *(C)* and the pituitary gland *(P)* can be readily observed along the posterior wall of this sinus cavity, and the impression of optic nerve *(*)* is seen in the superolateral corner of this sinus.

Access the review questions online at http://www.expertconsult.com

Review Questions

1. In what quadrant of the sphenoid face is the sphenoid natural ostium located?

   a. **Inferior and medial**

   b. Inferior and lateral

   c. Superior and medial

   d. Superior and lateral

2. Onto what structure does the sphenoid face insert laterally?

   a. Planum sphenoidale

   b. **Lamina papyracea, sometimes optic nerve**

   c. Carotid artery

   d. Superior turbinate

3. What artery may be encountered during inferior enlargement of the sphenoid ostium?

   a. Internal carotid artery

   b. Maxillary artery

   c. **Posterior septal branch of the sphenopalatine artery**

   d. Posterior ethmoid artery

Trephination of the Frontal Sinus

Phillip Huyett, and Barry Schaitkin

Introduction

Trephination of the frontal sinus can be used in three ways. Traditionally, it was used for the drainage of acute processes such as a Pott's puffy tumor or bacterial frontal sinusitis. Second, trephination can be combined with transnasal endoscopic approaches to the frontal sinus for severe inflammatory disease or challenging frontal recess anatomy, frequently referred to as a minitrephine.[1] Finally, it can potentially obviate the need for an osteoplastic flap to introduce endoscopes and/or instruments to access far superior and far lateral inflammatory and noninflammatory conditions of the frontal sinus in select cases. This chapter discusses the use of trephination to instill water (minitrephine) or of the trephine as a portal to aid in the performance or outcome of an endoscopic sinus procedure.

Key Operative Learning Points

1. Three-dimensional computed tomography (CT) analysis of the frontal sinus is essential before performing a frontal trephine (Fig. 111.1A).

2. The landmarks for the trephine are the two supraorbital nerve foramina. A line connecting these two points is drawn, with an entry site ideally placed in the medial brow (see Fig. 111.1B).

3. Computer navigation can be helpful in performing a frontal sinus trephine.[2]

Preoperative Period

History

1. History of present illness
   a. The patient being considered for frontal sinus trephination is one who has failed medical therapy and is a candidate for endoscopic sinus surgery with a current frontal sinus component.
2. Past medical history
   a. Prior endoscopic surgery
   b. Status of the bony boundaries of the frontal sinus and orbits
   c. History of facial trauma or external surgery for the frontal sinus

Physical Examination

1. Nasal endoscopy to assess visualization of the outflow tract of the frontal sinus. This should include the presence of ipsilateral septal deviation and the size and configuration of the middle turbinate.

2. Palpation of the forehead will give a general indication of the bony prominence of the frontal sinus and its likely extent above the brow.

3. Palpation of the supraorbital foramina and testing of sensory function

Imaging

- Maxillofacial CT scan reconstructed in three planes, preferably with navigation capability (see Fig. 111.1B)
- The dimensions of the frontal sinus in sagittal, axial, and coronal planes should be reviewed on CT to establish the safe external position and depth of safe penetration for the trephine burr.

Indications

As endoscopic techniques have improved, so too has the ability of sinus surgeons to address frontal sinus pathology endonasally. The utility of frontal sinus minitrephine, therefore, has become increasingly limited.

Frontal sinus trephination does, however, remain a valuable tool as a stand-alone procedure, as an adjunct to frontal sinus endoscopy, and also as a combined endonasal and external approach for the following indications[3,4]:

1. Inflammatory frontal sinus pathology that meets criteria for endoscopic sinus surgery after medical therapy has failed
    a. Acute frontal sinusitis
    b. Chronic frontal sinusitis
    c. Pott's puffy tumor (subperiosteal abscess due to osteomyelitis of frontal bone)
    d. Mucocele
    e. Mucopyocele
2. Inability to resolve pathology with conventional endoscopic technique due to
    a. Inspissated secretions
    b. Altered nasofrontal anatomy (obstructing frontal cells, frontal recess scarring/stenosis and ossification)
    c. Inaccessible pathology (far lateral and superior)
3. Noninflammatory pathology of the frontal sinus
    a. Osteomas
    b. Fibrous dysplasia
    c. Inverted papilloma
    d. Repair of cerebrospinal fluid leak (CSF)
    e. Posterior table frontal sinus fracture
    f. Meningioma

Contraindications

1. Frontal sinus trephination is contraindicated in the patient with a small shallow frontal sinus due to the risk of unintentional drilling through the posterior table. Approximately 15% of nonhypoplastic frontal sinuses

will not accommodate safe trephination.[5]

Preoperative Preparation

1. Prepare the nose for traditional endoscopic surgery.

2. Prepare the forehead to include surgical landmarks.

3. Adjust the position of image guidance hardware if necessary to provide full access to trephine landmarks.

Operative Period

Anesthesia

- General: Although this procedure can be done with local anesthesia with awake sedation, general anesthesia is preferred for patient comfort.

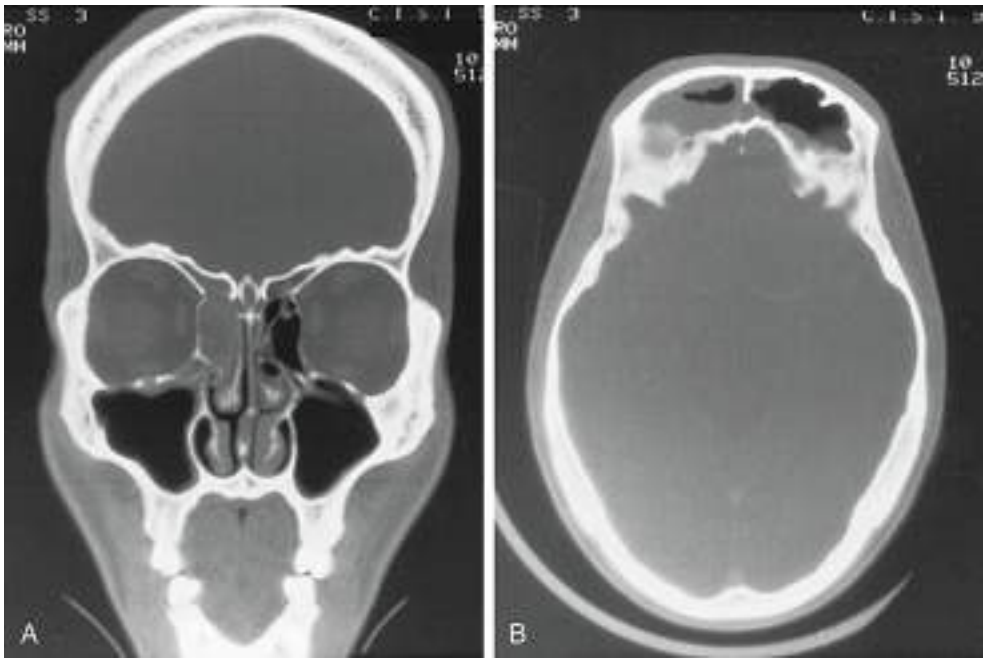

FIG. 111.1 **A,** Coronal computed tomography (CT) scan demonstrating right-sided frontal opacification with involvement of the anterior ethmoid sinus. **B,** Axial CT

scan displaying the air-fluid level in the right frontal sinus.

Positioning

- Supine: The patient is positioned the same as any endoscopic sinus procedure with the head turned slightly toward the surgeon.
- Palpation of the globe during instillation of saline is of utmost importance, so the use of a corneal shield is contraindicated.

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin to cover skin organisms unless a preoperative sinus culture suggests alternative coverage

Monitoring

- No routine monitoring required

Instruments and Equipment to Have Available

1. A #15 blade for incision

2. Most powered instrument companies manufacture a kit for frontal sinus trephination. Any drill can be used, but a kit will allow for the following advantages:

   a. Protection of the forehead soft tissue with a sleeve

   b. Ability to set a maximal depth of penetration

   c. The sleeve has teeth to grip the periosteum of the frontal bone, allowing for preservation and cannulation of the drill hole by the surgeon.

   d. A metal stylet for Seldinger technique

   e. A fluted irrigation canula to allow for a tight fit of the grommet to the frontal bone

3. Intravenous connecting tube

4. A 60-mL syringe

5. Culture swab

6. Normal saline for irrigation

7. Fast-absorbing 6-0 suture for closure

Key Anatomic Landmarks

1. A line connecting the supraorbital notches on each side guides the surgeon to a safe zone within which to enter the pneumatized portion of the frontal bone just above the medial brow (see Fig. 111.1).

Prerequisite Skills

1. Endoscopic techniques

2. Drilling skills

Operative Risks

1. Soft tissue burn of the skin of the forehead

2. Infection of the bone of the trephine site

3. Depression of the soft tissues into the trephine site if the trephine is large enough to allow for a scope and instrumentation and not just for the instillation of fluids

4. CSF leak if the posterior table is violated

5. Eye injury via irrigation into orbit from frontal bone dehiscence or corneal abrasion from working near globe

Surgical Technique

Mini–frontal sinus trephination (see Video 111.1)

- Complete endoscopic nasofrontal dissection to the extent necessary to

ensure trephination.

- Confirm anatomic landmarks with navigation, if available, or use palpable landmarks.
- Inject 1 mL of local anesthetic with epinephrine in planned incision site to provide vasoconstriction.
- Make a stab incision with a #15 blade in the medial brow along a line connecting the supraorbital foramina on a flat portion of the frontal bone.
  - The elasticity of the skin in this region will allow for the sinusotomy to be placed superiorly in the anterior table of the frontal sinus.

FIG. 111.2 Trephination of the frontal sinus for acute frontal sinusitis.

- While elevating the brow with the nondominant hand, dissect bluntly down to the frontal bone, leaving the periosteum in place.
- Place the soft tissue sleeve with the nondominant hand, and engage the soft periosteum with the teeth of the sleeve.
- Drill at a relatively slow speed with constant irrigation using preoperative sinus dimensions to guide maximum allowable penetration.
- Remove drill, maintaining the position of soft tissue sleeve.
- Insert a metal stylet, remove the sleeve, and, using the Seldinger technique, place the fluted frontal sinus grommet.

- Connect a 60-mL saline syringe and withdraw to confirm no clear fluid or blood.
- A diseased sinus may yield purulent material, a sample of which can be sent for culture. Air will be aspirated from an aerated sinus. Either confirms placement in the sinus.
- Slowly instill water, monitoring orbital tension with palpation and simultaneously observing endoscopically for confirmation of the frontal sinus outflow tract.
- Depending on indication, proceed with endonasal work on frontal recess or complete irrigation of sinus.
- The skin is closed with a single 5-0 or 6-0 fast gut suture. Alternatively, the grommet can be left in place for continued frontal sinus irrigation and removed at a later time.

Traditional frontal sinus trephination

- Once the need for a frontal sinus trephination has been determined, local anesthetic with epinephrine is injected into the medial brow.
- A 1-cm incision is made with a #15 blade in the medial brow.
  - Alternatively, if the trephine is being used to insert instruments, including scopes, many authors will use a Lynch incision and a more inferior approach, where the bone is thinner.
- Blunt dissection is performed down to the periosteum while retracting the brow superiorly with the nondissecting hand Fig. 111.2.
- The periosteum is incised with a #15 blade and elevated with a Freer elevator or cottle.
- A cutting burr is used to drill through the anterior table of the frontal sinus with care not to violate the posterior table Fig. 111.3.
- If a portal is to be used for instrumentation, create an adequate portal to
  - Visualize instrument endonasally
  - Or visualize frontal sinus via trephine and pass instrument endonasally
  - Or make an adequate portal for both instrument and endoscope and

address lateral pathology via the trephine portal

- Two-layer closure with a 4-0 absorbable suture deep and 5-0 or 6-0 fast gut suture superficially

Common Errors in Technique

1. Loss of brow hair follicles by beveling knife during incision

2. Inability to find drill hole after drill bit is removed because of slippage of sleeve protecting soft tissue or lack of use of a sleeve

3. Failure to irrigate or excessive drill speed leading to increased heat and a thermo injury to bone and soft tissue

4. Failure to prevent burr penetration beyond inner aspect of anterior frontal sinus table, causing CSF leak

5. Poor patient selection (patient with small sinus) or inability to reach pathology

Postoperative Period

Postoperative Management

1. Standard postoperative antibiotics, ideally culture-directed

2. Wound care to include 5 days of topical antibiotic cream to frontal suture site

3. Pain medication as in normal endoscopic sinus surgery

4. Saline irrigations

5. Resumption of anticoagulants/antiplatelet drugs

6. Rarely, a patient will be discharged home with the trephine grommet or catheter in place to perform self-irrigation, usually with antibiotics.

Complications

1. If soft tissue burn occurs from the drill, excise and close soft tissue.

2. If posterior table injury occurs with CSF leak, manage by whichever route may be required to provide adequate exposure, including, if necessary, conversion to open technique. Always obtain a postoperative CT scan to ensure that there is no intracranial extension.

3. If, during instillation of saline, the orbit begins to protrude, stop irrigation and withdraw. The body will reabsorb the saline fairly quickly with gentle orbital massage with no need for canthotomy. If, upon extubation, the patient has visual complaints, an ophthalmology consult should be obtained.

4. Continued frontal sinus process due to recurrent disease or scar

5. Forehead hypoethesia related to excessive retraction or inappropriate incision location in traditional trephination

6. Infection related to improper skin care postoperatively

Alternative Management Plan

1. Advanced frontal sinus technique (Draf 1 to 3)[6] (see Chapter 113)

2. Balloon sinuplasty (see Chapter 102)

3. Bicoronal incision with osteoplastic flap (see Chapter 114)

Discussion

Evidence-Based Medicine Question

Is minitrephination of the frontal sinus beneficial in identifying the frontal sinus outflow tract in the era of advanced endoscopic techniques?

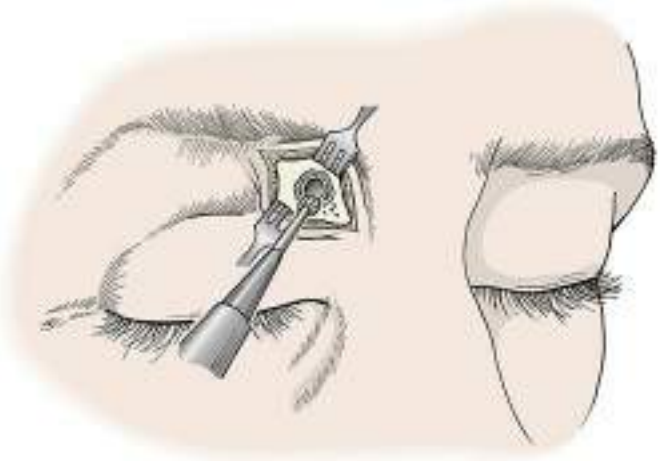

FIG. 111.3 Trephination is performed through an incision made in the medial aspect of the brow. The floor of the frontal sinus is exposed, and a drill with a cutting burr is used to create an opening in the floor of the frontal sinus. The lateral wall of the nasal frontal recess is then removed to provide communication between the frontal sinus and the middle meatus.

Yes, in a retrospective case series of 163 patients, the frontal sinus outflow tract was successfully identified in all cases.[7] There were a total of 149 bilateral and 39 unilateral frontal sinus minitrephines performed in patients undergoing frontal sinus surgery for severe inflammatory disease (mean Lund-Mackay score 17.5) Fig. 111.2. Minitrephine was indicated based on severe edema (n = 50), a narrowed frontal recess (n = 35), obstructing frontal cells (n = 26), and to assist in frontal sinus drill out (n = 77). There were seven patients who experienced complications, most commonly trephine site infection (n = 4). Follow-up was a mean of 25.5 months, with a 92% frontal sinus patency rate.

Editorial Comment

Frontal sinus trephine was more commonly performed prior to image guidance and more refined frontal sinus instrumentation. With this minimal incision, instillation of liquid via a trephination can aid in the identification of the frontal outflow tract as well as the irrigation of trapped secretions. Because extended endoscopic frontal sinus procedures are increasingly used and commonplace, the ability to

manage frontal sinus disease via an endonasal corridor has also increased. However, in certain anatomic locations, problematic cases of chronic frontal sinusitis remain challenging. When frontal sinus pathology is present lateral to the midpupillary line, external approaches to the frontal sinus, such as a trephine, are used to access the lateral frontal recess. Familiarity with this safe and effective technique remains invaluable for the Otolaryngologist who treats frontal sinus disease.

Review Questions

1. Landmarks for frontal sinus trephination include

   a. The lateral eyebrow

   b. A line drawn between supratrochlear notches

   c. **A line drawn between supraorbital notches**

   d. A line drawn between the infraorbital foramina

2. Potential complications of frontal sinus trephination include all of the following, except

   a. **Anosmia**

   b. Increased intraocular pressure due to irrigation

   c. CSF leak

   d. Soft tissue burn

3. What percentage of frontal sinuses will not accommodate trephination?

   a. 5%

   b. **15%**

   c. 40%

   d. 80%

Endoscopic Approach to the Frontal Sinus

Barry M. Schaitkin, and Li-Xing Man

Introduction

The endoscopic approach to the frontal sinus is predicated on understanding the anatomy of the frontal recess. The frontal sinus outflow tract is dependent on the anatomic relationships of various structures, including the uncinate process, middle turbinate, agger nasi, and frontoethmoid cells. Most commonly, the uncinate process ascends from its inferior and anterior attachments to the inferior turbinate and lacrimal bone, respectively, to blend in with the medial wall of the agger nasi cell (Fig. 112.1).[1] In such cases—85% of the time—the frontal sinus will drain between the uncinate process and the middle turbinate. In the remaining cases, the uncinate attaches to the middle turbinate or the skull base, resulting in the frontal sinus draining directly into the infundibulum. If the uncinate attaches both medially to the middle turbinate and laterally to the agger nasi, the frontal sinus will drain posteriorly.

Key Operative Learning Points

- Excellent understanding of frontal sinus anatomy is imperative to achieve optimal surgical outcomes.
- Preoperative preparation with review of computed tomography (CT) scan anatomy using imaging software capable of three-dimensional multiplanar reconstructions similar to the software incorporated by image guidance systems is strongly encouraged.
- Proper exposure and visualization are fundamental to good frontal

sinus surgery.

Preoperative Period

History

1. History of present illness

   a. Patients with chronic frontal sinus disease are considered surgical candidates according to the same criteria as for other endoscopic sinus surgery. They should have significant symptoms of sinusitis in accordance to the criteria proposed by the American Academy of Otolaryngology–Head and Neck Surgery despite maximal medical therapy.

   b. Those with isolated or severe forehead/frontal pain relative to other symptoms should be counseled that their main complaint may not improve with endoscopic sinus surgery even when imaging reveals frontal disease.

2. Past medical history

   a. Relevant comorbidities include the presence or absence of aspirin sensitivity, asthma, atopy, and eosinophilia.

   b. New or continued frontal sinus problems despite prior history of sinus surgery may suggest chronic inflammatory disease of the sinonasal mucosa or scarring of the frontal recess such as from synechiae between the middle turbinate and the lateral nasal wall or between the middle turbinate and the anterior face of a suprabullar cell.

Physical Examination

1. Nasal cavity

Nasal endoscopy may reveal significant inflammation in the middle meatus such as from nasal polyps. Patients who have previously undergone sinus surgery may have visible scarring in the frontal recess or anterior ethmoid cells. The location and quality of secretions should be noted.

2. Face

Although thankfully rare, complications from frontal sinusitis may present with abnormal findings on physical examination. Orbital complications may present as proptosis or orbital cellulitis. Visible, palpable swelling of the forehead may suggest osteomyelitis and subperiosteal abscess of the anterior table (Pott's puffy tumor).

Imaging

1. CT scan of the sinuses

All patients undergoing frontal sinus surgery should have a CT scan of the sinuses performed. Modern radiation dose-reducing CT scanners, which reduce radiation exposure by up to 40%, may be used to obtain fine-cut images (0.6 to 1.0 mm) through the sinuses that are adequate for creating multiplanar reconstructions for preoperative planning, as well as intraoperative image guidance with negligible increase in overall radiation dosage. Most frequently, fine-cut axial images are used to reconstruct coronal and sagittal images for image guidance, but some systems have the ability to reconstruct from coronal slices as well. Preoperatively, review of images in both the coronal and sagittal planes may be useful. When intraoperative image guidance is considered, we strongly encourage preparation with the use of imaging software capable of multiplanar reconstruction, often abbreviated as MPR, which allows the surgeon to review all three planes simultaneously with crosshairs in each plane much like what is provided during surgery.[2]

Radiographs should be reviewed carefully before surgery to evaluate the uncinate process, agger nasi region, and the size and depth of the frontal sinus. The most important aspect of surgical planning is accurate understanding of the three-dimensional impact of the size and configuration of all cells surrounding the frontal recess. Images should be reviewed to note the position of the anterior ethmoid artery and the presence or absence of supraorbital ethmoid cells. Patients should be suspected of having supraorbital ethmoid cells if multiple septations are seen within the frontal sinus on coronal images. Preoperative three-dimensional models may also be created to further understand the frontal sinus drainage pathway in preparation for surgery.[2]

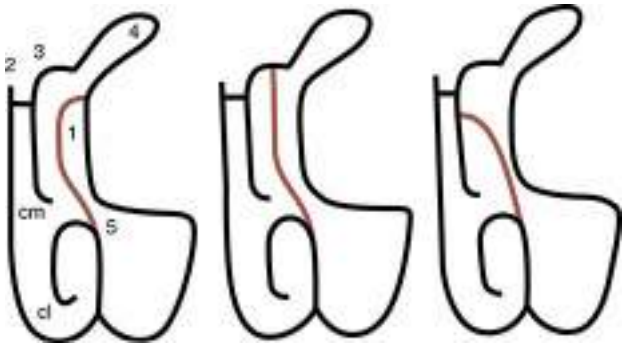

FIG. 112.1 Line diagram of the uncinate attachment.

2. Magnetic resonance imaging (MRI)

Although MRI is not routine, it may be helpful in patients with known or suspected tumors or mucoceles involving the frontal sinuses.

Indications

1. Chronic frontal sinusitis refractory to maximal medical therapy, including the following:
   a. Eosinophilic or noneosinophilic inflammatory chronic rhinosinusitis with or without nasal polyposis
   b. Mechanical obstruction
      1) Anatomic variants of frontal recess structures
      2) Osteomas
   c. Frontal sinus mucoceles
2. Acute frontal sinusitis with
   a. Severe disease refractory to medical management (i.e., intravenous antibiotics)
   b. Intracranial or orbital complications
3. Limited tumors involving the frontal sinus that do not require an open procedure

Contraindications

1. Uncomplicated acute frontal sinusitis

2. Extensive tumors involving the frontal sinus that may benefit from open surgery

3. Medical comorbidities with increased risk for general anesthesia

4. Inadequate surgical instrumentation or surgeon expertise

Acute frontal sinusitis is *not* usually a good indication for endoscopic frontal sinus surgery. These patients have significant hyperemia and inflammation, and there is a high likelihood of creating symptomatic scarring in the frontal recess. If there are intracranial or orbital complications from acute frontal sinusitis that are refractory to intravenous antibiotics, the decision to intervene surgically via a classic frontal sinus trephination versus an endoscopic approach may be considered on a case-by-case basis.

Preoperative Preparation

1. Discontinue antiplatelet drugs.

2. Systemic steroids and/or antibiotics may be used to decrease vascularity and edema in the frontal recess. Given the limited confines of the frontal recess, bleeding and the resultant decreased visibility may compromise the surgical dissection.

Operative Period

Anesthesia

- General anesthesia with oral endotracheal intubation is preferred for patient comfort and protection of the airway. Compared with monitored anesthesia, general anesthesia also minimizes the risk of unexpected patient movement during delicate dissection of the frontal recess.
- Taping of the endotracheal tube should be limited to the lower lip. For the right-handed surgeon an oral Ring-Adair-Elwyn (RAE) tube placed to the left of the tongue and taped to the left lower lip provides ideal

access to the nasal cavity.

Positioning

- The patient is positioned supine in the same way as any endoscopic sinus surgery procedure, per surgeon preference. The head may be turned slightly toward the surgeon.
- Elevating the head by 30 degrees may decrease intraoperative bleeding.
- The eyes should be undraped and available for visualization and palpation.

Perioperative Antibiotic Prophylaxis

- There is no evidence-based indication for intraoperative antibiotics, although frequently a first-generation cephalosporin (or clindamycin if patient is penicillin or cephalosporin allergic) is used at induction per surgeon preference.
- If postoperative packing material is used, the surgeon may elect to prescribe a first- or second-generation cephalosporin. The junior author will often prescribe 1 week of cefadroxil, a first-generation cephalosporin with twice daily dosing, to improve patient adherence rather than the more commonly prescribed cephalexin.

Monitoring

- No monitoring is necessary.

Instruments and Equipment to Have Available

1. Basic endoscopic sinus surgery set

2. Frontal sinus surgery set

3. 0-, 30-, 45-, and 70-degree endoscopes; “reverse-post” angled endoscopes are helpful to allow the light cord to up and away from

instruments

4. Angled microdébrider tips and/or drill burs, if the use of powered instrumentation is anticipated

5. Navigation system, if image guidance is to be used. Some authors prefer to use navigation in all frontal sinus cases and others just in revision or difficult cases. There is currently no evidence that image guidance improves outcomes.

Key Anatomic Landmarks

- The endoscopic approach to the frontal recess is predicated upon dissecting and navigating around surrounding structures, including the following:
  - Anterior—uncinate, agger nasi, and Kuhn-type frontal cells
  - Posterior—ethmoid bulla, suprabullar, and supraorbital ethmoid cells
  - Lateral—uncinate, agger nasi, and Kuhn-type frontal cells prior to dissection and lamina papyracea after removal of anterolaterally based cells
  - Medial—attachment of the middle turbinate and lateral lamellae of the cribriform plate
- The axilla of the middle turbinate as it attaches to the lateral nasal wall marks the anteroinferior limit of the agger nasi region.
- The slope of the posterior table of the frontal sinus as it joins the ethmoid skull base determines the anterior-to-posterior dimension of the frontal recess after frontal sinusotomy.
- If a supraorbital ethmoid cell is present, the true frontal recess will be medial and anterior to the opening of the supraorbital ethmoid cell.
- The anterior ethmoid artery is often at the posterior margin of the frontal recess (Fig. 112.2).

Prerequisite Skills

- Advanced endoscopic sinus surgery skills, including the facile ability to use angled 45- and 70-degree endoscopes
- Capability to integrate axial, coronal, and sagittal CT images into a three-dimensional understanding of the anatomy

Operative Risks

- Intraoperative hemorrhage, including injury of the anterior ethmoid artery
- Cerebrospinal fluid (CSF) leak
- Stripping of mucosa will increase the risk of postoperative synechiae formation

Surgical Technique

- To maintain a dry field, oxymetazoline 0.05% spray may be given at 10-minute intervals in the preoperative holding area for 30 minutes. Alternatively, the oxymetazoline 0.05% may be applied via ½- by 3-inch radiopaque neurosurgical patties in the nasal cavity after induction while the patient is being positioned for surgery.
- All procedures are done with the injection of local anesthetic, 1% lidocaine, and a vasoconstrictor, 1:100,000 epinephrine. The injections may include the superior attachment of the middle turbinate, the inferior aspect of the uncinate process, and the junction of the middle turbinate basal lamella with the palatine bone.
  - The junior author bends the needle at 45 degrees approximately 1.5 cm from the tip and enters the lateral nasal wall along the maxillary line just above the inferior turbinate, advancing the needle submucosally superiorly toward the axilla of the middle turbinate. The injection is performed while withdrawing the needle slowly (Video 112.1 Maxillary line injection). This results in a single puncture site inferiorly, away from the area of frontal sinus surgery.
  - A 25- to 27-gauge needle on a 3-mL syringe is ideal for the superior attachment of the middle turbinate and uncinate injection, and a 22-gauge spinal needle bent at 45 degrees 1.5 cm from the tip on a 3-mL

syringe allows for more rigidity and easy access to the area of the sphenopalatine artery branches as they exit the palatine bone (Video 112.2 Sphenopalatine area injection).

- Neurosurgical patties with oxymetazoline and/or adrenaline are then placed in the middle meatus and over the nasal swell body after the local is injected.
- The surgery commences after local anesthetic and vasoconstrictor have had 5 minutes to take effect.

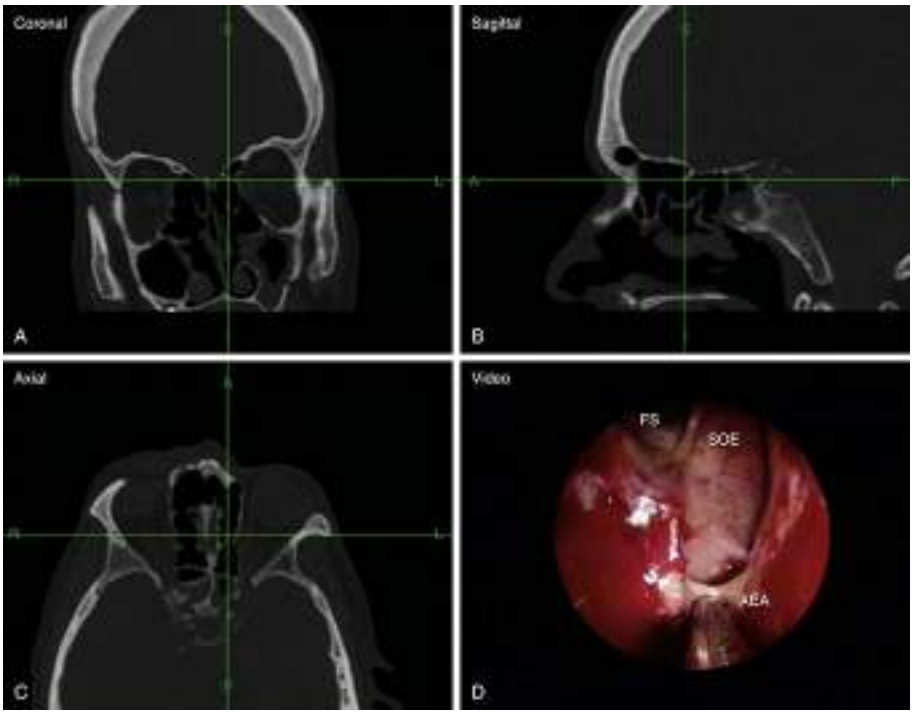

FIG. 112.2 Image guidance localization of the anterior ethmoid artery (AEA) at the posterior border of the opening to the frontal sinus (FS) and supraorbital ethmoid (SOE) cell in the coronal **A**, sagittal **B**, and axial **C** planes. The endoscopic **D** view shows the image guidance suction on the AEA. The suction navigator and crosshairs are localized on the bone surrounding the anterior ethmoid artery. Note the partition between the frontal recess and the supraorbital ethmoid cell. The frontal recess is medial and anterior to the supraorbital ethmoid cell opening.

Basic Endoscopic Surgery of the Frontal Recess

- The approach to the frontal sinus starts with uncinectomy. There are various techniques for uncinectomy that may be used depending on surgeon preference, including removal using (1) a backbiter and 90-degree Blakesley forceps; (2) microdébrider; and (3) sickle knife. A Hosemann punch or an angled Stammberger mushroom punch may be used to remove bone from the nasofrontal process between the anterior superior attachment of the middle turbinate and lamina papyracea, which forms the anterior wall of the agger nasi region (Fig. 112.3).[3] This allows the use of less-angled endoscopes in the initial dissection and may be understood conceptually as a simplified version of the axillary flap technique[4] when a mucosal flap is unnecessary.
- Dissection of the frontal recess requires frontal sinus instruments and a precise appreciation of the patient-specific anatomy of this region. Readers should review and understand the classification of frontoethmoid cells by Kuhn et al.[5] It is also useful to learn some of the other, more recently proposed, nomenclature systems.[6,7] An ethmoidectomy based on the extent of disease should be performed prior to dissection of the frontal recess to provide adequate space for instruments to work along the ethmoid skull base from a posterior-to-anterior direction.

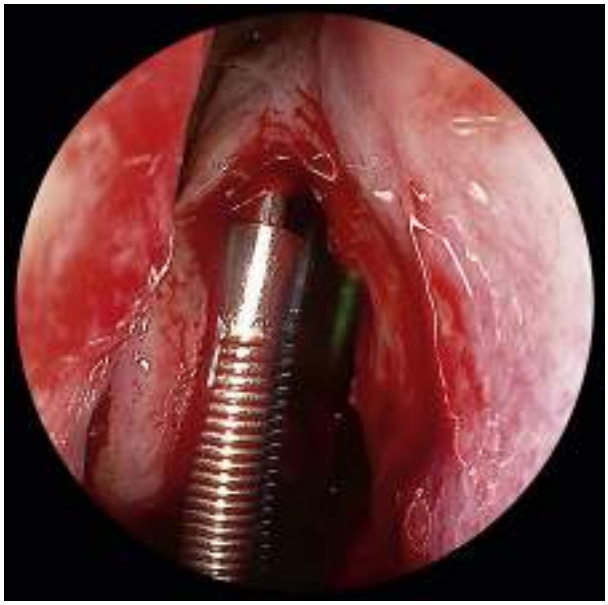

FIG. 112.3 Removal of bone from the nasofrontal process using a Hosemann punch.

- The frontal recess is approached from a posterior-to-anterior and a medial-to-lateral direction, staying anterior, lateral, and inferior to the thin lateral lamella of the cribriform plate and posterior table of the frontal sinus.
  - Generally a 30-degree reverse-post endoscope is used in the initial more posterior and inferior limits of dissection, gradually switching to more angled endoscopes as the dissection proceeds anteriorly and superiorly.
  - The anterior ethmoid artery is often identified at the posterior border of the supraorbital ethmoid cell (when present) or at the posterior aspect of the frontal recess as one advances from posterior to anterior.
  - If intraoperative image guidance is used, an angled 70- or 90-degree navigational seeker may be gently slipped into the frontal sinus to confirm the frontal drainage outflow pathway even before significant dissection has commenced (Fig. 112.4).
- Because the frontal sinus most commonly drains between the middle turbinate and the agger nasi-uncinate complex, the drainage pathway is most frequently medial and posterior to the posterior wall of the agger nasi. The medial and posterior walls of the agger nasi and type I

or II frontal cells are removed because they are not involved in the skull base. These cells may be resected either sharply with angled frontal sinus punches (Fig. 112.5, Video 112.3) or fractured in a posterior-to-anterior direction using 55- or 90-degree curette under visualization with a 45- or 70-degree endoscope. Bone fragments are then removed using angled non-cutting "giraffe" forceps or an angled microdébrider, taking care to avoid grabbing and stripping mucosa (Fig. 112.6, Video 112.4). During challenging dissections, sometimes changing the angle of view (e.g., from a 45- to 70-degree endoscope) may allow the surgeon to understand the anatomy in a new light and progress with the surgery.

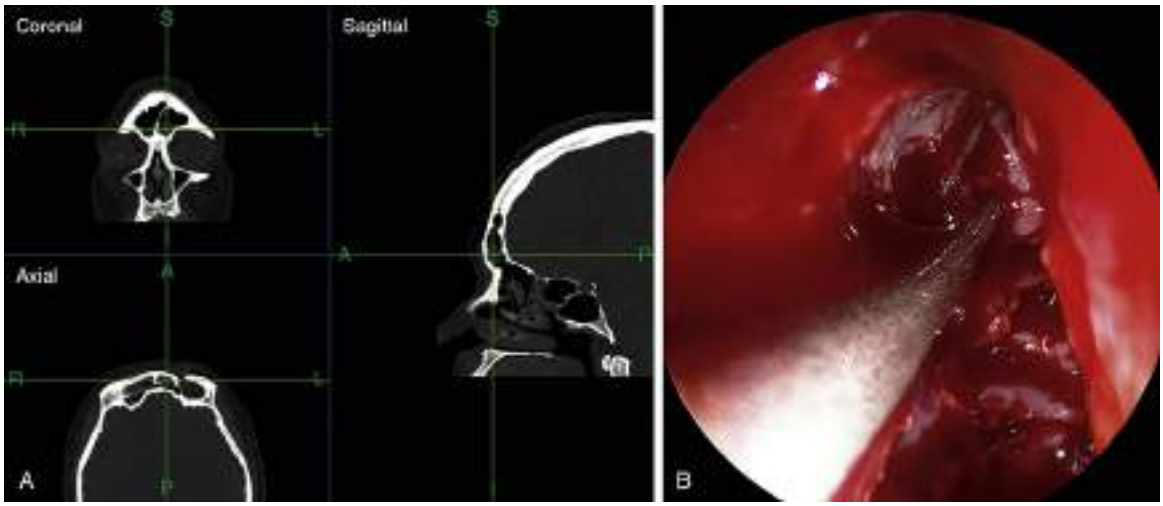

FIG. 112.4 Image guidance using tri-planar computed tomography imaging **A** with 45-degree endoscopic view **B**. Insertion of an angled image guidance seeker into the frontal sinus may help delineate the frontal outflow pathway even before significant dissection has occurred.

- After the agger nasi and any Kuhn frontal cells are removed, the opening to the frontal sinus may be enlarged anteriorly and laterally using a Hosemann frontal sinus punch (Karl Storz, Tuttlingen, Germany) or an angled Kerrison (Bachert) punch (Fig. 112.7). The frontal sinus is then typically left alone.
- Rarely, the frontal sinus opening is stented, depending on the diameter of the frontal sinus opening and degree of mucosal inflammation. Relative indications for stenting include (1) narrow ostial diameter (<5

mm); (2) extensive or circumferential mucosal trauma with bone exposure; (3) severe polyposis or mucosal hyperplasia; (4) destabilized or lateralized middle turbinate; and (5) frontoethmoid mucoceles indicative of long-standing chronic sinus disease or prior surgical failures.[8,9]

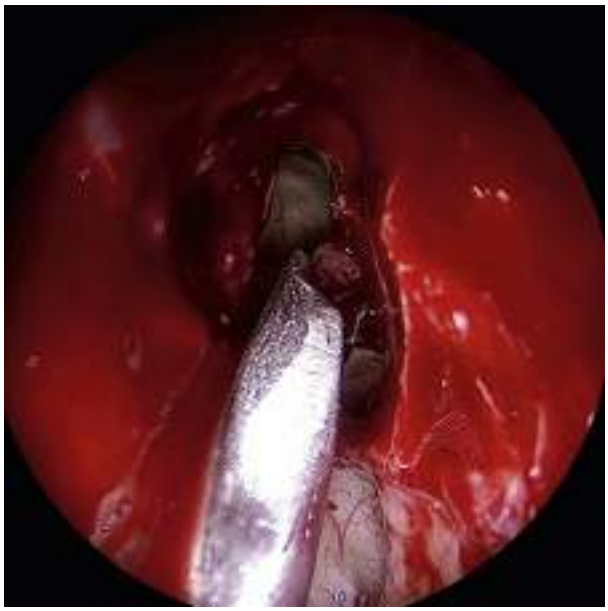

FIG. 112.5 Intraoperative photo demonstrating the use of a frontal sinus punch to remove a bony partition.

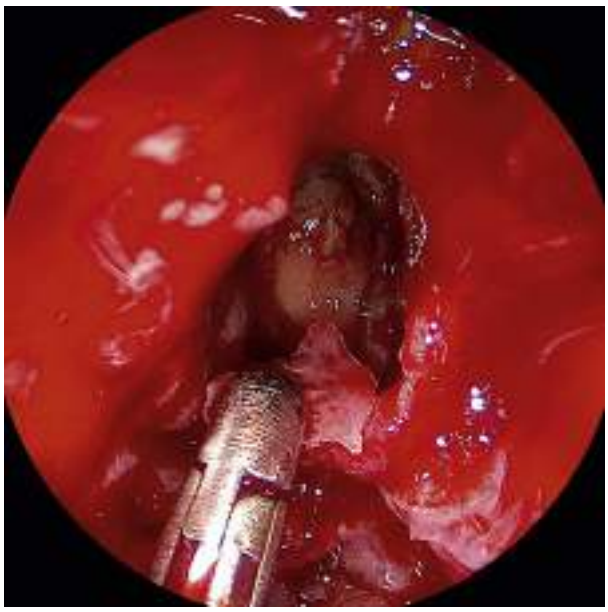

FIG. 112.6 Intraoperative photo demonstrating the use of an angled non-cutting forceps to remove a bone fragment.

Frontal Sinus Rescue

- Surgeons should have multiple techniques in their armamentarium for coping endoscopically with a troublesome frontal sinus. One of the most common problems encountered in revision endoscopic surgery of the frontal sinus is a lateralized middle turbinate stump when a previous surgeon has removed the inferior aspect of the middle turbinate. This may be effectively dealt with using the frontal sinus procedure as described by Kuhn et al.[10]
  - This procedure involves a mucoperiosteal flap rotation. The middle turbinate stump may be scarred to the agger nasi, Kuhn-type frontal cells, or the lamina papyracea.
  - The synechiae between the middle turbinate and lateral structures is removed, and the frontal recess is identified and entered.
  - The nasal mucosa and sinus mucosa are dissected off the medial and lateral aspects of the bony middle turbinate remnant, respectively.
  - Next, the middle turbinate bone and nasal mucosa are resected at the skull base. The flap of the frontal sinus mucosa is subsequently rotated superiorly and medially to cover the roof of the nasal vault.

Common Errors in Technique

- Through-cutting instruments should be used whenever possible to avoid stripping of mucosa.
- Punches such as the Hosemann should be cleaned regularly during the procedure to maintain sharp cutting surfaces and to avoid spillage of loose bone and mucosa in the surgical field.
- The angled scopes do not have to be constantly in the 12-o'clock position. The light post may be moved slightly to rotate the angle of view for improved visualization.
- Oozing of blood in the tight confines of the frontal recess may limit

visualization. Rather than continue with dissection through this blood, the oozing is usually easily controlled by temporarily placing oxymetazoline- and/or adrenaline-soaked neurosurgical patties prior to continuing with surgery.

FIG. 112.7 Intraoperative photo demonstrating the use of a Hosemann punch to enlarge the frontal sinus opening.

Postoperative Period

Postoperative Management

- These surgical procedures are typically performed on an outpatient basis.
- No packing, an absorbable or nonabsorbable dressing, or a steroid-eluting stent may be placed at the end of surgery, depending on surgeon preference. The authors typically use either no dressing or a self-absorbing dressing in the middle meatus and anterior ethmoid area, below the frontal recess. A dressing may be considered, especially if the middle turbinate has been destabilized during surgery or if treatment with topical steroids in the immediate postoperative period is desired.

- Frequent isotonic saline irrigations using a low-pressure, high-volume (240 mL) squeeze bottle, multiple times per day, are started on postoperative day 1.
- Meticulous and gentle postoperative débridement is performed in the clinic approximate 1 and 2 weeks after surgery. With respect to the frontal sinus, these procedures provide the opportunity to lyse early synechiae and to remove fibrinous debris from the frontal recess.

Complications

1. Hemorrhage

2. Synechiae

3. Unintended entry into the central nervous system and resultant cerebrospinal fluid rhinorrhea

4. Unintended entry into the orbit

Alternative Management Plan

- Limited frontal sinus disease may be addressed using balloon dilation techniques (see Chapter 102).
- Severe, complicated acute frontal sinusitis may be managed with classic frontal sinus trephination (see Chapter 19).
- More significant chronic frontal sinus disease may be managed with frontal sinus drill out procedures (Draf IIB, Draf III) (see Chapter 24).
- Select cases may require frontal sinus obliteration or cranialization, although the indications for such procedures are shrinking as endoscopic instrumentation and skills become more widespread.
- Patient disease, surgeon comfort and expertise, as well as the availability of surgical instrumentation may dictate that open frontal sinus surgery be performed.

Discussion

Evidence-Based Medicine Question

Does the use of image guidance for frontal sinus surgery reduce complications or improve outcomes?

Answer

Although navigation is often used for primary or revision frontal sinus surgery, most individual studies on image-guided surgery (IGS) do not show evidence of benefit to the patient or surgeon with the use of this technology. However, when data from multiple studies are pooled, there is evidence that the use of image guidance in endoscopic sinus surgery may reduce the risk of complications. In a meta-analysis of 14 studies comparing IGS versus non-IGS patient cohorts, major complications—defined as inadvertent entry into areas beyond the nasal cavity and/or paranasal sinuses, postoperative bleeding requiring surgical or angiographic intervention, and the need to abort the procedure for a surgical reason—were greater in the non-IGS group (relative risk [RR] 0.48; 95% confidence interval [CI] 0.28 to 0.82; P = .007). Total complications were also more common in the non-IGS group (RR 0.66; 95% CI 0.47 to 0.94; P = .02).

Editorial Comment

The indications for an endoscopic frontal sinusotomy remain an area of investigation. Endoscopic frontal sinusotomy has traditionally been classified using the Draf system. Draf I essentially is an ethmoidectomy without manipulation of the frontal recess. This chapter describes a Draf IIA, the most common endoscopic frontal sinus surgery. By removing the bony partitions of the frontal recess between the middle turbinate and the orbit, the maximum bony dimensions of the frontal recess are created with preservation of normal structures, specifically the middle turbinate. In general, this is a highly effective procedure in most cases of chronic

rhinosinusitis. In cases of severe polyposis, some surgeons advocate extended frontal sinus procedures, such as a Draf IIb and Draf III procedure, which extend the surgical resection beyond the frontal recess and resect part or all of the floor of the frontal sinus. However, there are limited data to determine when extended approaches should be favored over a Draf IIa frontal sinusotomy.

Review Questions

1. Approximately what percentage of the time will the frontal sinus drain between the uncinate process and middle turbinate?

   a. 65%

   b. 75%

   c. **85%**

   d. 95%

2. Which of the following is NOT a contraindication to the endoscopic approach to the frontal sinus?

   a. Squamous cell carcinoma involving the dermis of the forehead eroding into the frontal sinus

   b. **Bony dehiscence of the posterior table of the frontal sinus**

   c. Severe medical comorbidities resulting in general anesthesia putting the patient at high risk for poor outcome

   d. Isolated acute frontal sinusitis with cerebritis and seizures despite broad-spectrum intravenous antibiotics

3. All of the following are boundaries of the frontal recess, except

   a. **Middle turbinate basal lamella**

   b. Superior portion of the uncinate process

   c. Agger nasi

   d. Lamina papyracea

4. All of the following are ideal candidates for frontal sinus surgery, except

   a. **Patient with frontal headache**

   b. Patient with frontal sinus mucocele

   c. Patient with symptomatic frontal sinus obstruction from synechiae

   d. Patient with an osteoma occluding the frontal recess

5. The frontal sinus rescue procedure is designed to endoscopically manage which problem?

   a. A dehiscent posterior table

   b. A tier of frontoethmoid cells

   c. **A lateralized middle turbinate stump**

   d. A Keros type 3 configuration

Draf III, Endoscopic Modified Lothrop

Eric W. Wang, and Chirag R. Patel

Introduction

Chronic frontal sinusitis continues to be a challenge to treat both medically and surgically. Despite the advances in endoscopic sinus surgery, the wide variety of surgical options necessary for treatment of frontal sinusitis speaks to the difficult nature of managing disease in this location. Refractory frontal sinusitis in particular has challenged sinus surgeons for years.

In the early 1900s, ablation of the frontal sinus by removing the anterior table and stripping all of the mucosa was tried. This left a marked cosmetic deformity and carried a high failure rate. A period of conservative approaches followed, with a number of intranasal procedures being described to try to avoid the cosmetic defect; however, these were fraught with complications, including intracranial injuries. In 1914 Lothrop described a procedure in which an intranasal ethmoidectomy combined with an external ethmoid approach allowed him to create a common frontal nasal communication. He felt that this large frontal drainage pathway would prevent stenosis and closure, which was a problem with the other approaches in that time period. Unfortunately the lack of visualization made the procedure dangerous, and resection of the medial orbit resulted in enophthalmos.

Several authors at that time also described what has come to now be known as the osteoplastic approach. Little attention was paid to this approach due to the difficulty replacing the bone flap to its original position. It was not until the 1950s that an osteoplastic flap with frontal sinus obliteration was popularized, and it ultimately can be considered the gold standard in the treatment of refractory frontal sinusitis.

As endoscopic sinus surgery evolved in the 1980s, endoscopic frontal

sinus surgery also advanced. In 1991 Wolfgang Draf published a graduated approach to the frontal sinus that he classified as Draf I, II, and III. This classification system is now accepted as the standard for describing the extent of surgery performed during endoscopic frontal sinus procedures. Draf III is an adaptation of the Lothrop procedure performed completely endonasally and consists of forming a single large frontal neo-ostium by removing the floor of the frontal sinus, superior septum, intersinus septation, and nasofrontal beak. As such, it has also come be known as an endoscopic modified Lothrop procedure (EMLP).[1]

Key Learning Points

- The limits of the Draf III are the first olfactory fibers posteriorly, the anterior table of the frontal sinus anteriorly, and the periosteum over the frontal process of the maxilla laterally.
- Proficiency with revision sinus surgery and endoscopic frontal sinus surgery should be achieved prior to attempting Draf III.
- Careful patient selection will help avoid complications and rates of postoperative stenosis.
- Extending the head with a shoulder roll can improve the angle of approach and alleviate having the patient's chest as an obstacle.
- An anterior to posterior (AP) diameter neo-osteum greater than 1.5 cm will reduce the chances of stenosis.
- A small superior septectomy will limit visualization and increase the likelihood of postoperative crusting.
- The use of stents has not been clearly shown to reduce the rate of postoperative stenosis.

Preoperative Period

History

1. History of present illness

   a. Document a detailed account of the patient's current symptoms.

1) Up to 16% of people have no change in symptoms after Draf III, and 1.2% have worsening symptoms.[2]

2) Asymptomatic recurrent frontal sinus opacification does not necessarily require surgery.

b. For patients with a history of inflammatory sinus disease, document a thorough review of their sinusitis history, including prior and current medical management.

1) Presumed origin of underlying mucosal disease

2) Symptoms and their duration including forehead or frontal pressure

3) History of nasal polyps

4) Hyposmia or anosmia.

5) Previous culture results

6) Use of oral and/or topical antibiotics

7) Use of oral and/or topical steroids

8) Use of oral and/or topical antifungals

9) Use of nasal saline irrigations

10) Evaluation and treatment of allergy

11) Results of any immunologic studies performed

12) Document compliance to therapies, and ensure that proper techniques have been employed by the patient for topical drug delivery.

13) Response to medical management

c. Document any prior paranasal sinus surgeries with special attention to open or endoscopic frontal sinus surgeries.

d. Document any history of trauma.

2. Past medical history

a. Comorbidities, particularly those that may affect postoperative healing and portend poor outcome:

1) Asthma

2) Allergies

3) Nasal polyposis

4) Aspirin-exacerbated respiratory disease (Samter's triad)

5) Autoimmune disease

6) Mucociliary disease

a) Primary ciliary dyskinesia/Kartagener's syndrome

b) Cystic fibrosis

7) Immunodeficiency

8) Endocrine disorders

9) Coagulopathies

10) History of severe or refractory CRS

b. Social and family history

1) Tobacco smoking or frequent smoke exposure

2) Risk factors for malignancy

Physical Examination

1. Complete examination of the head and neck

a. Examination should always begin with a thorough examination of the head and neck, including a full examination of the cranial nerves.

b. Make note of the patient's intercanthal distance as a narrow intercanthal distance is associated with increased likelihood of stenosis postoperatively.

2. Nasal endoscopy

a. In patients with a neoplasm of the frontal sinus or mucocele where no prior surgery has been performed, nasal endoscopy may be completely normal.

b. Patients with inflammatory sinus disease will likely have had sinus surgery prior to being considered for Draf III.

1) Identify existing/remaining landmarks.

2) Is middle turbinate or uncinated process scarred laterally?

3) Take note of the degree of inflammatory sinus disease present.

4) Try to identify a frontal recess on either side.

Imaging

1. Computed tomography (CT) scan

   a. CT is the imaging study of choice for recurrent inflammatory sinus disease and revision endoscopic sinus surgery. It helps delineate residual sinus anatomy and the degree of sinus disease present. It also provides key information with regard to being able to successfully complete and maintain an open Draf III cavity.

      1) Assess AP diameter. Studies have shown that patients with an AP diameter less than 1.5 cm have increased rates of stenosis.[3]

      2) A thick nasofrontal beak will make it more difficult to complete the Draf III.

      3) Presence of osteitis, particularly of the nasofrontal beak, will also increase the likelihood of stenosis.

   b. CT can identify areas of bony erosion where the likelihood of cerebrospinal fluid (CSF) leak may be higher.

2. Magnetic resonance imaging (MRI)

   a. MRI can help differentiate between a mucocele, encephalocele, tumor, and mucosal edema. MRI can help better delineate the extent of the tumor versus trapped secretions due to obstruction by the tumor.

Indications

1. Recalcitrant *symptomatic* frontal sinus disease despite prior endoscopic frontal sinus surgery

2. Difficult revision sinus surgery

3. Failed prior obliteration surgery

4. Mucociliary disease

a. Primary ciliary dyskinesia/Kartagener's syndrome

b. Cystic fibrosis

5. Access to frontal sinus tumors such as inverted papilloma, fibrous dysplasia, and osteoma

6. Select trauma cases

7. Posterior table CSF leak

8. Anterior exposure for an endoscopic endonasal approach to the anterior skull base

Contraindications

1. Poor patient selection: The patient has narrow intranasal anatomy that would be considered a contraindication to performing a Draf III.

2. Medical comorbidities that place the patient at high risk for general anesthesia

3. Anterior-posterior diameter less than 1.5 cm

4. Thick osteitic nasofrontal beak (relative)

5. Deep radix

6. Asymptomatic inflammatory disease

7. Isolated disease located lateral to the mid-pupillary line

8. Poorly pneumatized/hypoplastic frontal sinus

Preoperative Preparation

1. Maximize medical management of inflammatory sinus disease.

2. Prepare for skull base reconstruction if necessary.

3. Prepare for possible trephination to help identify the frontal ostium intraoperatively.

4. If using image guidance, make sure imaging is done with the appropriate protocol and appropriate navigation capable frontal sinus

instruments will be available.

Operative Period

Anesthesia

General—The Draf III procedure should be performed under general anesthesia due to the length of the procedure, the need for drilling, and the potential for skull base injury and CSF leak.

Positioning

Supine—The patient is positioned the same as any endoscopic sinus procedure, with the head turned slightly toward the surgeon. Extending the head using a shoulder roll can improve the angle of approach and alleviate having the patient's chest as an obstacle.

Perioperative Antibiotics Prophylaxis

1. If prior culture data are available, perioperative antibiotics should be chosen according to the susceptibilities reported.

2. If no prior cultures have been performed, use a first-generation cephalosporin.

Monitoring

Somatosensory evoked potentials (SSEPs) may be useful for anterior skull base/intracranial tumor resection; otherwise no monitoring is necessary.

Instruments and Equipment to Have Available

1. Basic endoscopic sinus set (see Chapter 108)

2. Angled telescopes with reverse light posts

3. Frontal sinus surgery set (see Chapter 112)

4. Suction-irrigating drill

5. 4- or 5-mm drill bits

   a. Coarse diamond bits offer the best balance of efficient bone removal and control.

   b. Surgeons experienced with the Draf III procedure may consider the use of cutting burrs.

   c. A variety of angles should be available and selected based on choice of approach and patient's anatomy.

6. Instruments for potential trephination (see Chapter 111)

7. Image guidance system with navigation capable frontal sinus instruments

Key Anatomic Landmarks

1. Lateral limits of Draf III: Periosteum over the frontal process of the maxilla

2. Posterior limit of Draf III: First olfactory fibers

   a. The first olfactory fibers on both sides mark the anterior extent of the cribriform plate and thus demarcate the posterior limit of dissection.

3. Anterior limit of Draf III: Anterior table of the frontal sinus

4. Both middle turbinates, if present, and their attachment sites to the skull base

5. Lamina papyracea: This marks the location of the orbit. Identifying the lamina papyracea will help avoid inadvertent orbital injury.

6. Posterior table of the frontal sinus: The posterior table of the frontal sinus should be visualized early in the procedure to help prevent inadvertent injury to the skull base when commencing any drilling. However, the first olfactory fibers and the cribriform plate mark the true posterior limit of dissection.

7. Posterior aspect of the frontal recess: Care should be taken not to damage the mucosa of the posterior aspect of the frontal recess in order

to avoid circumferential scarring and stenosis postoperatively. It also helps to avoid inadvertent skull base injury and CSF leak.

8. Anterior ethmoid artery: The anterior ethmoid artery is located at the posterior limit of the frontal recess. Injury to these vessels can result in significant bleeding. If injured laterally, the vessel can retract into the orbit, resulting in retrobulbar hematoma.

9. Cribriform plate: The first olfactory fibers mark the anterior limit of the cribriform plate on either side of midline. It should be noted, however, that the midline portion of the cribriform plate may extent slightly more anterior, and care should be taken when removing bone in this area.

Prerequisite Skills

1. Revision endoscopic sinus surgery

2. Primary and revision endoscopic frontal sinus surgery

Operative Risks

1. Cerebrospinal fluid leak

2. Hemorrhage

3. Orbital injury

4. Retrobulbar hematoma

5. Cosmetic deformity due to excessive bone removal

6. Saddle deformity due to excessive septum removal

Surgical Technique

There are two approaches to the Draf III: inside-out and outside-in.

Inside Out

1. Identify the frontal recess on at least one side, typically the less diseased side.

a. This can be done using standard endoscopic sinus techniques with or without the assistance of image guidance.

b. A trephine can also be performed to allow for irrigation of the sinus from above, with saline or fluorescein-dyed saline solution to help identify the frontal recess.

2. Resect the head of the middle turbinate up to the posterior aspect of the identified frontal ostium.

3. Remove the floor of the frontal sinus from the identified ostium to the nasal septum (Draf IIb). This will help to clearly identify the posterior table of the frontal sinus and prevent inadvertent skull base injury (Fig. 113.1).

4. Resect approximately the superior 1 cm of bony septum from the frontal recess posteriorly to approximately 1 cm anteriorly. In general, the root of the contralateral middle turbinate and the upper one-third to one half of the turbinate should be easily visible. This allows wide binarial access to the frontal sinus floor and greater visualization (Fig. 113.2).

a. Like septal perforations, smaller septectomies tend to cause frequent crusting and impact patient quality of life, whereas larger septectomies tend to be asymptomatic.

5. Resect the head of contralateral middle turbinate to match the ipsilateral side.

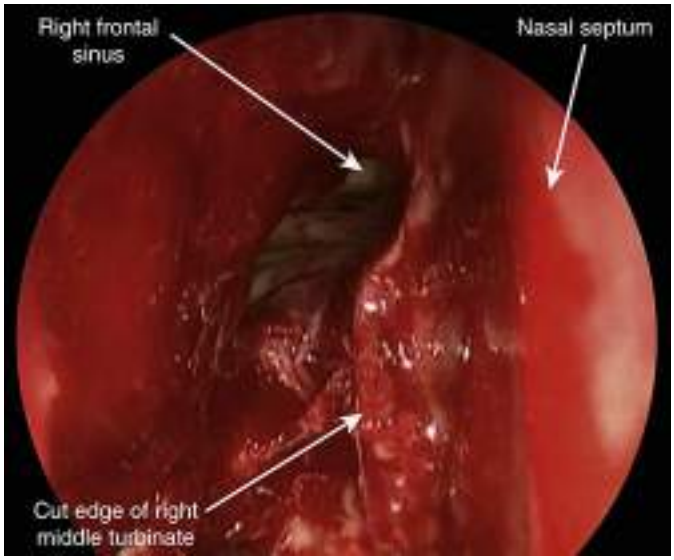

FIG. 113.1 Draf IIb completed on right side. Note the posterior table of the frontal sinus is clearly visible.

FIG. 113.2 Diagram of the septal window. May M, Schaitkin B: Frontal sinus surgery: Endonasal drainage instead of an external osteoplastic approach. Op Tech Otolaryngol Head Neck Surg 31:184-192, 1995.

6. Try to identify the contralateral frontal recess (Fig. 113.3).

7. Use the drill to remove the nasofrontal beak and remaining floor of the

frontal sinus in a horseshoe shape. A wide opening should be achieved from one lamina papyracea to the other, and a large anterior-posterior diameter is created without violating the glabella anteriorly or skull base posteriorly (Fig. 113.4).

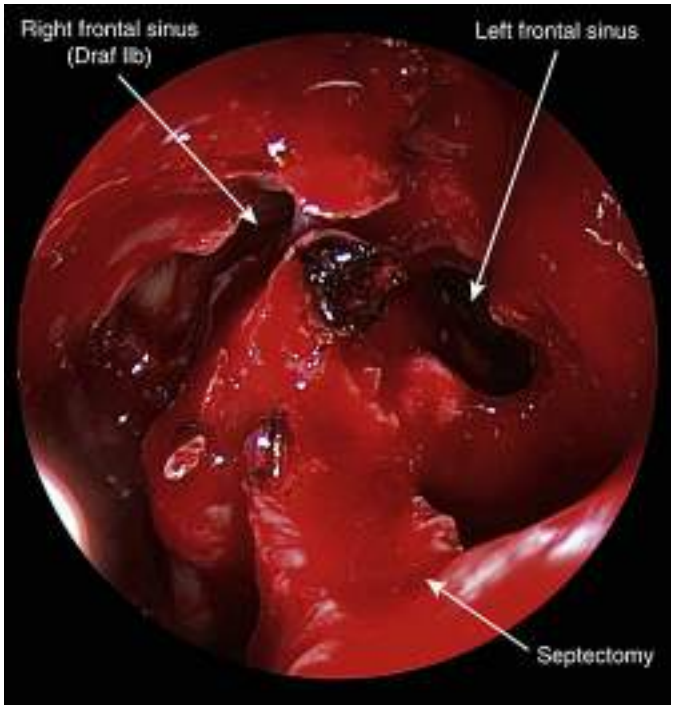

FIG. 113.3 Completed exposure of frontal sinus floor from an inside-out approach. Note a Draf IIb has been completed successfully on the right, the left frontal recess and sinus have been identified, a large septectomy has been completed to allow a view of both frontal recesses from one side, and the head of the middle turbinates has been trimmed.

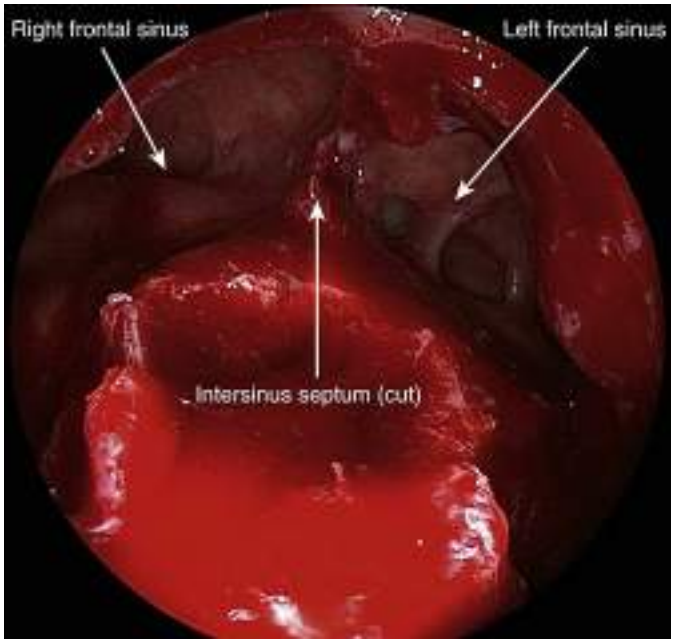

FIG. 113.4 Completed inside-out Draf III. The remaining floor and intersinus septation have been removed in a horseshoe pattern to connect both frontal sinus recesses and form a single common drainage pathway.

8. Be careful not to disrupt the mucosa of the posterior aspect of the frontal recess or posterior table unless bone removal of that area is anticipated for tumor resection.

9. Residual superior septum anterior to the cribriform can be resected with cutting instruments or the drill. Identifying the first olfactory fibers by elevating the mucosa off of the posterior septal remnant toward the olfactory cleft can help to identify the posterior limit of dissection.

Outside-In (Video 113.1)

1. In some cases, a frontal recess may not be easily identifiable on either side, due to scarring, osteoneogenesis from prior surgery, or tumor. This approach avoids initial identification and dissection of a narrow frontal recess by working below the frontal sinus floor initially to create wide exposure and identify the limits of the dissection.

2. When possible, an ethmoidectomy can be completed on both sides to identify the medial orbit laterally and skull base posteriorly.

3. A superior septectomy can be performed at this time. It can also be performed in conjunction with the following steps.

a. The incision starts at the nasal septal angle just opposite the superior attachment of the middle turbinate.

b. A full-thickness incision is then carried down on the septum angled anteriorly so that the incision ends 5 to 10 mm anterior to the head of the middle turbinate at the level of the upper third or one half of the turbinate. This marks the anterior aspect of the superior septectomy.

c. The inferior septal incision can be carried posteriorly to the level of the head of middle turbinate or middle meatus if the turbinate is missing.

d. The posterior incision extends vertically back up to the start of the septectomy, staying close to the anterior edge of the middle turbinate to avoid damaging olfactory mucosa (Fig. 113.5).

e. Through-cutting instruments or a microdébrider can now be used to remove the septal window.

f. An adequate septectomy allows visualization of both middle turbinates and their attachment sites from either nasal cavity (Fig. 113.6).

FIG. 113.5 A view of the left nasal cavity with anticipated superior septectomy outlined *(black dotted line)*.

4. The mucosa of the nasofrontal beak and frontal sinus floor is elevated to identify the first olfactory fiber on both sides.

   a. Bilaterally, an incision is made on the lateral nasal wall from just anterior to the attachment of the middle turbinate and taken superiorly to the nasal septal angle (Fig. 113.7).

   b. If a superior septectomy was already performed, the incision is carried to meet with the septectomy. If a septectomy is being performed at the same time as this step:

      1) A full-thickness incision is then carried down on the septum angled anteriorly so that the incision ends 5 to 10 mm anterior to the head of the middle turbinate at the level of the upper third or one half of the turbinate. This marks the anterior aspect of the superior septectomy.

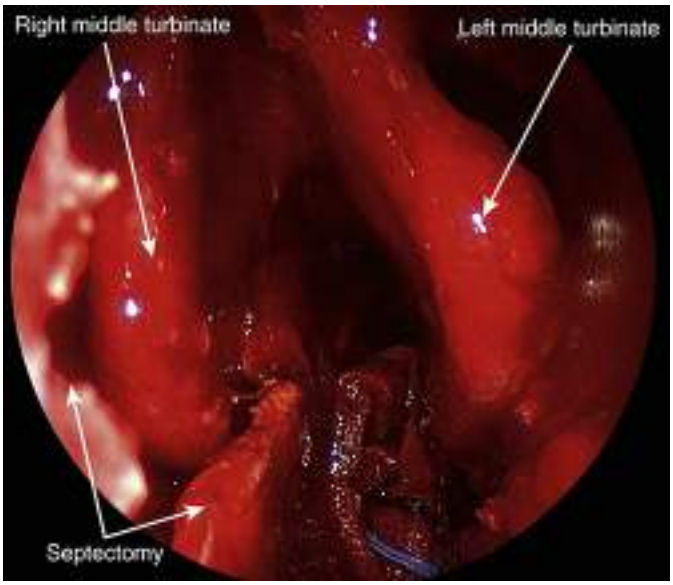

FIG. 113.6 View of both middle turbinates after septectomy. Notice how the heads of both middle turbinates are easily viewed from one side. Additional posterior septum has been removed for an anterior skull base approach in this particular case.

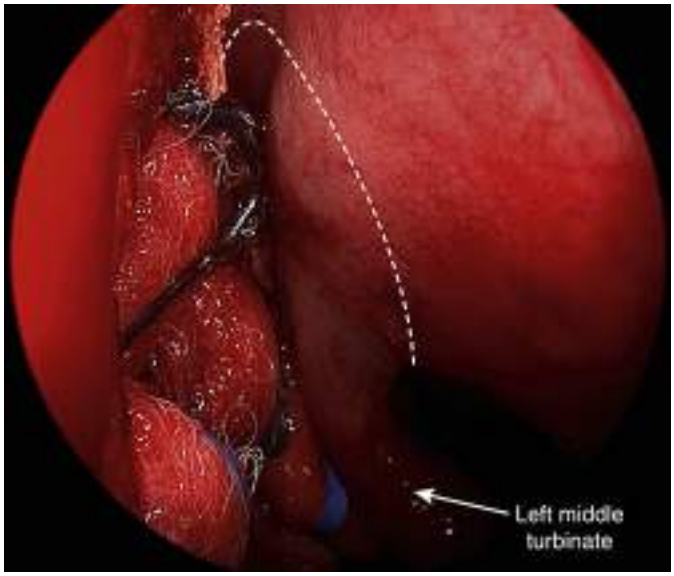

FIG. 113.7 A view of the left nasal cavity after septectomy. Cottonoid patties have been placed in the right nasal cavity for hemostasis and are clearly visible from the left. The mucosal incision has been outlined *(white dotted line)*, which will expose the frontal process of the maxilla laterally, nasofrontal beak superiorly, and allow posterior dissection to identify the first olfactory fiber.

2) The inferior septal incision can be carried posteriorly to the level of the head of middle turbinate or middle meatus if the turbinate is missing (Fig. 113.8).

c. An elevator can now be used to elevate the mucosa bilaterally, starting at the apex and elevating it off of the septum and lateral nasal wall to allow posterior dissection. The mucosal flap is elevated posteriorly and folded back into the olfactory cleft until the first olfactory fiber is identified (Fig. 113.9).

FIG. 113.8 Diagram outlining the mucosal incisions in the right nasal cavity when combining the lateral nasal wall incision with the septectomy. Note the septal incision angles anteriorly to allow clear view of the contralateral middle turbinate and its attachment site. The inferior incision is carried posteriorly to approximately the level of the anterior edge of the middle turbinate.

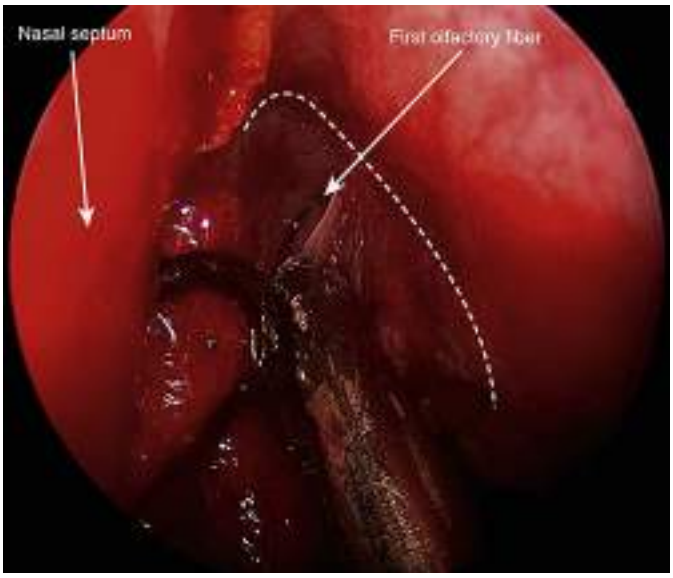

FIG. 113.9 Identifying the first olfactory fiber. The lateral and superior nasal mucosa are reflected posteriorly until the first olfactory fiber is identified. Note that the fiber is rather large and tightly adherent to the skull base. The *white dotted line*

corresponds to the mucosal incision previously demonstrated in Fig. 24.7.

d. A small emissary vein is often seen prior to the first olfactory fiber. This is usually small, runs laterally, and dissects away easily from the skull base. The olfactory fiber is larger and more tightly adherent to the skull base, so it is not easily dissected away in careful hands.

e. These olfactory fibers on each side now mark the posterior limit of dissection. The redundant mucosa that was elevated can be resected with through-cutting instruments or a microdébrider. The superior septal window can be completed staying anterior to the olfactory fibers.

5. Drilling begins in the midline to bring the residual crest of nasal septum flush with the lateral nasal walls at the apex (Fig. 113.10). Drilling then continues in a wide and meticulous fashion.

6. The bone of the lateral nasal wall is removed until the periosteum is identified. It often appears white compared with the yellow bone.

7. Once the periosteum is identified laterally, all of the limits of the Draf III have been identified. By staying anterior to the olfactory fibers, the skull base should not be entered unintentionally. Bone can now be removed in a wide horseshoe movement to approach the frontal recesses in a smooth controlled manner.

8. The mucosa of the floor of the frontal sinus in the midline will likely be identified early in the drilling process. If possible, this mucosa should be left intact to avoid unnecessary bleeding. However, if there is any concern about the posterior limits of bone removal, opening this mucosa can provide a view into the sinus and help with identification of the posterior table.

9. With continued bone removal laterally, the natural frontal recess will be encountered (Fig. 113.11). Once the bone is thin enough, rongeurs can be used to remove the remaining bone and connect the frontal recess to the remaining surgical cavity.

10. Intersinus septations can be removed.

11. Residual posterior superior bony septum can be carefully drilled away closer to the first olfactory fibers. This helps maximize the anterior

posterior diameter in the midline. Keep in mind that the midline cribriform can sometimes project more anterior than the first olfactory fibers (Fig. 113.12).

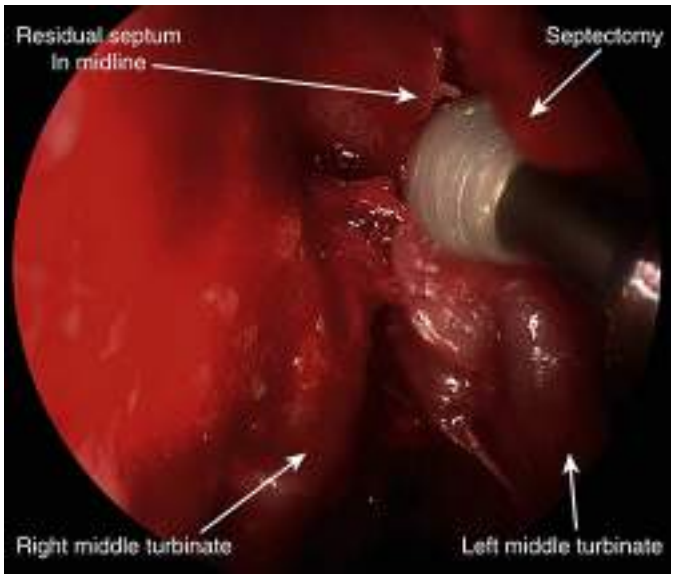

FIG. 113.10 Drilling with a 4-mm coarse diamond drill bit begins in the midline in order to bring the remainder of the nasal septum flush with the lateral nasal walls at the apex. The use of suction-irrigating drills improves visualization.

Stenting

1. The use of stents has been described in the literature for more than 100 years.

2. A variety of stenting options exist, which can be left in place for 1 to 6 weeks depending on the type of stent used. Some examples include:

   a. Silastic tubing

   b. Custom-shaped Silastic sheeting

   c. Rubber finger stall with sponge packing

   d. Dissolvable packing

   e. Steroid-eluting stents

   f. Steroid-coated dissolvable packing material

g. Chitosan

3. Prolonged stenting carries the risk of biofilm formation, which can form as early as 1 week postoperatively. The impact of biofilms in CRS and surgical failure is well established.[4]

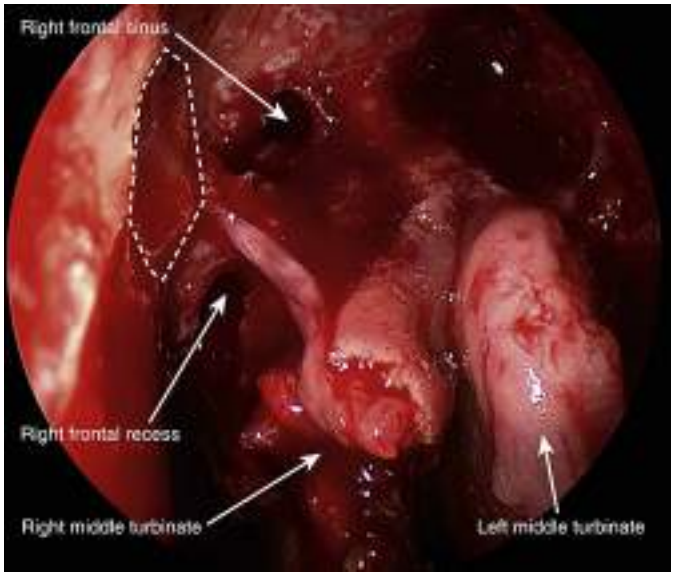

FIG. 113.11 The right frontal process of the maxilla has been drilled down to the periosteum. The right frontal recess has been exposed. The right frontal sinus has also been entered more medially by drilling through the nasofrontal beak and frontal sinus floor. Kerrison rongeurs can now be used to combine these areas and further widen the opening if the bone is thin enough.

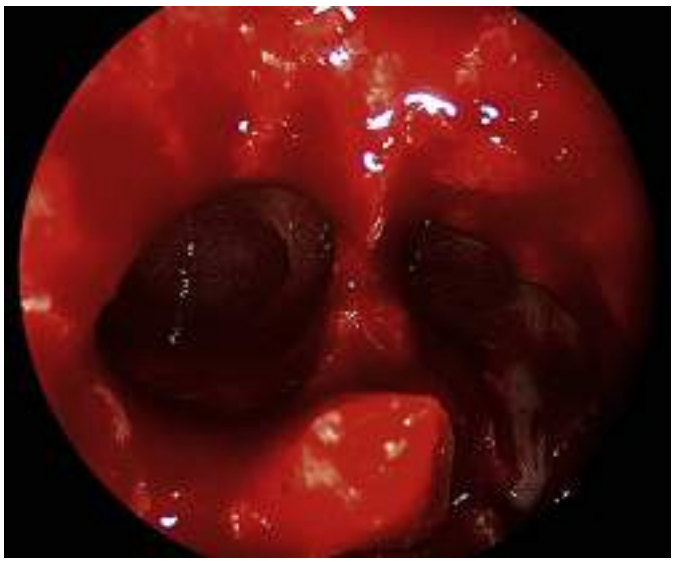

FIG. 113.12 Completed Draf III.

4. The current literature suggests that stents are used infrequently after Draf III.

5. The current data on stenting in Draf III are limited and have not shown any difference in the rate of stenosis.[2,4]

Mucosal Grafting

1. There have been reports in the recent literature on mucosal grafting of exposed bone to try and reduce the rates of stenosis.

2. Two papers to date discuss free grafting to the exposed bone of the nasofrontal beak.[5,6]

   a. One author updated his outcomes after 1 year of follow-up. Of 96 patients undergoing Draf III, only 2 cases developed more than 50% stenosis, neither of which required interventions.[7]

3. One paper reports a pedicled septal graft based on the anterior ethmoid artery to cover the posterior table.[8]

4. These studies suggest a reduction in the rate of osteoneogenesis and stenosis; however, the data are currently limited to these small case series.

Common Errors in Technique

1. Inadequate superior septectomy

2. Excessive circumferential mucosal loss

3. Inadequate removal of residual superior posterior bony septum, leaving a narrower AP diameter

4. Inadequate removal of the nasofrontal beak leaving a narrow AP diameter

Postoperative Care

Postoperative Management

1. Continued aggressive medical management of inflammatory mucosal disease

2. Saline irrigations

3. Oral antibiotics and oral steroids may be considered in select patients.

4. Frequent follow-up for removal of packing/stents, débridement, lysis of synechiae, or polyp removal (Fig. 113.13)

FIG. 113.13 Endoscopic view of a well-healed Draf III cavity 3 years after surgery.

Complications

Major Complications (<1%)

1. CSF leak (6% to 11%)
   a. Can be repaired endoscopically
2. Tension pneumocephalus
   a. Just as in a CSF leak, there is violation of the skull base and the dura, resulting in a fistula. This can be identified and repaired endoscopically.
3. Posterior table dehiscence

Minor Complications (4%)

1. Hemorrhage: The most significant and likely source of bleeding as a result of Draf III would be from the anterior ethmoid artery. Other sources such as posterior ethmoid artery, sphenopalatine artery, and distal branches of the sphenopalatine should be considered as possible sources if other sinuses were addressed in the same setting. Anterior ethmoid artery bleeding is difficult to control with packing. Endoscopic ligation or open ligation may be necessary.

2. Orbital injury/retrobulbar hematoma: This may occur as a result of direct injury of orbital fat or muscle or by retraction of an avulsed anterior ethmoid artery into the orbit. Management of this complication would be the same as with endoscopic sinus surgery (see Chapter 109).

3. Saddle nose deformity: This may occur if too much septum is removed during the superior septectomy, particularly if the septectomy is brought too far anteriorly into the dorsal cartilaginous strut.

4. Anosmia/hyposmia

5. Increased nasal crusting

6. Stenosis

Alternative Management Plan

1. Trephination

2. Osteoplastic flap approach with removal of floor of the frontal sinus

3. Frontal sinus obliteration

4. Frontal sinus cranialization

Discussion

Evidence-Based Medicine Question: Is Draf III Superior To Open Approaches Such As Osteoplastic Flap With Obliteration?

Frontal sinus obliteration was first described in the 1950s. It is considered by some to be the gold standard of treatment for patients with symptomatic refractory frontal sinusitis. Success rates have been reported to be as high as 93% at 8 years. However, complication rates are also relatively high, with major complications exceeding 20% in some series. Major complications include exposure of the dura, dural tears, CSF leak, and orbital injuries. Minor complications can include forehead paresthesia, pain, osteomyelitis of the bone flap, and mucocele formation due to incomplete obliteration.

A review of the literature in 2009 by Anderson and Sindwani[2] found that the Draf III procedure carried a major complications rate of less than 1% when performed by experienced surgeons. It was well tolerated and efficacious in the treatment of refractory frontal sinusitis, with 82% of patients reporting significant improvement or total resolution of preoperative symptoms. Sixteen percent reported no significant change, and 1.2% reported worsening symptoms; however, details regarding which symptoms worsened were not available. Fourteen percent of patients required further surgery, with 80% undergoing revision Draf III and 20% having an obliteration. No data were available as to improvement of symptoms after revision; however, it is likely the overall success of Draf III is greater when including revision cases. The majority of stenosis of the neo-ostium after Draf III seemed to occur within the first year after surgery in the majority of studies. The use of the Draf III procedure still preserves the option of obliteration in the future should it

be unsuccessful. Interestingly, a Draf III can also be used to rescue a failed case of obliteration in the highly selected patients.

While this paper suggests comparable outcomes with obliteration, the literature lacks a significant volume of data with regard to Draf III, given its relatively recent advent, technically challenging nature, and applicability. Moreover, these data are lacking in long-term follow-up, with most series limited to 2 to 4 years. A series published by Ting et al.[9] in 2014 was the first to have follow up greater than 10 years and consisted of 204 patients with a mean follow-up time of 10.2 years (range 0.9 to 17 years). This relatively large series provided an update to a previously reported cohort, and they found that the initially reported success rate decreased from 80% to 70% due to some patients developing late recurrences well beyond 2 years and extending as far as 10 years. This is believed to be from the ongoing process of mucosal inflammation present in patients with refractory frontal sinusitis. Nevertheless, the majority of failures requiring revision surgery occurred in the first 2 years.

A more recent publication by Morrissey et al.[10] in 2016 reported on 213 patients undergoing Draf III from January 2001 to December 2013. In this series, only 19 patients (8.9%) failed primary Draf III, requiring revision surgery. A majority of stenosis was reported as soft tissue or polyp obstruction, with only four demonstrating osteoneogenesis requiring drilling. Of the 19 revisions, four went on to have multiple revisions. The average time to revision was 44 months in contrast to the prior studies reporting 24 months. Risk factors associated with failure of primary Draf III were the presence of intraoperative purulence at time of primary surgery, more than 5 sinus surgeries prior to primary Draf III, and presence of aspirin exacerbated respiratory disease. Sex, age at time of primary Draf III, asthma, presence of nasal polyps, ostium size, and preoperative Lund-Mackay score were not found to be statistically significant. The only major complications in this group were two patients with minor intraoperative CSF leaks, which were successfully repaired at the time of surgery. One key difference with this study was that the mean follow-up time was reported as only 36 months.

In summary, it is felt that Draf III offers success rates similar to obliteration with significantly less morbidity, while still preserving the option for obliteration in the future if necessary. More long-term data are

needed to determine how durable it is as a treatment option. Overall it is a valuable intervention to consider in the treatment ladder in the management of refractory frontal sinusitis.

Editorial Comment

The frontal sinus remains the most challenging anatomic region for surgical intervention for chronic sinusitis. It is the only dependent sinus without a fontanelle, and therefore its bony confines make it less forgiving and more prone to stenosis. The nasofrontal recess anatomy is highly variable, and the important anatomic neighbors cannot be ignored. This chapter succinctly highlights the key points and limitations of advanced frontal sinus surgery. Wolfgang Draf perfected the transnasal drillout procedure beginning with a microscope in the prenavigation era (the Fulda concept). It was a classic and very effective operation, but it was done with irrigation making visualization difficult, and teaching the procedure was challenging. It was transitioned to a modern teachable endoscopic frontal sinus drillout procedure, which continues to be associated with his name, even though many refer to it as a modified Lothrop procedure. The procedure provides wide access for hygiene and topical therapy. It has become the gold standard, replacing the frontal sinus osteoplastic flap, which was always plagued by long-term failures with mucoceles and difficulty evaluating complaints postoperatively by imaging. Mastering the anatomy and using the key chapter information of indications, contraindications and surgical techniques coupled with significant cadaveric dissection will allow for the adoption of safe advanced frontal sinus surgery.

Review Questions

1. Which of the following is *not* a contraindication to Draf III?

   a. Thick osteitic nasofrontal beak

   b. AP diameter less than 1.5 cm

   c. **Mucociliary disease (e.g., Cystic fibrosis or Kartagener's)**

d. Asymptomatic inflammatory disease

2. Which of the following statements is true?

a. Patients with a narrow intercanthal distance have a decreased likelihood of stenosis.

b. **The midline portion of the cribriform plate extends more anterior than the first olfactory fibers.**

c. The lateral limit of a Draf III is the periosteum over the lacrimal sac.

d. Stenting is a common practice and has been shown to reduce the rates of stenosis.

3. According to a recent publication by Morrissey et al., which of the following is not a risk factor for failure of Draf III?

a. **Ostium size**

b. More than five sinus surgeries prior to primary Draf III

c. Purulence at the time of surgery

d. Aspirin-exacerbated respiratory disease

4. The majority of Draf III failures occur within what time frame?

a. 1 year

b. **2 years**

c. 5 years

d. 10 years

5. The majority of stenosis of the Draf III neo-ostium seems to occur within what time frame?

a. 3 months

b. 6 months

c. **12 months**

d. 18 months

Osteoplastic Obliteration of the Frontal Sinus

Matthew Mifsud, and John R. De Almeida

Introduction

In the preendoscopic era, the osteoplastic flap procedure was the accepted method of management of frontal sinusitis.[1,2] Initial approaches described in the late 19th century (e.g., the Reidel procedure) conceptualized the complete exenteration of the sinus, including the anterior wall, which of course resulted in a significant cosmetic deformity, reserved for only the most severe disease processes.[2,3] The more modern osteoplastic obliteration (using abdominal adipose tissue) was described in the 1940s and popularized by the 1970s.[1,2] It is a versatile surgical approach that provides wide exposure of the frontal sinus and allows for the definitive management of inflammatory, infectious, and neoplastic disease processes. The procedure has maintained a reputation for reliability, with long-term success rates greater than 90% in most reports, even when used in patients with refractory chronic frontal sinusitis.[1,2]

Advances in endoscopic techniques have largely replaced open sinus surgery.[4] Instead of an obliterative approach, transnasal surgery allows the restoration of function to a diseased sinus, by establishing a permanent drainage pathway.[1,4,5] This approach is preferred, as it avoids external scars and unlike open procedures maintains normal sinus physiology. However, there remain certain situations—for example, neoplasms of the frontal sinus or extreme lateral based pathology—in which endoscopic visualization is limited. The osteoplastic flap procedure continues to be an essential surgical approach in these instances.[4,5]

Key Operative Learning Points

1. The osteoplastic flap procedure should be considered in cases that are inaccessible to endoscopic techniques, particularly in the setting of refractory chronic sinusitis after previous surgical failure.

2. A bicoronal flap, raised in the subgaleal plane, is generally used to prevent injury to the scalp neurovasculature.

3. To prevent intraoperative complications, the frontal sinus must be accurately outlined using plain x-ray film, mini-trephination technique, or image guidance, prior to making the osteotomies.

4. For noninflammatory pathology, sinus obliteration may not be necessary; instead an endoscopic procedure can be used to create a patent nasofrontal outflow tract.

5. When sinus obliteration is necessary, key principles must be adhered to for long-term success.[1,6]

   a. Meticulous removal of all visible sinus mucosa

   b. Removal of the inner cortex of the anterior wall of the sinus with a cutting and/or diamond burr

   c. Permanent occlusion of the nasofrontal outflow tract

6. While abdominal adipose tissue is currently considered the standard tissue for obliteration of the frontal sinus, more recently described techniques including a rotational pericranial flap or tissue-engineered materials may also be considered.[6-8]

Preoperative Period

The key to the preoperative patient evaluation is determining which patient would be best served by an open surgical approach given the advanced instrumentation, surgeon comfort, and ease of access to the frontal sinus with standard endoscopic approaches. The osteoplastic flap approach will be of particular use in situations where wide surgical exposure for direct instrumentation of the sinus is necessary. It may be applied in multiple clinical settings (e.g., trauma, neoplasm, or chronic sinusitis), and thus the preoperative evaluation must address the

particular disease process at hand.

Successful endoscopic sinus surgery requires the establishment of an appropriate corridor to fully visualize the disease process and establish a patent sinus drainage pathway. Findings such as significant scar formation or osteoneogenesis within the frontal recess (usually due to previous surgical procedures) often portend poor long-term results with transnasal approaches. An anatomically inaccessible pathology located in the far lateral or anterior table of the sinus as well as large fibro-osseous lesions (e.g., osteoma) are difficult to remove endoscopically and may benefit from an osteoplastic approach.[4]

The indications for osteoplastic obliteration will likely continue to evolve over time, with advancement of endoscopic techniques and instrumentation. Perioperative planning requires the combination of a detailed examination of the head and neck, including endoscopy, and high-resolution imaging (usually computed tomography [CT]) to define the most appropriate surgical approach.

History

1. History of present illness
    a. A focused history should include questions about common symptoms of frontal sinus and nasal pathology, including frontal pressure/pain, headache, hyposmia/anosmia, nasal obstruction, epistaxis, generalized fatigue, or a sensation of postnasal drainage.
    b. For presumed chronic inflammatory disease, review the current medical regimen (e.g., nasal corticosteroids or saline irrigations) and the effectiveness of these nonsurgical treatments for control of symptoms.
    c. Signs of intraorbital pathology such as diplopia or decreased visual acuity should be specifically evaluated.
    d. Red flags for a malignant or acute life-threatening illness, such as mental status changes, weight loss, clear (cerebrospinal fluid [CSF]) rhinorrhea, sensory deficits along trigeminal nerve distribution, current history of immune suppression, or severe/progressive pain, should be considered.

2. Past medical history

a. Prior treatment

- All previous sinonasal procedures must be detailed, to help determine if an open frontal sinus procedure is indicated. This should include a review of past sinus procedures and pathologic specimens.
- Previous scalp incisions or surgical incisions are important to assess, as this may limit the viability of the standard bicoronal approach typically used for the osteoplastic flap procedure.

b. Medical illness

- Review for systemic comorbidities (particularly cardiac disease, chronic pulmonary disease, diabetes mellitus)

c. Past surgical history

d. Family history

e. Allergy assessment

f. Review of current medications

Physical Examination

1. Head/face:

a. Standard facial assessment, with a particular focus on facial symmetry and facial nerve function. Sensory examination particularly along V1 and V2 territories should be documented.

b. Palpation along the orbital rim and frontal bone should be carried out, both to assess for point tenderness and to address the integrity of the anterior table of the frontal sinus and the presence of a mucocele. The position of the eyes should be examined, and any displacement should be noted.

c. In the case of recent traumatic injury, a thorough inspection should be undertaken to review for facial lacerations, bruising, or bony step-offs that could be indicative of fracture sites. The overall stability of the midface and mandible should also be assessed.

2. Orbit:

a. Extraocular motion

b. Visual field assessment

c. Assess the position of the globe (i.e., proptosis or enophthalmos).

d. A referral to ophthalmology for any concerning abnormal findings is strongly suggested.

3. Nasal examination:

a. Standard external nasal examination with assessment of external/internal nasal valves. Note presence/absence of significant septal deformity or hypertrophy of the inferior turbinates.

b. Intranasal examination should evaluate for an intranasal mass, polypoid/inflammatory changes, or obvious purulence. If purulent sinonasal discharge is identified, a specimen should be taken for culture and sensitivities.

4. Nasal endoscopy:

a. This examination is critical to define the surgical approach for frontal sinus disease, particularly in the previously operated nose. Adequate topical anesthesia should be applied for patient comfort. This examination is often best performed with 0- and 30-degree rigid endoscopes, as additional instruments (i.e., curved suctions) can be used to clear debris when present.

b. The presence/absence of key anatomic landmarks should be noted, particularly the middle turbinate (and its basal lamella), uncinate process, and bulla ethmoidalis.

c. With an angled telescope, an attempt should be made to visualize the frontal recess. Particularly note the presence of polypoid disease or synechiae formation if previous surgery has been performed.

5. Comprehensive head/neck and general medical examination:

a. Overall health and mental status

b. A thorough examination of the head and neck should be carried out.

c. Cardiovascular, pulmonary, and neurologic examination

d. Skin assessment

Imaging

1. CT imaging:

   a. A high resolution CT scan of the sinuses is the most useful method in the evaluation of frontal sinus disease. This provides an optimal assessment of the position of the frontal sinus in relation to key landmarks such as the anterior skull base, crista galli, and frontal lobes. The interface between inflammatory pathology and the bony anatomy of this region is also clearly delineated (Fig. 114.1).

FIG. 114.1 Coronal computed tomography scan demonstrating a large lateral frontal sinus mucocele with erosion of the floor of the frontal sinus and encroachment on the orbit.

   b. The structure of the anterior and posterior table of the sinus should be visualized. Significant defects in the bony structure of the sinus may prevent safe obliteration of the sinus and require the use of a different surgical approach.

   c. If surgical image guidance is considered, image slice thickness should generally not exceed 2 to 3 mm.

   d. Evaluation of the bony anatomy of the frontal recess is best performed with CT. This will help classify the pattern of frontal cells

on the basis of the Kuhn classification, which may indicate a more challenging endoscopic dissection.

- Type I: Single frontal recess cell above the agar nasi
- Type II: Tier of cells above the agar nasi
- Type III: Large cell pneumatizing from the frontal recess into the sinus
- Type IV: Isolated frontal sinus cell

e. CT is also particularly useful for evaluating traumatic maxillofacial injuries and identifying benign fibro-osseous lesions (e.g., osteomas).

2. Magnetic resonance (MR) imaging:

a. Due to lack of detailed bony definition, MR is usually considered as an adjunctive modality. It is, however, particularly beneficial in certain situations due to the ideal soft tissue definition provided.

- Identifying benign/malignant neoplasms of the frontal sinus, with gadolinium-enhanced imaging
- For differentiating solid tumors from inflammatory secretions or expansile mucoceles that have specific signal characteristics, particularly on T2-weighted or contrast-enhanced imaging (Fig. 114.2)

b. MR is also particularly useful in the evaluation and diagnosis of pathology that has spread to intraorbital or intracranial compartments.

3. Radiography:

a. Traditionally a 6-foot Caldwell view plain film radiograph has been used for surgical guidance prior to the osteoplastic flap procedure.[3,9]

FIG. 114.2 Coronal contrast enhanced T1-weighted magnetic resonance imaging of the same lateral frontal sinus mucocele. Note the classic hyperintense appearance of the mucocele, which helps define this entity.

b. From this film, a template of the frontal sinus dimensions can be made to help with the proper placement of the osteotomies along the anterior table of the sinus.

Indications

1. Recurrent chronic sinusitis after failed endoscopic sinus surgery

2. Inaccessible frontal mucoceles, usually lateral to the midpupillary line and superior to half the height of the posterior table

3. Severe trauma involving the frontal sinus outflow tract or with CSF leak, not amenable to endoscopic management

4. Benign or malignant tumors of soft tissue or bone (osteomas) of the frontal sinus, unable to be completely resected via an endoscopic approach

Contraindications

1. Any disease process amenable to endoscopic management

2. Cases in which greater than 25% of the anterior or posterior table of the frontal sinus is absent. In these cases, obliteration will likely be unsuccessful due to a limited vascular supply. For anterior table defects, the Reidel procedure may be necessary, while frontal sinus cranialization should be considered for posterior table defects.

3. Patients whose medical comorbidities preclude a general anesthetic

Preoperative Preparation

1. Standard perioperative evaluation with history-directed preoperative testing and medical consultations, if indicated

2. Patient counseling and surgical consent

3. Review preoperative imaging, and ensure adequacy for image guidance, if deemed necessary.

4. Review pathology from any previous surgery.

5. A template outlining the frontal sinus should be made using the x-ray film from the 6-foot Caldwell view. The film should be sterilized for intraoperative use.

Operative Period

Anesthesia

- A general anesthetic with endotracheal intubation is required for this procedure.
- The patient can be positioned with head toward or rotated 180 degrees away from the anesthesia team based on surgeon and institutional preference.

Positioning

- The patient should be supine for the entire case.
- The entire scalp should be prepped down below the nasal tip, with both orbits exposed to ensure adequate visualization.
- Hair on incision lines may be trimmed for ease of access.
- Eye protection (e.g., bilateral tarsorraphies or corneal shields) should be used.
- The endotracheal tube should be positioned and secured away from the surgical field.
- The abdomen should be prepped and draped in a sterile fashion for harvest of abdominal adipose tissue.
- If an endoscopic approach to the frontal sinus is to be combined with the osteoplastic procedure, monitors must be able to be positioned at the head of the patient for appropriate surgeon comfort.
- If image guidance is necessary, a frameless system should be used to avoid interference with the planned incision sites.

Perioperative Antibiotic Prophylaxis

- There are no high-quality data to help clearly dictate the ideal prophylactic regimen for osteoplastic obliteration.
- As this procedure is considered "clean contaminated," due to exposure of sinonasal contents to a skin incision, empiric coverage against typical flora in the sinonasal tract such as gram-positive and anaerobic organisms is appropriate.
- Appropriate antibiotic choices include:
  - First-generation cephalosporin and metronidazole
  - Amoxicillin-clavulanate
  - Clindamycin (penicillin/cephalosporin allergic patient)
- For patients with chronic sinusitis, prolonged culture-directed antibiotics should be considered postoperatively in select cases.

Monitoring

- No specialized monitoring is required unless the osteoplastic procedure is to be combined with an intracranial procedure, in which case appropriate monitoring for the intracranial procedure should be used (e.g., somatosensory evoked potentials, motor evoked potentials).

Instruments and Equipment to Have Available

- Standard head and neck set
- Raney clips for hemostasis
- Image guidance system
- Powered saw and osteotomes to create the osteotomies
- Cutting and diamond burrs for removal of frontal sinus mucosa
- Craniomaxillofacial plating system

Key Anatomic Landmarks

- *Galea*: The surgical flap should be elevated in the subgaleal plain to prevent injury to the scalp neurovasculature.
- *Temporalis fascia/muscle*: The temporalis fascia blends with the pericranium of the skull. The temporal branch of the facial nerve is located in the loose areolar tissue, superficial to this temporalis fascia. If requiring extensive lateral dissection below the level of the temporal adipose tissue pad, elevation of the flap should proceed deep to the temporalis fascia to prevent injury to the nerve.
- *Subraorbital rim*: This marks the inferior border of the frontal sinus.
- *Neurovascular bundle*: This exits the orbit through a foramen roughly 2 to 3 cm from the midline. It can often be palpated as a subtle indentation along the supraorbital rim.
- *Frontal sinus outflow tract*: This will be found in the floor of the medial aspect of the opened frontal sinus. This region must either be widely opened using a transnasal route or completely obliterated from above, to prevent recurrent sinusitis and mucocele formation.

Prerequisite Skills

- Standard open otolaryngologic head and neck surgical technique.
- Ability to perform endoscopic approaches to the frontal sinus (Draf II and Draf III procedures; see Chapters 112 and 113)
- Comfort with the anatomy of the bicoronal incision
- Techniques of skull base reconstruction
  - Craniomaxillofacial plating
  - Pericranial flap
  - Harvest of an adipose tissue graft from the abdomen

Operative Risks

- Inappropriate placement of the superior or lateral osteotomies with the potential for injury to the dura, CSF leak, and injury to the superior sagittal sinus
- Periorbital injury and exposure of orbital adipose tissue can occur with fracture of the floor of the frontal sinus. This is generally, however, of little consequence if recognized intraoperatively and orbital adipose tissue is not manipulated.
- Unintentional fracture of the anterior frontal sinus wall can occur while doing the osteotomies, which may require miniplate fixation.
- Injury to the facial nerve (temporal branch) can occur if significant dissection within the preauricular area is required for exposure.

Surgical Technique: Osteoplastic Flap

1. Mark the surgical incision.

- A bicoronal incision is the standard approach, performed using an incision within the hairline that extends from helix to helix. This provides wide exposure and protects the scalp neurovasculature (Fig. 114.3).

- Alternate incisions:
  - Midforehead incision, utilizing an existing forehead skin fold, can be used in cases of male-pattern baldness.
  - Upper brow ("gull wing") incision provides the most direct approach and requires less operative time and blood loss. May be of particular benefit for patients who are not ideal candidates for prolonged general anesthesia.

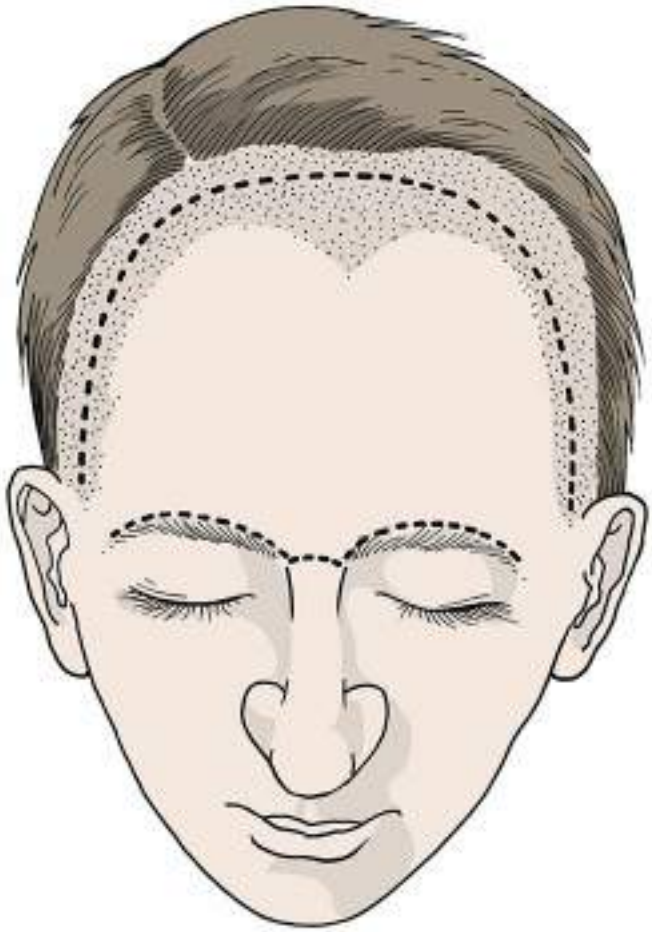

FIG. 114.3 A bicoronal or brow incision can be used to approach the frontal sinus. An incision within a midforehead rhytid (not shown) may also be of use in an older patient with significant male pattern baldness.

  - The brow incision will, however, require division of the scalp neurovascular bundle, causing permanent anesthesia of the forehead.

2. Raise the bicoronal flap.

- The bicoronal flap is raised in a subgaleal plane inferiorly to the level of the supraorbital rim, preserving the scalp neurovasculature.

3. Incise the pericranium.

- The pericranial incision should be made above the site of the expected superior osteotomy so that when the bone flap is replaced, the osteotomy will be covered by pericranium (Fig. 114.4).
- Elevate the pericranium inferiorly to expose the frontal bone. The remainder of the pericranium can be left in place on the planned frontal bone flap. This will allow the bone flap to be pedicled on the pericranium, maintaining a more robust vascular supply.
- A more generous pericranial flap can also be elevated at this point if desired (e.g., to be used for obliteration of the sinus).

4. Mark the dimensions of the frontal sinus.

- This has traditionally been done by sterilizing a template derived from tracing a 6-foot Caldwell view (occipital-frontal) radiograph. This provides an accurate definition of the frontal sinus.

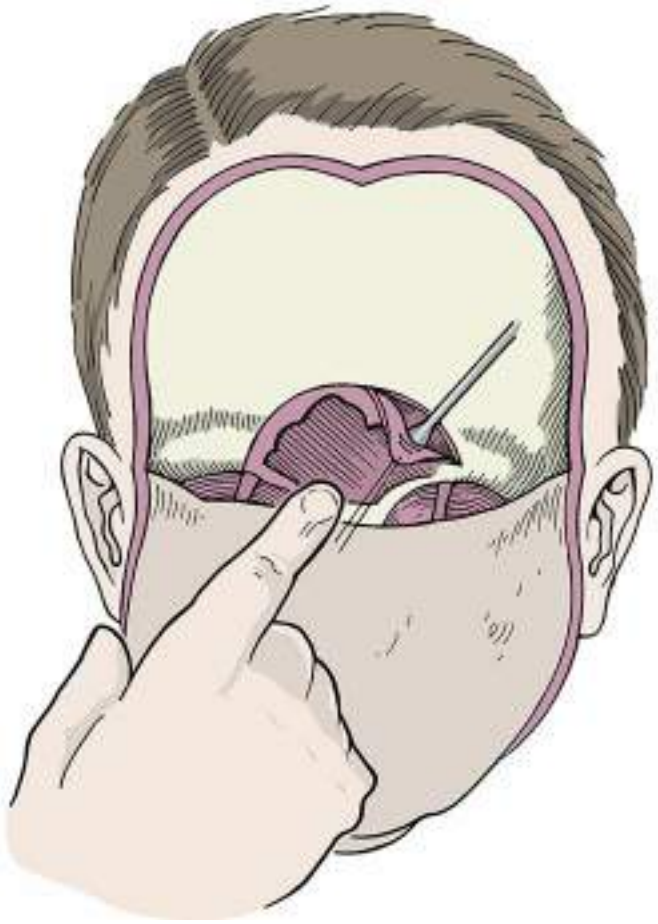

FIG. 114.4 After the template has been used to demonstrate the extent of the frontal sinus, the pericranium is elevated off of the planned osteotomies. The osteotomies can then be mapped on the frontal bone. The pericranium is maintained on the bone flap for closure at the end of the procedure.

- More recently, a variety of other techniques have been described, which likely can be employed to more accurately map out the frontal sinus dimensions.
  - Mini-trephination followed by probing of the sinus
  - Trans-illumination of the sinus via a combined endoscopic approach
  - Image guidance systems

5. Opening of the frontal sinus

- Generally a sagittal saw is used for this step, beveled at a 30- to 45-degree angle.[3,9] This creates a beveled edge that is useful for establishing a stable closure of the sinus at the end of the procedures.

- The osteotomies must be carried into the supraorbital rims along the lateral aspects of the frontal sinus. An osteotome is then used to cut through the intersinus septum and pry forward the anterior wall of the frontal sinus (Fig. 114.5).
- This maneuver will create a greenstick fracture through the supraorbital rims, allowing the osteoplastic flap to be hinged inferiorly. In practice, the fracture through the supraorbital rim may be more complete, creating a free-floating bone fragment. If no longer adequately attached to the overlying periosteum, this bone flap should be stored in saline and replaced before the end of the procedure.

6. Obliteration versus nonobliteration

- In situations where the nasofrontal outflow tract is not compromised, sinus obliteration is generally not required. Examples include frontal sinus osteomas, other benign neoplasms, or lateral mucoceles that can be easily marsupialized for drainage into the sinus. In these cases, a combined endoscopic frontal sinusotomy is often performed to ensure long-term patency of the nasofrontal outflow tract and allow postoperative examination of the frontal sinus.

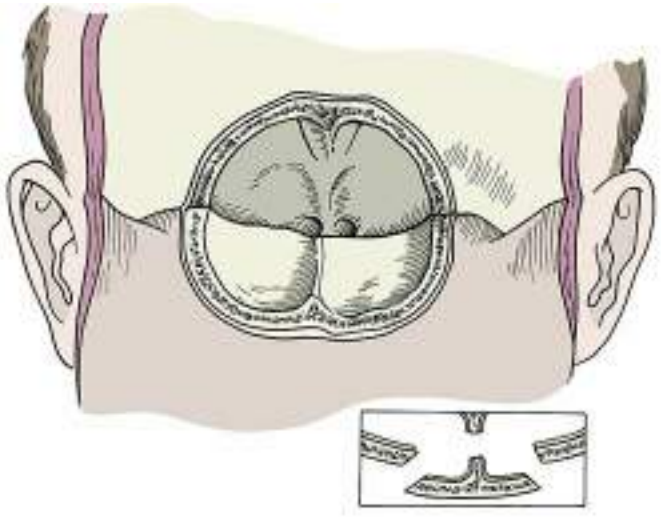

FIG. 114.5 Once the osteotomies have been outlined, a saw is used in a beveled fashion. This must be carried through the supraorbital rims inferiorly. An osteotome is then used to fracture the intersinus septum (*inset*). Ideally the bone flap is then greenstick fractured

downward (hinged on the remaining supraorbital rim), opening the sinus.

- In the setting of chronic inflammatory disease, obliteration is required to prevent recurrence. Thorough removal of all sinus mucosa, using magnification, is a fundamental principle of this surgery required for successful outcomes. This requires the use of a cutting burr along thick bone and potentially a diamond burr along the orbital roof or any area of exposed dura.
- The frontal outflow tract is specifically plugged using a multilayered plug combining bone dust or cartilage with an additional connective tissue layer (e.g., temporalis fascia).

7. Abdominal adipose tissue harvest

- A curvilinear periumbilical incision is generally used. The incision is taken through the skin/dermis until the subcutaneous abdominal adipose tissue is encountered.
- The skin flaps are made inferiorly and laterally (avoiding the umbilicus) until a suitable volume of tissue can be harvested.
- The adipose tissue is then retracted out of the incision with a soft tissue clamp (e.g., Allis clamp), and scissors are used to remove the graft as a single block of tissue.
- Hemostasis is obtained with bipolar cautery, and the wound is irrigated and closed over a small rubber drain with absorbable sutures. Steri-Strips are applied to complete the closure of the abdominal wound.
- The tissue is cleaned with saline and trimmed appropriately. The adipose tissue graft is then brought into the head/neck operative field to completely obliterate the frontal sinus.

8. Replace the osteoplastic flap.

- The osteoplastic flap is then replaced to close the frontal sinus.
- The pericranium is closed using 4-0 chromic catgut sutures.
- Miniplates are then applied for stability.
- Some authors, however, advocate the use of fibrin glue alone to secure the bone flap, if adequately beveled osteotomies were initially

performed.[9]

9. Skin closure

- Multilayer closure of the bicoronal incision over a suction drain
- To prevent brow ptosis, the soft tissue of the scalp flap should be resuspended to the superior, unelevated pericranium.

Reidel's Procedure

- Originally described in the 1890s, this is a radical/early variant of the osteoplastic approach.[10] The classic description includes complete exenteration of the contents of the frontal sinus, along with resection of the anterior wall and floor of the sinus. The forehead skin flap was then draped onto the exposed bony posterior wall of the frontal sinus, creating a significant cosmetic deformity, which has prevented widespread adoption of this technique.[1-3,10]
- More modern modifications of the original Reidel procedure (e.g., as proposed by Killian and Lothrop) may, however, continue to be applicable, in those rare instances when the anterior wall of the frontal sinus requires resection.[10]
- Indications:
  - Recalcitrant frontal sinusitis that has failed attempted osteoplastic obliteration
  - Chronic osteomyelitis of the anterior wall of the frontal sinus
  - Benign or malignant neoplasm causing significant erosion/remolding of the anterior table requiring its resection

Surgical Technique: Reidel's Procedure

1. Mark the skin incision.

- Once again, the bicoronal incision is optimal to provide wide exposure and to allow preservation of the anterior scalp neurovasculature.

2. Raise the bicoronal flap, incise the periosteum, and open the frontal sinus.

- The initial steps are completed in much the same fashion as the osteoplastic procedure described previously.
- The osteotomies into the frontal sinus are now performed with the intention of removing the anterior wall and thus need not be precisely beveled.
- To maintain the aesthetic contour of the brow region, it is essential to leave a supraorbital rim of bone (unless resection is absolutely required for disease clearance).

3. Contour edges of bony defect

- The edges of the surgical defect are now contoured with a polishing burr, to create a gentle symmetrically sloping surface toward the posterior wall of the frontal sinus.[10]
- The supraorbital rim is preserved, including the supraorbital and supratrochlear neurovascular bundles.

4. Closure of the incision

- A standard multilayered closure is performed with the skin flap, allowing it to fit directly onto the posterior wall, thereby obliterating the frontal sinus.
- The aesthetic defect can further be improved by augmenting the surgical site with an abdominal adipose tissue and/or pericranial graft.[5]
- In appropriate patients, reconstruction of the anterior wall can also be considered. Split calvarial grafts are particularly useful in this situation, given proximity to the operative site, ease of harvest, limited patient morbidity, and natural contour to the defects.[5] Free grafts should, however, be used with caution in causes of sinonasal malignancy, given the need for radiotherapy. In patients with extensive bone defects, free tissue reconstruction of the frontal region would be required.

Common Errors in Technique

- Failure to bevel the initial skin incision in the direction of hair follicles, with a higher risk of localized alopecia

- Inaccurate definition of the frontal sinus, with improper placement of osteotomies
- Performing osteotomies that are not appropriately beveled (osteoplastic flap procedure), which makes closure of the sinus more challenging
- Inadequate removal of the mucosa of the frontal sinus (assuming sinus obliteration) leading to high likelihood of mucocele formation
- Failure to resuspend soft tissue of the scalp flap, with an ensuing risk of brow ptosis

Postoperative Period

Postoperative Management

- Standard inpatient management of the drain
- Pain control as necessary
- Resume normal diet and activity as tolerated.
- Generally no need for specialized wound or nursing care at the time of discharge
- After frontal sinus obliteration, physical examination will not adequately assess for surgical failure and mucocele formation. Magnetic resonance imaging (MRI) is considered an ideal technique for postoperative surveillance, particularly when abdominal adipose tissue is used for obliteration. In a series of 82 patients, Weber et al. in particular advocate scheduled MRI scans at 1, 2, and 5 years after surgery.[1]

Complications

1. Acute:

- Hematoma, wound site infection, or surgical site dehiscence
  - Identified as swelling, redness, or breakdown of the incision
  - Will generally require reoperation with drainage of the hematoma,

irrigation of the wound, and reclosure

- Prolonged (at least 2 to 4 weeks) culture-directed antibiotics will be required if active infection is identified.

- Fracture of the bone flap requiring operative repair or bone grafting
- Dural injury and CSF leak
  - Common presenting symptom will be clear rhinorrhea or oropharyngeal drainage, often with a salty taste.
  - Definitive diagnosis often requires fluid collection and testing for beta-2 transferrin. CT or MR techniques may also be used to help localize the site of the leak.
  - Depending on the severity of the leak, initial treatment is often CSF diversion via lumbar drainage.
  - If unsuccessful, operative exploration and repair are necessary.
- Periorbital injury with possible orbital hematoma
  - This is a true postoperative emergency that will present with proptosis and limitation in eye movement and can progress to irreversible loss of visual acuity if not managed.
  - Immediate surgical treatment within the postoperative care unit or surgical ward is required with a formal lateral canthotomy to relieve intraorbital pressure.
  - It is then prudent to proceed to formal reoperative exploration and evacuation of the hematoma.
- Scalp paralysis (facial nerve injury)
  - If identified intraoperatively, direct nerve repair should be performed to improve the outcome.
  - If no obvious evidence of nerve transaction, an observation approach is often used given the likelihood of neuropraxia.
- Temporary anesthesia of the scalp

2. Chronic:

- Failure of operation or extrusion/infection of the obliterative material
  - Recurrent sinusitis with mucocele formation occurs in roughly 10%

of patients.

- This is first managed with culture-directed antibiotics to control the acute infection and inflammation.
- This can often be salvaged with an endoscopic approach to the frontal sinus.
- If this is unsuccessful, a revision osteoplastic versus Riedel procedure will be required.

- Frontal embossment or depression, due to resorption of the frontal bone
  - Over time, a depression at the surgical defect will be noted with increasing cosmetic deformity.
  - This will require operative exploration with removal of scarring. Cranioplasty either with autogenous bone or alloplastic grafts can then be performed to improve the aesthetic contour.
- Poor aesthetic result (e.g., brow ptosis, hypertrophic scar, or localized alopecia)
- Permanent anesthesia of the scalp (supraorbital/supratrochlear nerve injury)

Alternative Management Plan

1. Medical management of inflammatory frontal sinus disease

2. Endoscopic approaches to frontal sinus (e.g., Draf II and Draf III procedures; see Chapters 112 and 113)

3. Frontal sinus trephination

4. Frontal sinus cranialization

Discussion

Evidence-Based Medicine Question

What materials can be used for frontal sinus obliteration?

The goal of sinus obliteration is to completely seal the nasofrontal outflow tract.[9] Abdominal adipose tissue was widely popularized for this indication, and thus there is a long clinical experience. The success of this material is attributed to its ability to promote vascular in-growth, with eventual replacement of the adipose tissue with stable fibro-osseus tissue.[6] While successful in most cases, osteoplastic procedures with obliteration using abdominal adipose tissue have an approximately 10% risk of long-term failure. Harvest of abdominal adipose tissue is also associated with a not insignificant donor site morbidity.[8]

A variety of autologous materials were initially investigated to potentially improve the limitations of abdominal adipose tissue. Animal studies comparing adipose tissue, autogenous muscle, and cancellous bone have failed to show significant differences in successful sinus obliteration.[5,6] Consequently autogenous muscle and cancellous bone have never been widely used clinically. Exogenous materials (e.g., hydroxyapatite bone cement) have also been used, with some initial success. However, these materials seem to promote a higher rate of extrusion/infection and thus should be used with caution.[1,4-6,8]

With advances in skull base surgery and reconstructive techniques, novel approaches have been more recently described. A vascularized pericranial flap is a particularly attractive obliterative material due to its location within the operative field.[8] This is a well-vascularized flap, which does not depend on vascular in-growth from potential diseased/osteitic frontal sinus bone for survival. Moshaver et al., for example, reported a series of 12 patients, successfully managed with pericranial flaps for obliteration, with no long-term treatment failures (average 5-year follow-up).[8] Tissue-engineered materials, specifically platelet-rich/fibrin-rich composite matrix, are also potentially attractive due to the lack of donor site morbidity and success within other regions of the craniomaxillofacial skeleton. A small series by Mendonça-Caridad et al. demonstrated promising results with no surgical failures reported.[7]

As there are no high quality comparative clinical data, no “ideal” obliterative material can be considered to exist. Due to long-term clinical use with reliable (but imperfect) results, abdominal adipose tissue graft should be considered the standard material of choice. However, initial evidence suggests that localized vascularized flaps and tissue-engineered materials may also be appropriate for frontal sinus obliteration.

Editorial Comment

The management of frontal sinusitis and its complications prior to the widespread use of antibiotics following World War II was challenging to say the least. Not only did patients suffer from infection confined to the sinus itself but often from severe complications such as meningitis, brain abscess, periorbital abscess, and osteomyelitis of the frontal bone.

Montgomery reported a series of 250 consecutive cases of osteoplastic frontal sinus operations performed at the Massachusetts Eye and Ear Infirmary from 1956 to 1972 and found that 12% of the patients in this series had presented with one or more of the previously mentioned complications. Obviously many of these patients would have died of these complications prior to the widespread use of antibiotics.

Surgery in the preantibiotic era for frontal sinusitis and its complications was limited to drainage procedures such as trephination or obliteration procedures such as the Reidel procedure (1898) described in this chapter, which was designed to eliminate chronic osteomyelitis of the frontal bone. However, removing the entire anterior wall and floor of the frontal sinus was quite disfiguring. Killian's operation (1904) was similar to the Reidel procedure but left a portion of the supraorbital rim that resulted in less alteration of the contour of the forehead but was also less effective in obliterating the sinus. The Lynch frontal operation (1920) became the most frequently employed operation for the treatment of chronic frontal sinusitis. The procedure consisted of an ethmoidectomy, removal of the middle turbinate, and resection of the entire floor of the frontal sinus. A tube was placed between the frontal sinus and the nasal cavity to establish drainage, and there was no resultant disfigurement.

Full credit should be given to William W. Montgomery, MD, Professor of Otolaryngology in the Harvard Medical School and Senior Surgeon at the Massachusetts Eye and Ear Infirmary, for reintroducing and modifying the osteoplastic frontal sinus operation. Attributed to Beck, of Chicago (1903), the anterior wall of the sinus becomes a "hinged boney trapdoor flap" that affords total visualization of the interior of the frontal sinus, thereby allowing complete removal of the disease, whether it is chronic sinusitis, mucoceles, or osteomas, and without deformity. In Montgomery's series of osteoplastic frontal sinus operations, 42% of 250 patients had failed previous frontal sinus surgery, including Lynch and

Reidel procedures and trephination.

Since the osteoplastic flap procedure has been around for a long time, what contributed to its success when Montgomery reintroduced it? Obliteration of the sinus cavity with adipose tissue taken from the abdominal wall made the difference. Montgomery's experimental work obliterating the frontal sinus with abdominal adipose tissue using the feline model demonstrated that varying amounts of the tissue survived due to revascularization of the adipose tissue by in-growth of blood vessels from the osseous sinus walls.

However, no operation is perfect, and in Montgomery's series, 20 of the 208 patients with follow-up required revision frontal sinus surgery from 4 days to 14 years after the osteoplastic procedure. It is of interest that only 4% of those patients whose sinus was obliterated with abdominal wall adipose tissue were later revised, compared with 10% of those patients whose sinus was not obliterated. In the modern era it is well known that adipose tissue from the abdominal wall is the richest source of stem cells, and I wonder if the introduction of stem cells into the frontal sinus was the secret of soft tissue healing so well in a bony cavity.

Review Questions

1. Which of the following is not a typical indication for the osteoplastic flap procedure?

   a. **Chronic frontal sinusitis**

   b. Osteoma of the frontal sinus

   c. Mucocele within the far lateral aspect of the frontal sinus

   d. Large inverting papilloma of the frontal sinus

2. Which obliteration material has a relatively high rate of postoperative infection and extrusion?

   a. Abdominal adipose tissue

b. Autogenous muscle

c. **Bone cement**

d. Pericranial flap

3. Each of the following are known acute complications of the osteoplastic flap procedure with frontal sinus obliteration, except

a. Dural injury and CSF leak

b. **Cosmetic depression of frontal scalp**

c. Anesthesia of the scalp

d. Periorbital/orbital injury

4. When raising a bicoronal flap, where is the temporal branch of the facial nerve located within the temporal region?

a. Subcutaneous tissue

b. **Deep to the temporoparietal fascia**

c. Deep to the true temporal fascia

d. Deep to the temporalis muscle

5. What complication is prevented by raising a bicoronal flap in the subgaleal plane?

a. Brow ptosis

b. Wound infection

c. Postoperative hematoma

d. **Anesthesia of the scalp**

Frontal Sinus Cranialization

Amit Goyal, Ramachandra P. Tummala, and Emiro Caicedo-Granados

Introduction

The first description of frontal cranialization was in 1978 by Donald and Bernstein.[1] It consists of meticulous removal of the mucosa of the frontal sinus, eliminating the posterior wall of the sinus and allowing the frontal lobe to come to rest against the anterior table of the frontal sinus.

Historical Perspective

The concept of cranialization came from the evolution of treatment of extensive wounds in the frontal sinus and anterior skull base. The initial paradigm in the management of complex fractures of the frontal sinus was to remove all the bone fragments, resulting in a defect that allowed for expansion of the edematous frontal lobes. As a result, cosmetic issues were significant because of the resultant deformity of the forehead. With this paradigm, mucocele formation and mucocele-related infections remained a serious issue. In an attempt to address these issues, the surgery of the frontal sinus evolved into "cranialization." The anterior table is maintained, thereby avoiding a deformity of the forehead. The posterior table of the frontal sinus and the mucosa of the frontal sinus are meticulously removed. The anterior cranial fossa is permanently separated from the frontal recess. This eliminates the presence of the frontal sinus, provides additional space for the brain to expand, and decreases the risk of mucocele formation.

Initial reports by Donald[2] in 1982 and Luce[3] in 1987 concluded that the mucosa of the frontal sinus should be removed and the sinus ostia occluded in order to isolate the frontal sinus from the nasal cavity. Donald introduced the term "cranialization" in 1982, referring to removal

of the posterior table of the frontal sinus, leaving the brain and dura to expand into the former frontal sinus cavity.[2] Rodriguez (in 2008) clarified the debate between cranialization and frontal sinus obliteration with a seminal work summarizing his 26-year experience with fractures of the frontal sinus. He reported a complication rate for cranialization of 10%, compared with 22% for frontal sinus obliteration.[4]

Key Operative Learning Points

Knowledge of frontal sinus embryology and anatomy is critical for the surgical management of the frontal sinus.

- Secondary pneumatization of the frontal sinus commences between 1 and 4 years of age.
- The frontal sinus can be defined as a cavity after 4 years of age and will become more pneumatized by the age of 8 years.
- Significant pneumatization occurs during early adolescence and continues until the age of 18 years.[5]
- The frontal sinus can be divided in three surgical anatomic regions: the frontal sinus cavity, the frontal sinus ostium, and the frontal sinus recess. Frontal sinus cranialization will address the first two anatomic regions.
- It is important to understand the pneumatization and the posterior wall of the frontal sinus in addition to the variants of frontal sinus cells —mainly frontal sinus types II, III, and IV.[6] These frontal sinus cell variants need to be addressed, if present, when cranializing the frontal sinus.
- It is important to understand that there is no anatomic structure known as a naso-frontal duct, and by recent international agreement, the use of this term is now strongly discouraged.[7]
- The veins of Breschet transverse the posterior table of the frontal sinus through small foramina.[8] Meticulous removal of this mucosa within these foramina is critical for reducing the risk of postoperative formation of a mucocele.

Preoperative Period

History

Patients who require frontal sinus cranialization classically present with a history related with the following:

- Patients with a malignant tumor of the anterior skull base usually have a history of nasal obstruction, epistaxis, hyposmia or anosmia, diplopia, facial pain, or sinus pressure associated with purulent rhinorrhea.
- Regarding patients with facial trauma, it is important to determine the type of trauma, either penetrating or blunt trauma. The history in these patients should include symptoms such as visual loss, diplopia, clear rhinorrhea (CSF leak), neurologic symptoms of meningitis, and mass lesions such as intracranial hematoma.
- Patients with inflammatory processes (chronic sinusitis) usually present with purulent rhinorrhea, facial pain, or pressure.

Physical Examination

Physical examination for patients requiring frontal sinus cranialization should emphasize the underlying pathology mentioned earlier.

- A complete examination of the head and neck must be performed, including the cranial nerves.
- It is important to evaluate for cervical metastasis in those patients with suspected underlying malignant disease.
- The use of nasal endoscopy is critical to obtain valuable information on tumor characteristics such as vascularity and extent.
- In patients with trauma, a complete examination of the orbit is mandatory, including checking pupillary reflexes and extraocular movements. In addition, the examiner should check for ptosis, chemosis, and proptosis.
- In trauma patients, one must be suspicious for CSF rhinorrhea.

- Ophthalmologic consultation should be obtained in patients with abnormal signs/symptoms involving the eyes.
- Examination of the anterior wall of the frontal sinus will determine its integrity.
- In patients with suspected frontal sinus inflammatory disease, palpation of the anterior table of the frontal sinus is important to rule out bone erosion or soft tissue mass (e.g., Pott's puffy tumor).

Imaging

Patients with tumors of the anterior skull base require both a computed tomography (CT) scan and magnetic resonance imaging (MRI) with and without contrast. These studies complement each other in determining the bony anatomy, bone erosion, extension of tumor, involvement of the dura, and edema of the brain. In patients with facial trauma, MRI should be obtained in selected cases. Sinus or head CT scan should be obtained to evaluate the following:

- Anatomy and integrity of the frontal sinus, with particular attention to the integrity of the anterior and posterior tables.
- Anatomy and integrity of the frontal sinus recess, especially with fractures through the frontal recess. This will allow the surgeon to predict stenosis of the frontal recess.
- Integrity of the facial bones and orbit.
- Acute neurosurgical sequelae of facial trauma, including pneumocephalus or intracranial hemorrhage that may need emergent management.

Indications

The main indication for frontal sinus cranialization is determination that the frontal sinus drainage cannot be restored. Examples of indications for cranialization are as follows:

- Severe traumatic injury of the frontal sinus with involvement of both anterior and posterior tables

- Displaced fracture of the frontal recess (outflow tract)
- Displaced fracture of the posterior wall of the frontal sinus with the presence of a CSF leak
- Need for neurosurgical intervention
- Cranialization should be considered as the final remedy for refractory chronic frontal sinusitis.
- Tumors of the anterior skull base or frontal sinus with erosion of the posterior table of the frontal sinus

Contraindications

- Patients who are poor surgical candidates because of associated injuries or severe medical comorbidities should not undergo this procedure.
- Patients with unresectable tumor determined by invasion of the brain, cavernous sinus, or orbit may not benefit from this surgical procedure.
- If the posterior table component is nondisplaced or minimally displaced with an intact frontal sinus outflow tract, consider a less aggressive procedure such as open reduction and internal fixation (ORIF) of the anterior table and close follow-up leaving salvage surgery using endoscopic frontal sinus procedures in reserve.

Preoperative Preparation

- Because most patients are unfamiliar with the concept of this operation, the surgeon must provide a detailed explanation. It is important to discuss with the patient the expectations, risk, and benefits of this surgical procedure. The patient needs to be aware of potential acute and long-term complications.
- MRI and sinus CT scan with and without contrast are critical for preoperative planning. In the case of a benign or malignant tumor, the extent of the disease should be determined in detail. MRI is an excellent tool to differentiate between tumors and retained sinus secretions. MRI and CT help evaluate involvement of the orbit, brain, cavernous sinus, and dura. This information is critical in planning the

surgical procedure and in counseling the patient.

- In cases where the tumor is readily accessible through the nose or sinuses, a preoperative biopsy is indicated to aid in securing a diagnosis and planning for definitive resection.
- Patients with ophthalmologic or neurologic symptoms should be seen in consultation by ophthalmology and neurosurgery.

Operative Period

Anesthesia

- Patients are placed under general endotracheal anesthesia. Administration of paralysis is recommended, and the endotracheal tube can be secured to the teeth using a wire or a 2-0 silk suture.
- Placement of an arterial line provides accurate and instantaneous hemodynamic monitoring.

Positioning

- The patient is placed in the supine position. The head is secured in the neutral position. If an endoscopic endonasal approach is expected, the head should be slightly hyperextended for better access to the frontal sinuses. The head can be positioned on a foam pad or a horseshoe or fixated in a head clamp.
- Frameless stereotactic navigation may be useful, especially in cases of distorted anatomy.
- Lower extremity compression devices are applied, and a Foley catheter is inserted.
- Bilateral tarsorraphies are placed.
- The patient's head and face are prepped and draped in a sterile fashion.
- A narrow strip of hair (about 2 cm) is shaved behind the anterior hairline.

Perioperative Antibiotic Prophylaxis

- A third-generation cephalosporin (e.g., ceftriaxone) is used as the main prophylactic antibiotic.
- If the patient is allergic to penicillin or cephalosporin, vancomycin and metronidazole are used.

Monitoring

There is typically not a need for intraoperative neurologic monitoring. Rarely, electromyography (EMG) may be useful for monitoring the extraocular cranial nerves in cases of orbital extension.

Instruments and Equipment to Have Available

A standard neurosurgical craniotomy and endoscopic sinus set. An operating microscope should be available if a transcranial intradural approach is planned.

Key Anatomic Landmarks

- The frontal branch of the facial nerve runs immediately deep to the temporoparietal fascia.
- The zygomatic arch has to be identified by palpation to plan the incision of the temporalis fascia. This incision is usually 2 cm above the zygomatic arch.

Prerequisite Skills

- Knowledge of the anatomy of the frontal sinus, anterior cranial fossa, and orbits
- Proficiency with the endoscope, operative microscope, and high-speed electric drill

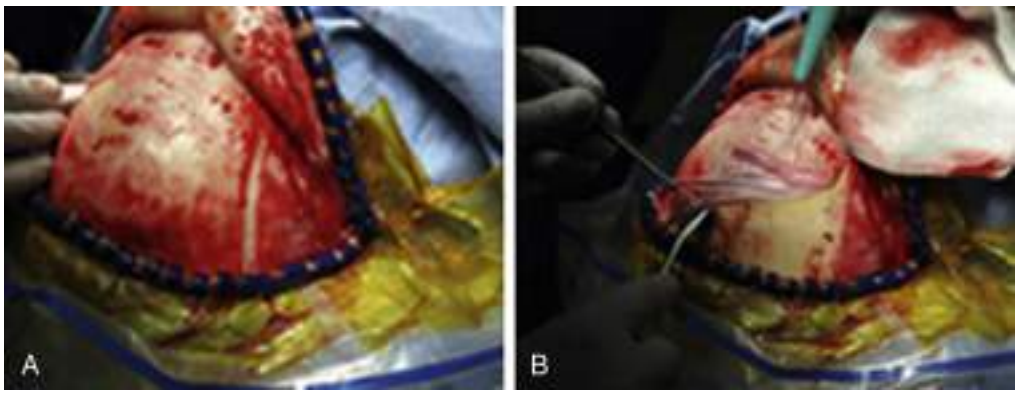

FIG. 115.1 Scalp flap.

A, Scalp flap is elevated, and Raney scalp clips are applied. The pericranium is still attached to the calvarium. An incision is made at the transition between the pericranium and the superficial temporoparietal fascia. **B,** Elevation of the pericranial flap. The pericranial flap is elevated using a wide elevator. Gentle elevation and dissection are a must to maintain the integrity of the flap.

Operative Risks

- Damaged hair follicles: This can be avoided by using a knife blade to incise the scalp instead of an electrocautery. The incision has to be parallel to the hair follicles to minimize this risk.
- Injury to the frontal branch of the facial nerve (see section "Surgical Technique")
- Injury to the supraorbital or supratrochlear vessels, which will compromise the vascular supply of the pericranial flap
- Cerebrospinal fluid leak: Use the appropriate drill when performing burr holes and craniotomy to avoid injury to the underlying dura.
- Careful separation of the bone flap from the dura is critical to avoid dural tears or injury to the superior sagittal sinus.

Surgical Technique

- A bicoronal incision beginning just anterior to each tragus is made behind the hairline.
- The planned incision can be directed more posterior if a large pericranial flap is required.
- The incision can be linear or parallel to the hairline.
- The incision is carried down through the galea, and the scalp is dissected sharply with a scalpel along the loose areolar plane. This will reveal the pericranium overlying the frontal bone and the temporalis fascia in the temporal region (Fig. 115.1A).
- The pericranium is incised laterally on each side, just above the superior temporal line. The posterior incision in the pericranium is placed a few centimeters posterior to the initial skin incision.
- The vascularized pericranial flap is elevated off of the skull and carried anteriorly, with its blood supply preserved (see Fig. 115.1B).
- Any defects in the pericranium can be repaired with absorbable sutures.
- The degree of elevation of the scalp depends on how anterior an exposure is necessary (i.e., close to the nasion).
- If a very anterior exposure is needed, the temporalis fascia is incised, and a subfascial dissection is performed to retract the scalp and temporalis fascia as one flap. This dissection reduces the risk of injury to the temporal branch of the facial nerve.
- The dissection can be carried anteriorly enough so that the superior orbital rims are exposed bilaterally.
- For routine cranialization procedures, such low exposure is unnecessary.
- After the pericranial flap has been elevated, a bifrontal craniotomy is performed.
- The extent of the craniotomy varies, depending on how much exposure is necessary.
- Access to the frontal sinus can be gained through a relatively small craniotomy, but a large craniotomy flap is usually made for cosmetic

purposes.

- The posterior aspect of a large craniotomy flap will lie behind the level of the hairline.
- A burr hole is typically placed at each keyhole, with one in the midline.
- For cosmetic reasons, placing burr holes low on the forehead is avoided.
- The midline burr hole is placed at the level of the hairline (Fig. 115.2A).
- If the dura is densely adherent to the inner table of the skull, additional burr holes are made to facilitate separation of the dura. This is especially important if the superior sagittal sinus is adherent to the skull.
- A high-speed craniotome is used to complete the single, bifrontal bone flap (see Fig. 115.2B).
- Once the bone flap has been removed, the frontal sinus is exposed bilaterally (Fig. 115.3A).
- The dura of the frontal lobe is dissected off the posterior wall of the frontal sinus.
- If necessary, the frontal lobes can be relaxed with head elevation, administration of osmodiuretics such as mannitol, or hyperventilation.
- Additional relaxation can be achieved with cerebrospinal fluid drainage from a ventricular or lumbar catheter.
- In the postoperative period, these drains may augment any repair of a CSF leak.
- If the frontal sinus has not been entered with the craniotomy, the posterior wall can be drilled off at this point. The remainder of the posterior wall is removed with a drill or rongeurs (see Fig. 115.3B).
- The mucosa of the frontal sinus is removed entirely using curettes, diamond burrs, and blunt dissectors.
- A diamond burr is used to take down boney prominences within the sinus, which allows hidden areas of mucosa to be removed. The frontal sinus infundibulum is obliterated using a combination of pieces of temporalis muscle, fascia, and fibrin glue.

- The pericranial flap is then laid down and reinforced with fibrin glue such that it covers the defect in the posterior wall of the frontal sinus and provides an additional layer of separation between the frontal sinus and the dura.
- In order to adequately employ the pericranial flap for this purpose, it should be laid down along the floor of the anterior fossa between the bone and dura.

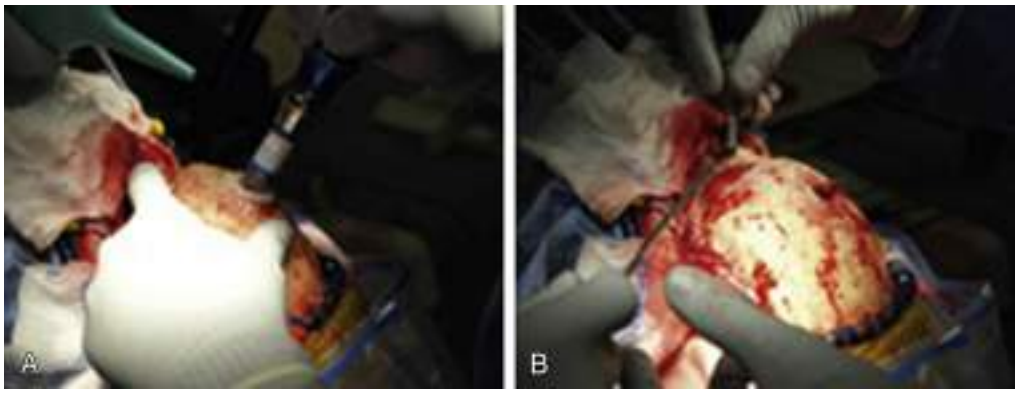

FIG. 115.2 Frontal craniotomy.

A, A high-speed drill is used to create three burr holes, as described in the "Surgical Technique" section. The picture shows the creation of a midline burr hole at the level of the hairline. Notice the perpendicular orientation of the drill shaft and continuous irrigation. **B,** A high-speed craniotome is used to complete the single, bifrontal bone flap.

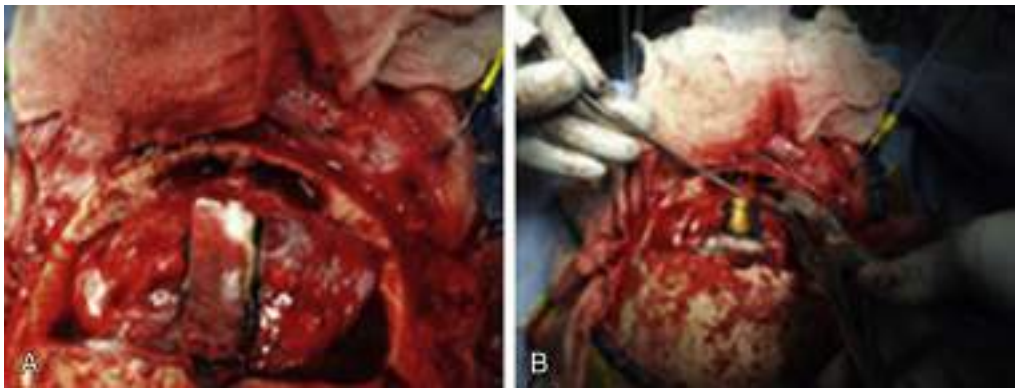

FIG. 115.3 Exposure of the frontal sinus.

A, The frontal sinus is exposed, and, **B,** the posterior wall of the frontal sinus is removed using rongeurs and a high-speed drill as needed.

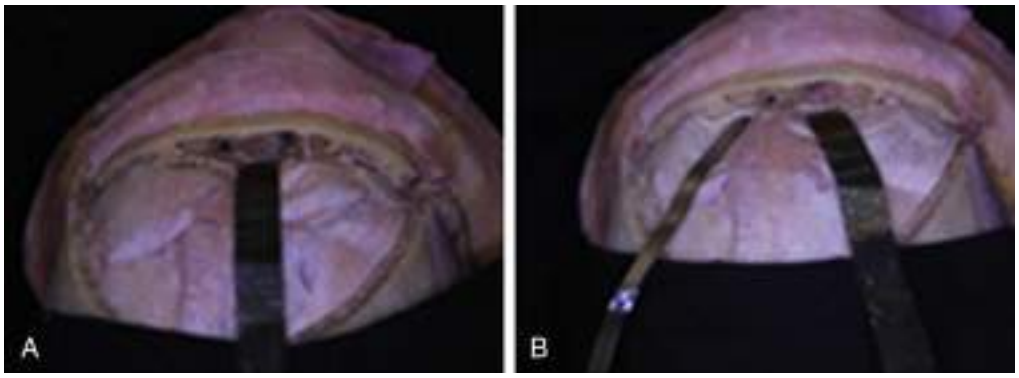

FIG. 115.4 Exposure of the frontal sinus infundibula.

A, The posterior wall of the frontal sinus has been removed, and both frontal sinus infundibula are exposed. **B,** Occlusion of the right frontal sinus infundibulum with muscle and fascia.

- Care must be taken during this critical step to avoid any tearing or bunching up of the pericranial flap.
- Any dural defects are repaired directly with suture or indirectly with dural grafts and fibrin glue.
- The bone flap is repositioned and secured using mini-plates and screws once the fibrin glue has congealed (Fig. 115.4).
- The bone flap is replaced in such a way that will not crush and devascularize the pericranial graft.
- Leaving too much of a gap for the pericranial flap may create a cosmetic defect in the forehead.
- Any defect encountered or created in the anterior wall of the frontal sinus can be repaired using a combination of split calvarial bone graft, titanium mesh, and mini-plates.
- The scalp is closed in two layers after hemostasis has been ensured.

- Placement of a subgaleal drain can reduce postoperative periorbital edema. However, a drain is avoided if durotomies or CSF leaks are encountered in order to reduce the risk of a persistent CSF fistula.

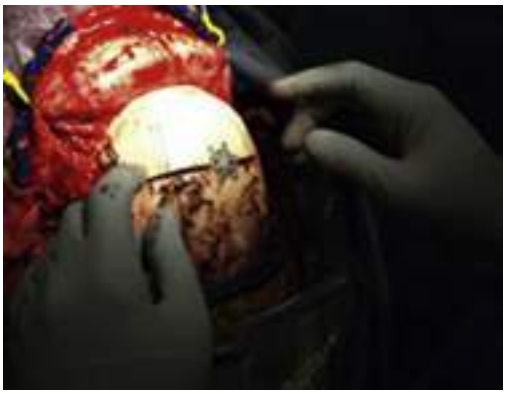

FIG. 115.5 Reconstruction of bone flap.

The frontal bone flap is replaced in the anatomic position and is secured with mini-plates.

Common Errors in Technique

- Making the skin incision perpendicular to the hair follicles
- Not extending the scalp incision down to the root of the helix will limit the rotation of the scalp.
- Dissecting between the temporoparietal fascia and the superficial layer of the deep temporal fascia will increase the risk of injury to the frontal branch of the facial nerve.
- Failure to harvest an adequate pericranial flap: The flap must be large enough to cover the resected posterior wall of the frontal sinus.
- Cosmetic defects low on the forehead: The craniotomy should be low on the forehead, but the thickness of the frontal sinus cavity will prevent the craniotomy drill from advancing too low. Attempts to go lower than what the sinus will allow will simply erode the anterior aspect of the frontal bone, leaving an unsightly gap upon replacement of the bone flap.
- Inadequate removal of the mucosa from the frontal sinus: A

microscope or endoscope should be used to visualize and illuminate the depths of the frontal sinus and remove as much mucosa as possible. Using a diamond burr will allow the rest of the mucosa to be removed.

- Devascularization of the pericranial flap: The bone flap should be replaced in a manner that the pericranial flap is not crushed by the anterior edge of the bone flap (Fig. 115.5).

Postoperative Period

Postoperative Management

- Depending on the extent of the surgical procedure, patients are admitted to the neurosurgical intensive care unit or a step-down unit.
- A #15 flat Jackson-Pratt drain connected to a small lower pressure suction bulb and a pressure dressing is used. Usually the drain and the pressure dressing are removed within 2 to 3 days.
- The patient is usually discharged to the next level of care in 3 to 5 days.
- Skin sutures are removed 7 to 10 days after surgery.

Complications

- Postoperative alopecia
  - Prevention: Skin incision should be parallel to the hair follicles; avoid using electrocautery for skin incision.
  - Diagnosis: Physical examination will demonstrate alopecia along the incision line.
  - Treatment: Observation; dermatology consultation is an option
- Hematoma
  - Prevention: Ensure good hemostasis throughout the surgical procedure.
  - Diagnosis: Physical examination will demonstrate a subgaleal fluid collection.

- Treatment: Incision and drainage

- Loss of the skin flap
  - Prevention: Avoid dissection in the subcutaneous plane. Make sure that the dissection of the skin flap is done in the subgaleal plane.
  - Diagnosis: Physical examination will demonstrate ischemia of the skin.
  - Treatment: Débridement and consultation with a reconstructive surgeon
- Paralysis of the forehead muscles due to injury to the frontal branch of the facial nerve
  - Prevention: When 2 cm above the zygomatic arch, the dissection transitions under the superficial layer of the deep temporal fascia.
  - Diagnosis: Postoperative physical examination will demonstrate brow ptosis. Patients may also complain of decreased visual fields and tension headaches and report seeing their eyebrows in their visual field.
  - Treatment: Surgical reanimation by an experienced reconstructive surgeon
- CSF leak
  - Prevention: Watertight closure of any dural tears is a must. The pericranial flap should rest on bony structures such as the roof of the orbita and planum.
  - Diagnosis: Evidence of clear rhinorrhea and a positive beta-2 transferrin test
  - Treatment: Spinal fluid diversion (lumbar drain) or surgical revision of the skull base closure
- Meningitis
  - Prevention: Prophylactic antibiotics
  - Diagnosis: Physical examination showing findings compatible with meningitis
  - Treatment: Antibiotic therapy accordingly with culture results

- Contour defect
  - Prevention: Usually a result of trauma, not surgical technique
  - Diagnosis: Physical examination
  - Treatment: Split thickness calvarial or alloplastic grafts for cranioplasty to correct the deformity
- Frontal sinus mucocele or mucopyocele
  - Prevention: Remove the entire mucosa from the frontal sinus.
  - Diagnosis: Most of the mucoceles are asymptomatic and are diagnosed with follow-up imaging. A group of patients will develop acute infection in a mucocele (mucopyocele).
  - Treatment of the mucopyocele is with antibiotics, followed by incision and drainage (usually done endoscopically). If not infected, the recommendation is to remove the mucocele to prevent problems in the future.
- Frontal bone osteomyelitis
  - Prevention: Prophylactic antibiotics
  - Diagnosis: Patient history and physical examination supplemented by CT and MRI scans
  - Treatment: Aggressive intravenous (IV) antibiotics and possible surgical débridement with sequestrectomy of frontal bone if necessary
- Brain abscess
  - Prevention: Prophylatic antibiotics
  - Diagnosis: Patient history and physical examination supplemented with MRI scan
  - Treatment: For epidural and subdural empyemas, surgical evacuation followed by IV antibiotics; intracerebral abscess warrants needle aspiration followed by IV antibiotics
- Temporal wasting if adipose tissue pad was elevated and devascularized
  - Prevention: Dissection in the correct plane when elevating the

temporalis muscle, while ensuring not to injure the frontal branch of the facial nerve

- Diagnosis: Physical examination
- Treatment: Because this primarily presents as a cosmetic deformity, many times it can be left untreated; otherwise, an adipose tissue graft can be used to help with cosmesis.

Alternative Management Plan

Currently, with the establishment of advanced endoscopic skull base techniques, cranialization has been increasingly replaced by Draf III frontal sinusotomy.

Discussion

Evidence-Based Medicine Question

Does frontal sinus cranialization decrease the rate of postoperative complications when compared with frontal sinus obliteration in the treatment of frontal sinus tumors?

There is a lack of literature comparing the results between frontal sinus obliteration and cranialization. Horowitz et al.[9] analyzed 69 patients who underwent excision of benign frontal sinus lesions by an open approach using frontal sinus obliteration in 41 patients (59%) and frontal sinus cranialization in 28 patients (41%).

The frontal sinus lesions treated were osteoma, mucocele, encephalocele, and fibrous dysplasia. The complication rate in the obliteration group was 29.2% and 17.8% in the cranialization group. In the obliteration group mucocele formation happened at a median time of 4.3 years. Patients who developed mucocele in the obliteration group were treated with frontal sinus cranialization, and none of those patients required a second revision surgery. Statistical analysis demonstrated that frontal sinus cranialization is not inferior to obliteration in preventing secondary mucocele formation.

Editorial Comment

Frontal sinus cranialization is a critical technique in the management of both frontal sinus trauma and malignancies of the anterior cranial base. Despite the advent of endoscopic techniques, severe traumatic disruption of the posterior table and malignancies that extend anteriorly in the frontal sinus are often best managed with this procedure. While conceptually straightforward, the many nuances highlighted in this chapter, including careful placement of the craniotomy, differential dissection to preserve the adipose tissue pad containing the frontal branch of the facial nerve, and allowing adequate space for the vascular pedicle of the pericranial flap below the anterior table, are critical for the functional and aesthetic outcome of the procedure. Meticulous removal of the entire posterior table and the mucosa from the frontal sinus is critical and is generally the most challenging in highly pneumatized frontal sinuses with large supraorbital ethmoid cells. Finally, obliteration of the frontal outflow tract can be performed with a variety of substrates and is often surgeon dependent. However, autologous grafts are generally favored, as exposure of porous foreign material to the sinonasal cavity can result in long-term infectious complications.

Review Questions

1. A key anatomic feature of the posterior wall of the frontal sinus is:

   a. The lack of bone marrow

   b. It is usually a flat surface

   c. Its vascular supply is mainly from branches of the middle cerebral artery

   d. **The presence of the veins of Breschet**

   e. All of the above

2. The following are indications for frontal sinus cranialization, except

   a. Recalcitrant frontal sinusitis

b. Severe frontal trauma with displaced fracture of the posterior table

c. **Benign tumor located in the frontal recess**

d. Malignant tumor of the anterior skull base with erosion of the posterior table of the frontal sinus

e. None of the above

3. The frontal branch of the facial nerve in the temporal region runs

a. Deep to the deep layer of the deep temporal fascia

b. Superficial to the deep layer of the deep temporal fascia

c. Within the temporal adipose tissue pad

d. Superficial to the temporoparietal fascia

e. **Deep to the temporoparietal fascia**

4. Which of the following is the least likely complication following frontal sinus cranialization?

a. CSF leak

b. Seizures

c. Mucocele formation

d. **Blindness**

e. Brain abscess formation

5. All of the following can be used to relax the brain, except

a. Mannitol

b. Reverse Trendelenburg position

c. **Hypercarbia**

d. Hyperventilation

e. Lumbar drain

Endoscopic Management of Cerebrospinal Fluid Leaks

Christopher J. Chin, Ricardo Carrau, Carl H. Snyderman, and Allan Vescan

Introduction

A cerebrospinal fluid (CSF) leak defines a fistula between the subarachnoid space and the sinonasal tract. Patients with CSF leaks present with symptoms such as clear nasal discharge and headache or complications such as pneumocephalus, meningitis, or brain abscess. The main indication for repairing a CSF leak is to prevent these potentially life-threatening complications.

CSF leaks can be classified in a number of ways; etiology and anatomic site are commonly used to classify CSF leaks. Etiologic classification can be subdivided into traumatic and nontraumatic origin. Within the traumatic group, leaks can be either accidental or iatrogenic. Most CSF leaks are caused by traumatic fractures of the cranial base or by injuries produced during endoscopic sinus surgery (ESS) or cranial base surgery. CSF leaks are diagnosed in 3% of patients suffering closed head injuries and in up to 30% of patients with a fracture of the skull base.[1] Iatrogenic trauma, such as traditional cranial base surgery and ESS, can also be associated with CSF leaks. ESS remains one of the most common etiologies for CSF rhinorrhea, despite an overall incidence of less than 1% in patients undergoing ESS.[2,3] Nontraumatic CSF leaks may occur secondary to tumors of the skull base, congenital malformations, and/or high-pressure hydrocephalus (HPH). The etiology of HPH includes tumors, trauma, infections, and hemorrhagic cerebrovascular accidents (CVAs). Occasionally, no etiology is identified for the HPH, and it is therefore deemed "idiopathic."

Multiple techniques have been reported for the repair of a CSF fistula. The modern era of CSF leak repair was ushered in when, in 1985,

Calcaterra[4] described the use of free muscle or fascia grafts to treat CSF fistulas. This was followed in 1989 by Papay et al.,[5] who described an endoscopic technique that has become the standard of care. Recently, a vascularized nasoseptal flap has been devised to reconstruct skull base defects of various etiology, and early follow-up data reveal a remarkable improvement in CSF fistula rates following expanded endonasal approaches to the skull base.[6] The endoscopic endonasal approach has become the standard repair option and has been shown to have low complication rates with high success rates.[7]

The availability of the biologic material and the experience and familiarity of the operating surgeon with various techniques are the most predominant factors influencing the choice of which is used during the endoscopic endonasal closure of CSF fistulas. Most techniques yield similar results in experienced hands, as confirmed by a meta-analysis of the literature by Hegazy et al.[8] After analyzing all reports in the English literature, these authors found no significant differences in outcome regardless of which surgical technique or which homologous material was used for the repair.

Key Operative Learning Points

- Biochemical confirmation is essential in diagnosing CSF leaks.
- After the diagnosis is confirmed, imaging can be used to help to localize the lesion.
- Complete exposure of the skull base, and the site of the leak, will facilitate a more thorough repair.
- Image guidance can be used to help to confirm the location of the leak if it is seen on preoperative imaging.
- The underlying cause of the leak should be addressed; if the patient has intracranial hypertension, this should be treated to prevent failure of the repair.
- The first-line treatment for a spontaneous CSF fistula should not include a lumbar drain.

Preoperative Period

History

- The diagnosis and management of a CSF leak involves three critical steps:
  - Distinguishing a CSF leak from other sources of rhinorrhea
  - Locating the fistula
  - Ruling out high intracranial pressure secondary to altered CSF dynamics
    - Demographic information can help to guide the workup; spontaneous CSF leaks are most commonly seen in young or middle-aged obese females.
    - Hydrocephalus can be the result of posttraumatic, postsurgical, and postinfectious scenarios due to obstruction of the arachnoid villi.
- A clinical diagnosis of a CSF leak is based on a history of rhinorrhea:
  - Clear, watery nasal drainage
  - Usually the rhinorrhea is unilateral.
  - Commonly associated with headache
  - Increased rhinorrhea when the patient leans over, tilts the head forward, or performs a Valsalva maneuver
- History of tumor, trauma, or previous surgery involving the paranasal sinuses or cranial base heightens the level of suspicion.
- Occasionally, a life-threatening complication arising from the CSF leak, such as pneumocephalus, or ascending bacterial meningitis may be the initial presentation.
- Conditions such as vasomotor rhinitis and sympathetic denervation can cause profuse rhinorrhea that may be confused with a CSF leak.
- Nasal irrigations during ESS (or used as part of the postoperative care) may accumulate in the paranasal sinuses and later present as postoperative rhinorrhea.

Physical Examination

- A full examination of the head and neck, including endoscopic examination of the nasal cavity, should be completed to attempt to identify the source of CSF rhinorrhea.
- Having the patient "provoke" the leak, by bending over in a "head down" position, can sometimes help to identify the site of an active leak.
- When CSF rhinorrhea develops after sinus surgery, the endoscopic surgeon typically has an impression as to the possible site of injury to the cranial base.
  - A thorough endoscopic office examination of the nasal cavity may corroborate the site of the leakage.
  - Fistulas with low-pressure leaks are difficult to identify, especially in the presence of postoperative tissue edema and blood clots.

Imaging

- Biochemical testing is indicated to confirm the true nature of the nasal drainage and should be done prior to ordering expensive imaging tests.
  - CSF will typically be high in glucose and low in protein.
  - Normal nasal discharge has been shown to be falsely positive for glucose in 45% to 75% of cases.
  - β_2-Transferrin is a protein found in CSF, aqueous humor, and perilymph but not in blood or nasal secretions; therefore β_2-transferrin is a reliable chemical marker of CSF leakage.
  - A second protein, β-trace protein, is also available but not as widely used as β_2-transferrin.
- Multiple imaging modalities have been advocated for the diagnosis of CSF leak, each with their own advantages and disadvantages.
  - Scintigraphy with indium (In-111) is one test that has been advocated for the identification of a CSF leak.

- Radiotracing is a very sensitive test; however, it is associated with a high false-positive rate and has poor resolution that precludes establishing the specific point of leakage; at our institution, scintigraphy is rarely performed.

- In our practice, the presence of the CSF leak is typically confirmed with β_2-transferrin electrophoresis, and its site of origin is identified by computed tomography (CT), magnetic resonance (MR) or CT cisternography (Fig. 116.1), and/or endoscopy.
- An important consideration in a patient presenting with spontaneous rhinorrhea or rhinorrhea after skull base trauma is to distinguish whether the CSF rhinorrhea arises from the sinonasal tract or from other sites, such as the middle ear or mastoid (Fig. 116.2).
- A CSF fistula in the temporal bone may drain into the nose through the eustachian tube.
- Radiographically, a high-resolution computed tomography (HRCT) can be used to identify a cranial base defect.
  - HRCT is our preferred initial imaging study to aid in the identification of the site of injury and its extent (see Fig. 116.1).

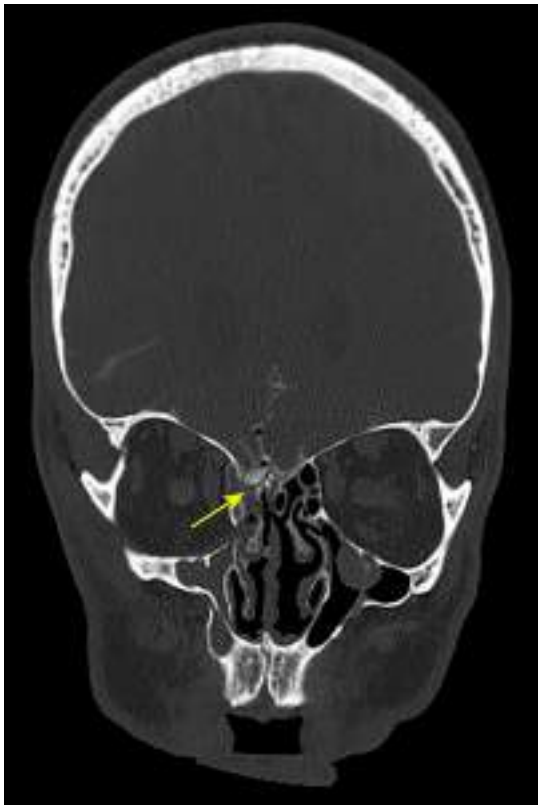

FIG. 116.1 Coronal computed tomography cisternogram demonstrating a posttraumatic cerebrospinal fluid fistula *(arrow)* of the right cribriform plate.

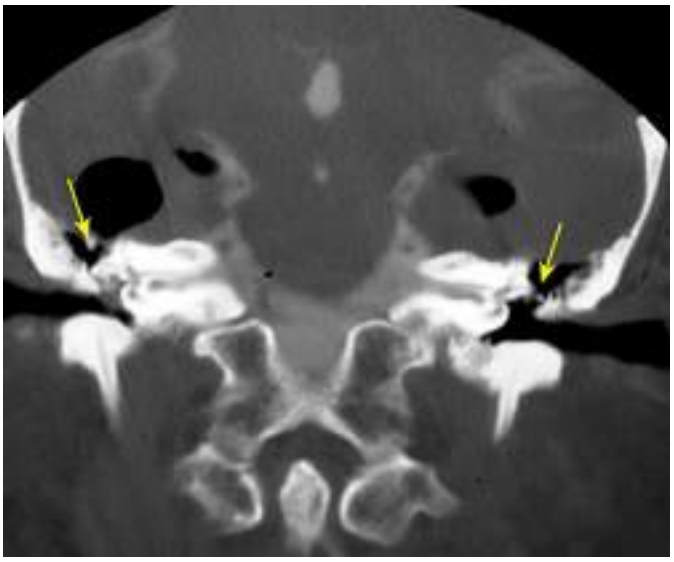

FIG. 116.2 Coronal computed tomography cisternogram demonstrating bilateral tegmen defects with contrast penetrating existing defects *(arrows)*.

- HRCT with contrast also provides information about the possibility of intracranial complications, such as hematoma or brain contusion, that occur in the setting of acute trauma (iatrogenic or accidental).
- HRCT with cuts taken in the coronal and sagittal planes is essential to evaluate the integrity of the bony wall in question.
- Coronal CT views are best to evaluate defects of the cribriform plate, fovea ethmoidalis, or planum sphenoidale, whereas axial views are superior to evaluate the posterior wall of the frontal or sphenoid sinuses.

FIG. 116.3 Sagittal magnetic resonance imaging demonstrating a large meningoencephalocele *(arrows)* of the anterior cranial base.

- Indirect signs of a CSF leak include collection of fluid in a sinus and pneumocephalus.

- We use magnetic resonance imaging (MRI) to differentiate meningocele and meningoencephalocele (Fig. 116.3), as well as to better delineate the vascular anatomy, which is important when considering a surgical repair.

- HRCT, although an excellent first imaging choice, may not identify small areas of surgical trauma or linear nondisplaced fractures.
  - HRCT can be used in conjunction with intrathecal contrast to identify the fistula, a so-called CT cisternogram; this test has been documented to be both sensitive and reliable.
  - However, identification of the fistula using contrast studies requires the presence of an active leak, which is not always the case clinically.
  - Intermittent leaks that are temporarily sealed by edema, inflammation, or brain herniation may yield a false-negative result.
  - Intrathecal injection of saline solution to increase the CSF pressure, a "saline challenge," enhances the sensitivity of the test.
- MR cisternography has been suggested to complement the information offered by an HRCT; however, in our experience this technique has yielded inconsistent results.

Indications

- CSF leak with biochemical confirmation

Contraindications

- Failure to confirm the presence of a CSF fistula on biochemical testing
- Patient medically unfit for general anesthetic
- Active infection of the sinonasal tract

Preoperative Preparation

- Intrathecal fluorescein may be used to aid in the diagnosis and localization of the CSF leak.
- During this test, 0.15 mL of fluorescein, of a concentration no greater than 5%, is diluted with 10 mL of CSF, obtained through a lumbar puncture, and is then injected slowly intrathecally over 3 to 5 minutes.
- Fluorescein is neurotoxic and a low concentration–low volume

injection is mandatory to avoid the neurologic complications associated with higher concentrations.

- After intrathecal injection of the fluorescein solution, the CSF leak may be visualized using the nasal endoscope.
  - Under a Wood lamp (i.e., black light), fluorescein will appear as bright yellow-green; nonetheless, the yellowish color of fluorescein may be identified without the need for special lighting.
- Some clinicians have been discouraged from using fluorescein because of:
  - The logistics of performing a lumbar puncture in an outpatient setting
  - Medicolegal considerations (the fluorescein drug package insert includes an advisory warning against intrathecal use)
- Intrathecal injections, in any case, are rarely critical to the identification of the CSF fistula.
- Exceptional patients are those with multiple fistulas, such as those who suffered skull base fractures, and the rare patient who presents with repeated episodes of meningitis in the absence of an apparent cranial base defect or other predisposing factors, such as rhinosinusitis or otitis media.
- Others have advocated the intrathecal injection of air, which can "bubble" out at the fistula site, thus aiding in its identification.
  - Of note, air is an irritant to the brain and may induce seizures.
  - Alternatively, normal saline solution may also be injected into the intrathecal space to increase the pressure within the subarachnoid space and increase flow at the site of the leak.

Operative Period

Anesthesia

- As with all ESSs, controlled hypotension is beneficial in improving visualization.

- An oral Ring, Adair, Elwyn (RAE) tube may be beneficial to ensure the anesthesia circuit does not interfere with the surgery.
- The use of topical vasoconstrictors is essential to improve visualization, and communication with anesthesia is important because of their vasoactive properties.
- It is important to communicate with the anesthetist and anesthesia team that theoretically there is a risk of pneumocephalus with an open skull base defect and positive pressure mask ventilation should be avoided; a nasal airway can be considered.

Positioning

- The patient should be supine, in reverse Trendelenburg position, to decrease bleeding and improve visualization.
- Extension of the neck provides increased access to the anterior cranial base.
- The eyes should be covered with clear tape and exposed during the surgery.

Perioperative Antibiotic Prophylaxis

- Although commonly used, the evidence for antibiotic use is limited (see Evidence-Based Medicine Question later).
- If an antibiotic is used, it is recommended to use an antibiotic with good penetration of the blood-brain barrier, such as ceftriaxone.

Monitoring

- Routine anesthesia monitoring should be used.
- Muscle paralysis can be used because no intraoperative nerve stimulation is anticipated.

Instruments and Equipment to Have Available

- Standard ESS set
- If a fascia lata graft is to be harvested, a soft tissue set should be available.
- A full complement of angled endoscopes, including a 30- and 70-degree scope, is often helpful for visualizing the skull base.
- A "needle tip" cautery is useful when planning to raise a nasoseptal flap.
- An image guidance system is useful for identifying the site of the leak.
- If intraoperative intrathecal fluorescein is to be used, a lumbar puncture (± lumbar drain insertion) must be performed preoperatively.

Key Anatomic Landmarks

- The site of the leak determines which landmarks are most important.
  - The lateral lamella of the cribriform plate is a frequent site for iatrogenic leaks; the middle turbinate, anterior ethmoidal artery, and bulla ethmoidalis are important landmarks.
  - If the leak is in the sphenoid sinus, the optic nerve and internal carotid artery (ICA) are important to identify, in addition to potential exposure of the lateral recess of the sphenoid, foramen rotundum, and the vidian nerve (which acts as a reliable landmark for the ICA).

Prerequisite Skills

- The surgeon should have the ability to perform a thorough endoscopic sinus operation, including a wide sphenoidotomy and frontal sinusotomy.
- Comfort with skeletonizing the skull base

Operative Risks

- As with any surgery, risks include postoperative bleeding, infection, and the standard risks with general anesthesia (such as myocardial

infarction and pulmonary embolism).

- Injury to the rectus muscles and/or optic nerve can result in diplopia, decreased visual acuity, or blindness.
- Injury to the brain or dura can result in neurologic impairment or meningitis.
- Injury to the carotid artery can result in life-threatening bleeding.

Surgical Technique

Ethmoid Sinus Roof and Cribriform Plate

- If a CSF leak is suspected during ESS, the overlying mucosa should be reflected away to closely examine the area and to determine the extent of injury.
- If the injury is iatrogenic from a microdébrider, it is important to rule out an intracranial vascular injury, highlighting the importance of preoperative imaging.
- An inlay or onlay free tissue graft may be used to patch the site of injury; entire exposure of the defect is essential.
- Fascia lata, temporalis fascia, abdominal adipose tissue, septal or middle turbinate mucosa or composite grafts, periosteum, and perichondrium are all suitable grafting tissues.
- Whenever possible, the dural edges are undermined with a small elevator, and the edges of the graft are tucked between the dura and the bone (i.e., epidural inlay graft).
  - Mucosa should not be used as an inlay graft; it should be reserved for use as an onlay graft.
  - Alternatively, the dura may be separated from the brain, and the inlay graft may be placed in the subdural space.
  - When an inlay graft is not possible due to technical difficulties or because the fistula involves a linear fracture that does not expose the dural defect, the graft is placed as an onlay over the defect (i.e., outside the cranial cavity).

- Free muscle or adipose tissue grafts can also be used as a dumbbell-type plug.

- Fibrin glue, platelet-rich serum, or other biologic glue may be used to increase the adhesiveness of the muscle or fascia graft.
- The graft is typically supported in place with layers of Gelfoam (Pharmacia and Upjohn Co., Kalamazoo, Michigan), followed by packing with bacitracin-impregnated gauze, sponge packing, or the inflated balloon of a Foley catheter.
- Gelfoam prevents adherence of the packing material to the graft, preventing accidental avulsion when the packing is removed, 3 to 7 days after the surgery.
- Alternatively, a vascularized tissue flap may be designed and harvested transnasally using mucoperichondrium from the middle turbinate or septum.[6]
- If the fistula involves the cribriform plate, the mucosa and bone of the medial aspect of the middle turbinate are removed and the remaining mucoperiosteal flap is rotated to cover the defect or to cover a muscle or free fascial graft.
  - Similarly, the mucosa and bone of the lateral aspect of the middle turbinate may be removed and the remaining mucoperiosteal flap is rotated to cover a defect of the fovea ethmoidalis.
  - An additional option includes the removal of mucosa from a portion of the ipsilateral septum, removal of the corresponding septal cartilage or perpendicular plate of the ethmoid, and rotation of the contralateral mucoperichondrial flap to cover the defect. However, this will result in a septal perforation.
- The flap is then supported by Gelfoam and bacitracin-impregnated gauze.
- The Hadad-Bassagasteguy flap consists of a septal mucoperichondrial/mucoperiosteal flap based on the posterior septal artery and can be used to effectively cover very large defects of the skull base.[6]

Sphenoid Sinus

- The sphenoid sinus is most commonly approached transnasally with endoscopic visualization, as when performing pituitary surgery (see Chapter 117).
- CSF leaks involving the sphenoid sinus are amenable to a repair that includes obliteration of the sinus.
- After proper identification of surgical landmarks, such as the carotid canal, optic nerve canal, and optic carotid recesses, and identifying the leak, the mucosa of the sphenoid sinus is thoroughly removed.
  - This helps with establishing the extent of the defect and preparing the sinus for obliteration.
  - Onlay or inlay free tissue, nonmucosal grafts are placed, and the sinus is then obliterated with an abdominal adipose tissue graft.
  - Anteriorly the exposed adipose tissue is covered with a layer of Surgicel (Ethicon, Neuchatel, Switzerland) followed by Gelfoam, and the nose is packed with ½-inch nasal strip that has been impregnated with antibiotic ointment or with the inflated balloon of a Foley catheter.
- An intraoperative CSF leak arising from the sella turcica during pituitary surgery most often can be repaired by obliterating the sella with adipose tissue and reconstructing the floor of the sella with a free bone or cartilage graft harvested during the endoscopic approach.
  - It does not require postoperative packing or the removal of the entire mucoperiosteum of the sinus.
- Alternatively, standard techniques such as inlay grafts with fascia lata, followed by the previously described nasoseptal flap, have been very effective in repairing these defects.
- The risk of accidental injury to adjacent neurovascular structures is a critical consideration when dealing with defects of the lateral wall of the sphenoid sinus; adequate visualization of this area is mandatory.
- Leaks that arise in the lateral recess present technical difficulties due to their poor visualization after a traditional sphenoidotomy (Fig. 116.4).
- Repair often requires ligation of the sphenopalatine artery and extension of the sphenoidotomy toward the pterygopalatine fossa.

- The transpterygoid approach can be combined with an endoscopic medial maxillectomy as necessary, to allow adequate range of motion and visualization of even the most lateral of sphenoid defects.
  - Through this extended lateral approach to the sphenoid sinus, the endoscopic surgeon is now able to use a zero-degree scope and straight instruments to replace angled scopes and working around corners.
  - In addition, a contralateral approach with removal of the sphenoid rostrum can facilitate instrumentation and access.

Frontal Sinus

- CSF leaks involving the frontal sinus are usually repaired using an open, transfrontal sinus approach.

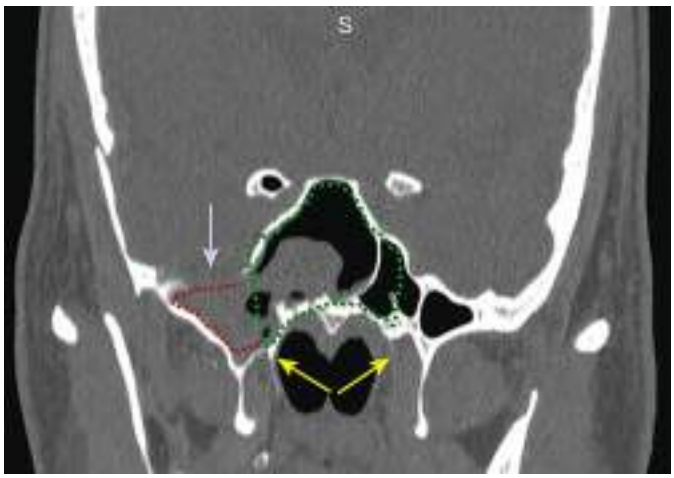

FIG. 116.4 Coronal computed tomography scan of the sphenoid sinus depicts the limits of visualization of a traditional sphenoidotomy *(green dots)*. The medial pterygoid plates *(yellow arrows)* are useful anatomic landmarks and a defect in the skull base *(grey arrow)*. The lateral recess of the sphenoid sinus can be visualized with a trans-pterygoid approach *(red dots)*, and dissection is facilitated with a bilateral approach with removal of the sphenoid rostrum and posterior septum.

- The Draf III approach, which involves medial widening of the frontal

recesses and removal of the superior nasal septum and inferior intersinus septum, may provide exposure of leaks around the frontal recess, thus allowing an endoscopic repair.

Common Errors in Technique

- Failure to adequately identify the site of the leak on preoperative imaging
- Failure to recognize a vascular injury, especially in the iatrogenic setting
- Failure to completely remove all sphenoid mucosa before obliterating with adipose tissue
- Failure to adequately expose the site of the leak, particularly in the lateral recess of the sphenoid sinus
- Failure to use meticulous technique when placing the graft may lead to an unsuccessful repair.
- When harvesting the nasoseptal flap, injury to the posterior nasal artery can compromise the vascularity of the flap. Failure to use the full length of the nasal septum may lead to a flap of inadequate length.

Postoperative Period

Postoperative Management

General Principles

- The general principles of managing a CSF fistula include adjunctive measures that may facilitate healing of the repair, including:
  - Avoidance of activities that raise the intracranial pressure, such as straining, bending forward, coughing, or lifting weights greater than 15 lbs
  - Bed rest
  - Stool softeners

- 30 to 45-degree elevation of the head of bed
- Sneezing with an open mouth
- Absolute avoidance of nose blowing
- "Deep extubation," to prevent straining and coughing, is encouraged, and positive pressure mask ventilation is contraindicated.

- The use of prophylactic antibiotics for the prevention of meningitis in patients with CSF fistulas continues to be controversial; however, the use of antibiotics when the patient has an active sinus infection is warranted.
- Nasal irrigations with nasal saline solution and gentle débridement of crusting are started postoperatively.
- In patients with indwelling lumbar spinal catheters, prophylactic antibiotics are routinely administered and, although the concept is not universally accepted, antibiotics are thought to decrease the incidence of catheter-related infections.
- However, the routine use of antibiotics for traumatic CSF leaks is not of proven efficacy, and they may select resistant bacteria.
  - We favor the use of perioperative prophylactic antibiotics during the repair of the CSF leak.
  - Antibiotics, usually aimed at gram-positive bacteria, are continued until nasal packing is removed.
- A postoperative CT scan without contrast within the first 24 hours after surgery is important to rule out evidence of intracranial bleeding, parenchymal injury, or tension pneumocephalus.
  - We favor a routine CT scan of the brain, even in the absence of any neurologic deficit.
- In our practice, we usually work in conjunction with a neurosurgical team during the repairs, although we do not consider it necessary in all cases.
- Neurosurgical consultation provides an important perspective on intraoperative and postoperative management, especially on the need for a CSF drain or a shunt.

- A lumbar drain is helpful to control intracranial pressure with a designated amount of CSF removed daily based on CSF production but is only used for those patients suspected to have HPH.
  - Overdrainage should be avoided because this creates a negative intracranial pressure that may result in pneumocephalus and promote bacterial contamination of the CSF with resultant meningitis.

High-Pressure Hydrocephalus

- Normal intracranial pressure ranges from 5 to 15 cm of water when the patient is in supine position.
  - Intracranial pressure increases with positional changes, with Valsalva maneuver, and during rapid eye movement (REM) sleep.
- An increased intracranial pressure (i.e., HPH) is defined as sustained or intermittent pressures of 20 to 30 cm of water.
- Posttraumatic, postsurgical, and postinfectious hydrocephalus can result from the obstruction of the arachnoid villi, thus preventing adequate CSF reabsorption with subsequent increased intraventricular pressures.
- In post-CVA and posttraumatic and postsurgical hydrocephalus, the obstruction arises from subarachnoid hemorrhage, whereas in the case of infection, inflammatory changes are responsible for obstructing the arachnoid villi (Fig. 116.5).
- Radiation therapy causes vascular changes in the brain and elevation of CSF protein, scarring, and adhesions, all of which may contribute to the impairment of the CSF reabsorption.
- Likewise, meningitis causes scarring of the CSF cisterns and absorptive sites, thus leading to chronic hydrocephalus.
- Patients with recurrent CSF leaks, a past history of head and/or cranial base trauma, a history of cranial base surgery, and those with "spontaneous" CSF leaks are considered at high risk for HPH and are enrolled in the following protocol (Fig. 116.6):

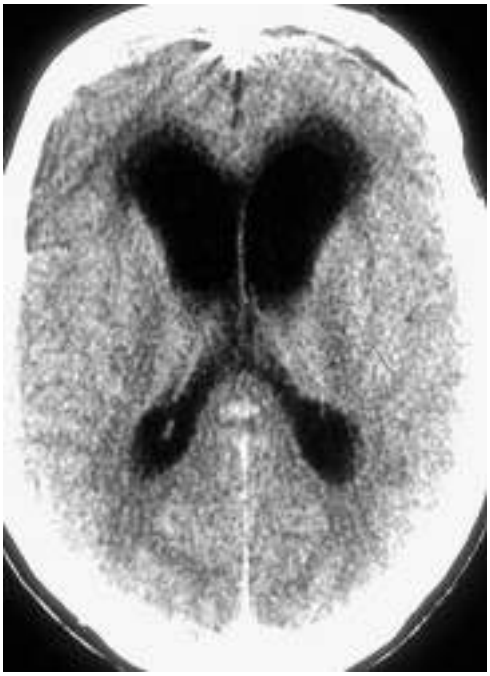

FIG. 116.5 Axial computed tomography scan of the head in a patient with high-pressure hydrocephalus and ventriculomegaly of the temporal horns.

- The CSF leak is repaired via an endonasal endoscopic approach following surgical principles such as adequate exposure, hemostasis, preparation of the fistula for grafting, and stabilization of the graft.
- A lumbar spinal drain is inserted intraoperatively or immediately after the surgery.
- Three to 5 days postoperatively, the lumbar spinal drain is clamped, and if no CSF leak is identified for 24 hours, the lumbar drain is removed.
- Twenty-four to 48 hours later, a lumbar puncture is performed to measure the CSF opening pressure.
- A Ventriculoperitoneal (VP) shunt is recommended if the CSF opening pressure is elevated.
- If the CSF opening pressure is normal, the patient is discharged home and followed in our outpatient office.

- Patients with CSF leaks in the sphenoid sinus are treated with obliteration of the sinus using an abdominal adipose tissue graft, which is then stabilized with nasal packing.

- A postoperative lumbar spinal drain is not required.
- A lumbar puncture is performed 3 to 5 days postoperatively to measure the opening pressure and establish the need for a VP shunt.

- In those patients with normal CSF opening pressure, a CT scan of the brain is performed 6 weeks after the surgical closure.
  - Ventriculomegaly of the temporal horns or transependymal edema will identify those patients with HPH who may have escaped identification (false negative).
- CSF leaks in patients who did not present with any of the previously mentioned high-risk factors are repaired endoscopically and without the use of a spinal drain.

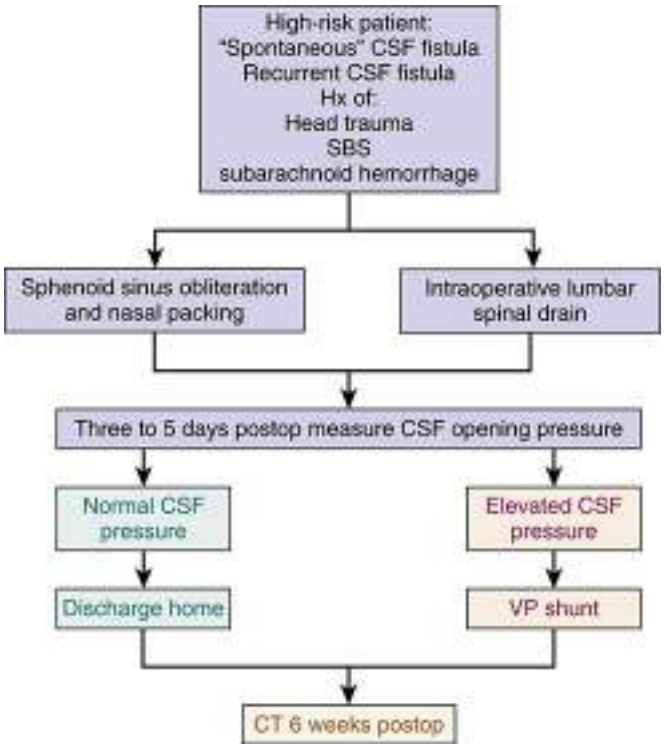

FIG. 116.6 Management algorithm for patients at high risk for failure of cerebrospinal fluid (CSF) fistula repair. *CT,* Computed tomography; *postop,* postoperatively; *SBS,* skull base surgery; *VP,* ventriculoperitoneal.

Complications

- Postoperative epistaxis may require packing if ongoing and uncontrolled with topical decongestants.
  - This is typically from an artery (i.e., the sphenopalatine artery) that has been transected at the time of surgery and was in vasospasm, allowing it to escape detection at the time of surgery.
- Retrobulbar hematoma: Immediately remove the packing, and, if in the recovery room, perform a lateral canthotomy and cantholysis.
  - Return to the operating room for medial orbital wall decompression.
  - This complication typically results when the anterior ethmoidal artery is transected and retracts into the orbit, allowing blood to accumulate in the closed space and increasing intraocular pressure rapidly.
- Meningitis: Treat with antibiotics.
- CSF rhinorrhea: Collect a sample of fluid to send for β_2-transferrin to confirm the diagnosis.
  - Conservative management (bed rest, stool softeners) should be instituted.
  - Consider lumbar drain.
  - Return to the operating room if failure of medical management.

Alternative Management Plan

- A conservative approach with medical management can be considered for any patient with a CSF leak, although this should not be used as first-line treatment in cases of spontaneous CSF leak due to the risk of meningitis and high failure rate; delaying surgical repair may inadvertently increase the risk of developing meningitis.
- Conservative management includes:
  - Bed rest
  - Stool softeners
  - Lumbar drain
  - The use of acetazolamide

- Acetazolamide can cause electrolyte disturbances, and it is generally recommended that the electrolytes are monitored while on this medication.
- Acetazolamide therapy should be avoided in cases of adrenal insufficiency and cases of hepatorenal failure.

Discussion

Evidence-Based Medicine Question

What is the evidence of prophylactic antibiotics in CSF leak repair?

- Intuitively, a patent connection between a clean-contaminated area (the nasal cavity) and a sterile region (the subarachnoid space) predisposes the patient to meningitis, and therefore antibiotic prophylaxis should be used.
- However, the evidence supporting the routine use of antibiotics is limited.
  - A recently updated Cochrane review did not find evidence to support the use of antibiotic prophylaxis in patients who had basilar skull fractures (with or without CSF leak).[9]
  - A recent review by Oakley[10] found that the evidence does not support the routine use of prophylactic antibiotics; however, they were unable to comment on intraoperative or postoperative antibiotic use.
- Based on these reviews, our practice is to not prescribe prophylactic antibiotics for CSF leaks, but we routinely use perioperative antibiotic prophylaxis.

Editorial Comment

One of the biggest errors in the initial management of patients with spontaneous CSF leaks is to treat with CSF diversion (spinal drain). Spontaneous leaks will not close without surgical management. Surgical delay predisposes the patient to meningitis.

Small CSF leaks can be effectively repaired using a variety of techniques. For larger defects, superior results are achieved using vascularized tissue for reconstruction. Although some surgeons choose to add cartilage or bone for rigid reconstruction, it is not necessary.

Review Questions

1. Where is β_2-transferrin found in the body?

   a. CSF

   b. Aqueous humor

   c. Perilymph

   d. **All of the above**

2. Which of the following adjuncts is helpful for improving visualization during a CSF leak repair?

   a. Trendelenburg position

   b. Controlled hypertension

   c. **The use of topical vasoconstrictors**

   d. None of the above

3. Which of the following statements is false?

   a. There is limited evidence to support the use of preoperative antibiotic use.

   b. "Deep extubation," to prevent straining and coughing, is encouraged, and positive pressure mask ventilation is contraindicated.

   c. **A mucosal inlay graft is a good first-line repair and should be covered with a vascularized flap if possible.**

   d. Retrobulbar hematoma is a serious emergency, and, if it occurs in the recovery room, the nasal packing should be removed as soon as

possible.

Additional Source

Oakley G.M, Alt J.A, Schlosser R.J, et al. Diagnosis of cerebrospinal fluid rhinorrhea: an evidence-based review with recommendations. *Int Forum Allergy Rhinol*. 2016;6(1):8–16.

This systematic review summarizes the diagnostic tests and workup for suspected CSF rhinorrhea. Beta-2 transferrin was found to be the most reliable confirmatory test and HRCT was noted to be the best initial imaging study.

Endonasal Approach to the Sella and Parasellar Areas

Eric W. Wang, and J. Kenneth Byrd

Keywords

Endoscopic endonasal approach; pituitary adenoma; skull base

Introduction

Surgery of the central cranial base has evolved over the past several decades from open transcranial or transfacial approaches that require significant retraction or disruption of normal anatomy, to endoscopically assisted approaches that maintain surgical principles, improve visualization, and preserve normal function. Surgical approaches to the sella and parasellar areas exemplify this principle and are the keystone to other endoscopic approaches to the anterior skull base. The sella was traditionally approached via a microscopic sublabial or transnasal, transseptal approach. The problem with this approach included limited visualization and freedom of movement of instruments, incomplete tumor resection and limited ability to deal with severe complications, such as carotid artery injury. The advent of endoscopic approaches to the paranasal sinuses in the 1980s, followed by widespread adoption in otolaryngology, gradually led to the expansion of endonasal techniques beyond inflammatory sinus disease. After neurosurgeons experimented with endoscopic assistance for microscopic pituitary surgery for several years, a solely endoscopic approach to the sella was described in the mid-1990s.[1]

Subsequent improvements in technology have included improved optics, high-definition displays, navigation systems, and better instrumentation for endoscopic cranial base surgery. The next step using

techniques devised for endoscopic pituitary surgery was the resection of suprasellar pathologies, cavernous sinus dissection, and more advanced procedures in the sagittal and coronal planes. The team approach, involving neurosurgeons and otolaryngologists, has led to excellent patient outcomes with a midline transnasal approach.[2] For the purposes of this chapter, discussion will be limited to the sellar and parasellar regions.

Key Operative Learning Points

1. The sella lies in the midline of the posterior wall of the sphenoid sinuses, bounded laterally by the cavernous internal carotid artery (ICA) siphon and superiorly by the superior intercavernous sinus and optic nerves. Recognition of the medial and lateral opticocarotid recesses is important to prevent injury to these structures.

2. The need for a vascularized nasoseptal flap reconstruction should be considered prior to sphenoidotomy in order to preserve the vascular pedicle.

3. Exposure of the cavernous sinuses lateral to the sella is a safe way to identify the course of the parasellar ICA.

Preoperative Period

History

1. History of present illness
   a. A thorough history should be taken to elicit visual changes, including decreased visual fields or diplopia, endocrine symptoms, headaches, clear rhinorrhea, and frequent urination.
   b. Specifically, symptoms of Cushing's syndrome and acromegaly should be elicited.
   c. A rapid onset of headache and visual symptoms may represent pituitary apoplexy, which is a surgical emergency.
2. Past medical history

a. Prior treatment:

1) Medical treatment for pituitary tumor (dopamine antagonists)

2) Prior radiation therapy (stereotactic or intensity-modulated)

b. Medical illnesses:

1) Heart disease

2) Intracranial hypertension (may be undiagnosed in obese patients)

3) Diabetes mellitus

4) Diabetes insipidus

5) Recurrent acute or chronic rhinosinusitis, particularly nasal polyposis with pulmonary symptoms

a. Cystic fibrosis

b. Allergic fungal rhinosinusitis

c. Samter's triad

c. Surgery:

1) Prior endoscopic, transseptal, sublabial, or transcranial approach to the sella

2) Nasal surgery including septoplasty or functional endoscopic sinus surgery

d. Family history:

1) Bleeding disorders

2) Pituitary tumors (multiple endocrine neoplasia Type 1)

e. Medications:

1) Anticoagulants or antiplatelet drugs

2) Dopamine antagonists

3) Insulin or oral hypoglycemic agents

4) Steroids

5) Nasal steroids

6) Topical nasal decongestants (intraoperative topical

decongestant is less effective)

f. Social history: alcohol, tobacco, or illegal drugs

1) A history of or active cocaine abuse may result in perforation, submucosal cartilage loss, and/or submucosal scarring of the septum; topical decongestants are less effective.

Physical Examination

1. General

a. Features of Cushing's syndrome: abnormal distribution of adipose tissue, "buffalo hump" or "moon facies"

b. Features of acromegaly: frontal bossing, macroglossia, prognathism, enlarged hands and feet

2. Eyes

Assessment of visual fields, visual acuity, and proptosis or abnormal position of the globe. Full examination by an ophthalmologist is warranted if there is any involvement of the optic nerve, chiasm, or orbit on imaging.

3. Neurologic

A thorough cranial nerve examination should be performed with particular attention to nerves III, IV, V, and VI.

4. Skin

Note the presence of striae, abnormal pigmentation, or ecchymoses suggesting Cushing's syndrome.

5. Nasal endoscopy

Assess for intranasal pathology, including septal deviations or perforations, polyps, purulence, or intranasal masses. If prior surgery has been performed, assess for adequacy of nasoseptal flap pedicles.

Imaging

1. Maxillofacial computed tomography (CT) with contrast

a. Allows for delineation of bony anatomy of paranasal sinuses, orbits, and skull base

b. Coronal and sagittal reconstructions are helpful to evaluate the slope of the skull base, the position of the anterior ethmoid arteries, and the presence of posterior ethmoid cells associated with the optic nerve (Onodi cells).

c. Contrast angiography allows for delineation of the interface with intracranial vessels and improved visualization of the ICA.

2. Magnetic resonance imaging of skull base with gadolinium

a. Extent of tumor

b. Location of residual pituitary gland and stalk

c. Cavernous sinus invasion

d. ICA anatomy

e. Relation to optic chiasm

Indications

- Infectious/inflammatory sphenoid sinus disease
- Sinonasal tumors involving the sphenoid sinus
- Fibro-osseous lesions
- Pituitary adenoma
  - Functional tumors uncontrolled with medical therapy
  - Macroadenomas with visual compromise
  - Interval growth of macroadenoma
- Craniopharyngioma
- Rathke's cleft cyst or pituitary cysts with headaches or visual compromise
- Meningoceles/meingoencephaloceles
- Planum sphenoidale or tuberculum meningioma
- Select lesions extending into the medial or anterior compartments of

the cavernous sinus

- Medial optic nerve and orbital apex decompression

Absolute Contraindications

- Cardiopulmonary disease that prohibits surgery
- Pathology that is on the deep side of a nerve or vessel

Relative Contraindications

- Significant lateral extent
- Bleeding disorder
- Prolactinoma that has not been trialed on medical therapy
- Vascular encasement

Preoperative Preparation

- Evaluation by otolaryngology and neurosurgical teams
- Endocrine consultation for pituitary tumors
- Ophthalmologic consultation for visual disturbances
- Discontinue aspirin and anticoagulants prior to surgery.
- It is important to manage acute bacterial rhinosinusitis before endoscopic endonasal skull base surgery.

Operative Period

Anesthesia

- General endotracheal anesthesia should be induced. If nerve monitoring is to be performed, only short-acting paralytics should be used during induction.
- For medically fragile patients, and for cases in which significant

vascularity is involved, an arterial line should be placed, and adequate venous access should be obtained.

- If a dural defect is present or will be created, the anesthesia team should be notified that mask ventilation is contraindicated.
- An orogastric tube placed at induction allows the stomach to be suctioned at the end of the case to prevent vomiting.
- In cases with visual compromise, mean arterial pressures should be maintained at greater than 80 mmHg. Adjunctive corticosteroids should also be considered (Solu-Medrol 100 mg or Decadron 10 mg intravenous [IV]).
- Stress dose steroids also should be administered to patients with hypopituitarism.

Positioning

- Supine
- Mayfield head pins or a horseshoe may be used based on the surgeon's preference.
- The head of the bed should be rotated to allow both surgeons access to the face and nose.
- Reverse Trendelenburg position can be used to reduce venous bleeding.

Perioperative Antibiotic Prophylaxis

- Ceftriaxone 2 g IV
- Clindamycin 600 mg IV or vancomycin 1 gm IV if the patient has a cephalosporin allergy

Monitoring

- Somatosensory evoked potentials are monitored for all cases to identify impending ischemic events and prevent permanent neurologic

sequelae.

- If cavernous sinus dissection is performed, electromyography of the relevant cranial nerves is performed by the neurophysiology team.

Instruments and Equipment to Have Available

- Oxymetazoline (0.05%) or epinephrine (1:1000) on cotton pledgets for decongestion
  - Not used when the dura is violated to avoid the introduction of alpha agonists into the cerebrospinal fluid (CSF)
- Endoscopes: 0 and 45 degrees
- Endoscopic sinus instruments
- Endoscopic neurosurgical dissectors
- Endoscopic drill: 4- or 5-mm coarse diamond bur
- Transnasal Doppler probe
- Endoscopic bipolar electrocautery
- Two suction setup
- Image guidance navigation system
- Needle-tip cautery can be used for nasoseptal flap elevation.
- Suction monopolar electrocautery

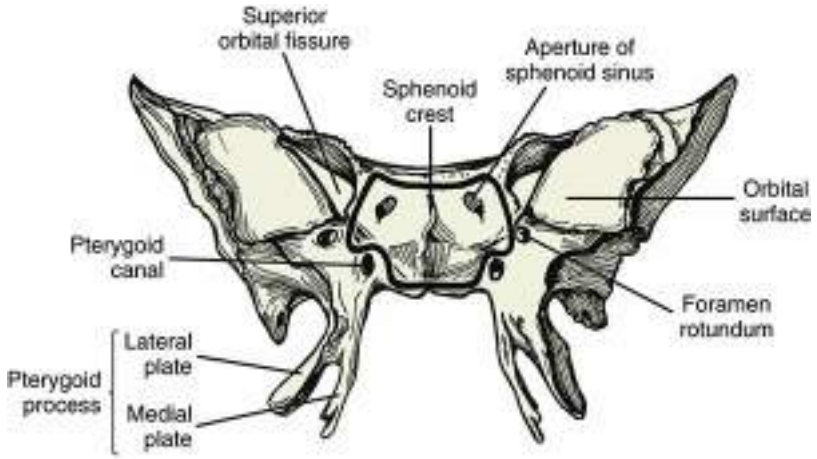

FIG. 117.1 Anterior view of the sphenoid bone with bony landmarks identified. The extent of the sphenoidotomy is outlined; it extends between the foramen rotundum and the pterygoid canal and includes the lateral recess.

Key Anatomic Landmarks

- Fig. 117.1 demonstrates the anatomy of the sphenoid bone.
- The natural ostium of the sphenoid sinus is located approximately one-third of the way between the arch of the choana and the skull base, behind the superior turbinate.
- The midline face, or rostrum, of the sphenoid forms the "keel" at its attachment to the vomer.
- The roof of the sphenoid sinus is the planum sphenoidale and is continuous with the ethmoid roof and cribriform plate anteriorly.
- Initial visualization of the structures within the sphenoid sinus depends on the pattern of sellar pneumatization: conchal, presellar, or sellar.
- The optic nerves lie lateral and superior and track posteriorly over the sella turcica in the midline. The optic canal may lie within an Onodi cell, which is most easily recognized on sagittal imaging. Bony dehiscence around the optic nerve is common in an Onodi cell.
- The clival recess is inferior to the sella.
- Superiorly, the face of the sella meets the planum at the tubercular

strut, which overlies the superior intercavernous sinus.

- After exiting the petrous segment, the ICA courses superomedially from the lacerum segment into the paraclival segment before entering the cavernous sinus immediately lateral to the sella. The ICA then enters the paraclinoidal segment, which is the most medial and prominent segment of the artery (anterior protuberance). This segment is just medial to the lateral opticocarotid recess.
- The intersinus septum often deviates laterally to insert on the anterior protuberance of the carotid.
- The lateral opticocarotid recess lies between this portion of the cavernous carotid and the optic nerve superolaterally. This represents the pneumatization of the optic strut between the ICA and floor of the optic canal. The medial opticocarotid recess is less well defined in most patients. Fig. 117.2 demonstrates the anatomy of this region.
- Inferolaterally, the vidian nerve traverses the floor of the sphenoid sinus toward the foramen lacerum and crosses over the petrous segment of the carotid artery. With a very well-pneumatized lateral recess, one can appreciate the protuberance of V2 superolateral to the pterygoid canal.

Prerequisite Skills

- Endoscopic sinus surgery: sphenoidotomy, ethmoidectomy
- Reconstruction: free mucosal graft, nasoseptal flap
- The otolaryngologist and neurosurgeon should both be skilled in endoscopic anatomy and dissection and should have experience working together as a four-handed team.

Operative Risks

- CSF leak
- Carotid artery injury
- Cavernous sinus hemorrhage

- Optic nerve injury
- Cranial nerve injury
- Endocrinopathies including diabetes insipidus
- Epistaxis
- Postoperative hematoma, especially with incomplete tumor resection

Surgical Technique

Approach

- The nasal cavity is decongested with topical oxymetazoline or epinephrine on pledgets.
- The 0-degree endoscope is used to visualize intranasal structures.
- The right middle turbinate can be medialized or transected at the junction of its upper and middle two-thirds (below the skull base).
  - Resection allows for additional working space for the endoscope and the neurosurgeon's left-handed instrumentation.
  - The branch of the sphenopalatine artery (SPA) to the middle turbinate is cauterized carefully without damaging the main artery.
  - The mucosa of the middle turbinate can be harvested for a free mucosal graft, if needed.
- A nasoseptal flap is elevated if the need is anticipated.
  - Dural violation or carotid exposure
  - For sellar and parasellar approaches, a left or right nasoseptal flap may be used based on the surgeon's preference and pre-existing septal deviations.
- Superior turbinates are either lateralized or partially resected. Bilateral sphenoidotomies are performed exposing the planum and orbit bilaterally.
  - The intersinus septum is removed conservatively with cutting hand instruments until the two-team approach is used to drill the septum until it is flush with the sphenoid bone.

- A posterior septectomy exposes the anterior sphenoid rostrum, which may be removed with rongeurs or the drill allowing for binarial access.
  - A Cottle elevator is used to separate the junction of the vomer with the anterior sphenoid rostrum.
  - Additional anterior exposure is obtained by resecting the posterior margin of the septum with a backbiting forceps. Care should be taken to avoid resecting olfactory mucosa from the nasal septum, which extends approximately 1 cm inferiorly from the skull base.

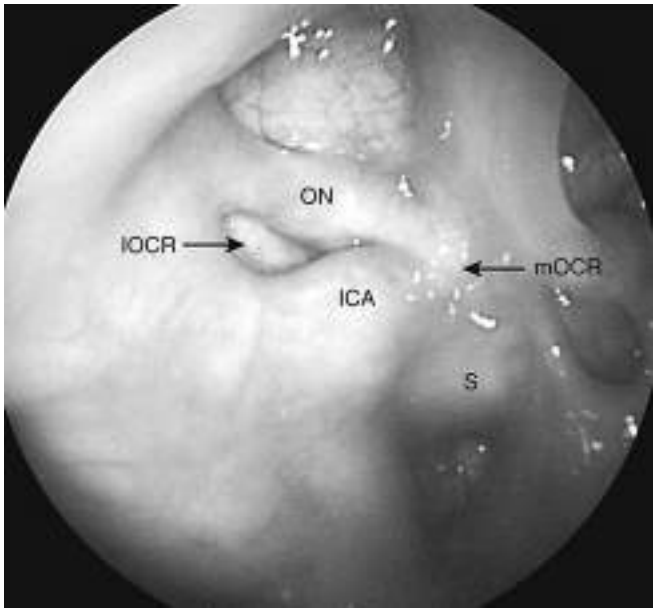

FIG. 117.2 Cadaveric dissection with a view of the right optic nerve (ON) and internal carotid artery (ICA). The pneumatization of the anterior clinoid forms the lateral optic-carotid recess (lOCR). The medial junction of the ON and ICA is the medial optic-carotid recess (mOCR). *S*, sella.

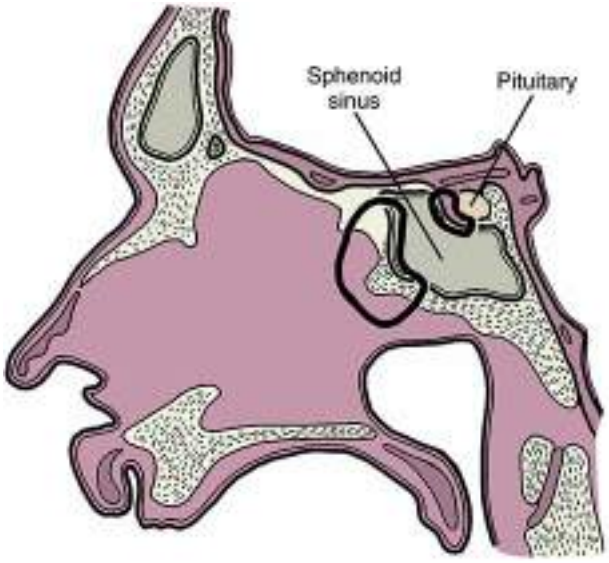

FIG. 117.3 Bone is removed from the sphenoid face, posterior nasal septum, and sella for standard sellar surgery.

  - The size of the septectomy depends on the lateral and anterior extent of dissection.

- Fig. 117.3 demonstrates the sphenoid and sellar exposure required for tumors confined to the sella.
- Additional inferior exposure may be obtained by drilling the rostrum and floor of the sphenoid.
  - The sacrifice of one posterior septal artery may be helpful for inferior exposure, but it is not always required.
  - Alternatively, a releasing incision or window in the posterior septum can be created. Subsequently the mucosa of the face of the sphenoid below the sphenoid ostium can be mobilized and displaced inferiorly to preserve the posterior septal branch of the SPA, the arterial supply to the nasoseptal flap.

FIG. 117.4 Both sphenoid sinuses have been opened widely and the intersinus septum removed. The right middle turbinate has been preserved and is seen on the left. A rescue flap (inferior to the suction) has been maintained by preserving the nasoseptal artery in case a nasoseptal flap is needed.

  - Fig. 117.4 demonstrates the bilateral wide sphenoidotomy with exposed sella and a preserved nasoseptal artery pedicle, or "rescue flap," on the right side.

- The posterior ethmoid air cells can be removed to expose the skull base anterior to the planum sphenoidale.
  - A posterior ethmoidectomy on the right allows for scope positioning superior to the working corridor of the neurosurgeon.
  - The extent of posterior ethmoidectomy depends on the anterior limit of dissection. For sellar cases, a conservative posterior ethmoidectomy should allow for a three-handed technique with clear visualization.
  - A more complete posterior ethmoidectomy should be performed when access beyond the planum is required.

Exposure of the Sella

- Image guidance is used to confirm the location of the sella, ICAs, and optic nerves.

- The intersinus septations are drilled until they are flush with the bone.
  - Team surgery with a three-handed technique is advisable from this point forward.
- Mucosa is removed over the sella with a Cottle elevator and suction.
  - Additional mucosal stripping may be necessary for visualization of bony structures or if extrasellar access requires drilling of the planum, lateral sphenoid, or clivus.
  - Fig. 117.5 demonstrates a wide-angle view of the sella after bony septations have been drilled.
- The bone over the sella is carefully thinned and removed with an elevator or Kerrison rongeur.
  - Rather than biting with the Kerrison rongeur, it should be used to elevate the thinned bone to avoid injury to the carotid artery.
- Drilling is carried out laterally to expose the margin of the cavernous sinus dura on each side. Fig. 117.6 demonstrates the exposed sellar dura, as well as the blue hue of each cavernous sinus.

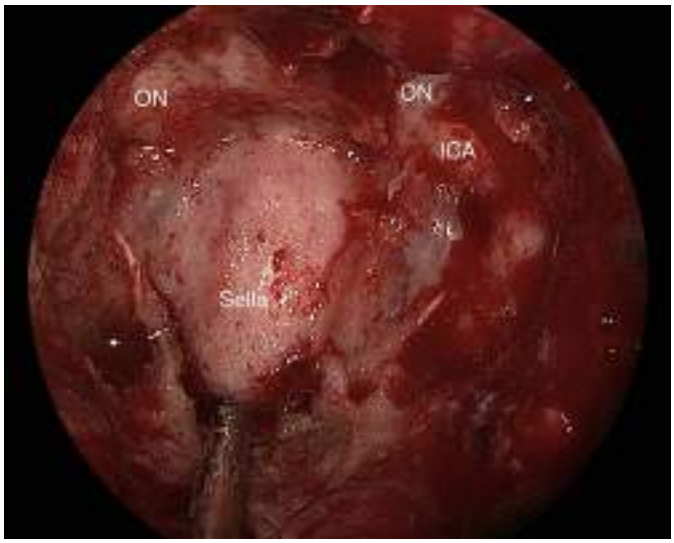

FIG. 117.5 A wide-angle view of the sella after partitions have been drilled posteriorly. The suction is in the remaining clival recess. The left internal carotid artery siphon is visualized (ICA), as are both optic nerves (ON).

FIG. 117.6 The bone over the sella has been drilled to expose the sellar dura. The cavernous sinuses (CS) are visible on each side.

Suprasellar Exposure

- If suprasellar access is needed, bone should be carefully drilled in the midline superiorly with visual or image guidance confirmation of the ICA position.
  - The ICA is prone to injury at the medial opticocarotid recess.
  - The planum is drilled until it is the thickness of an eggshell and is removed in an anterior to posterior fashion.
  - The bone of the tuberculum must be very thin before it is carefully removed to avoid CSF leak or bleeding from the superior intercavernous sinus.
- Fig. 117.7 demonstrates the additional bony exposure required for tumors with suprasellar extension.

Lateral Recess Access

- Transpterygoid dissection is usually required to access the lateral recess of a well-pneumatized sphenoid sinus.

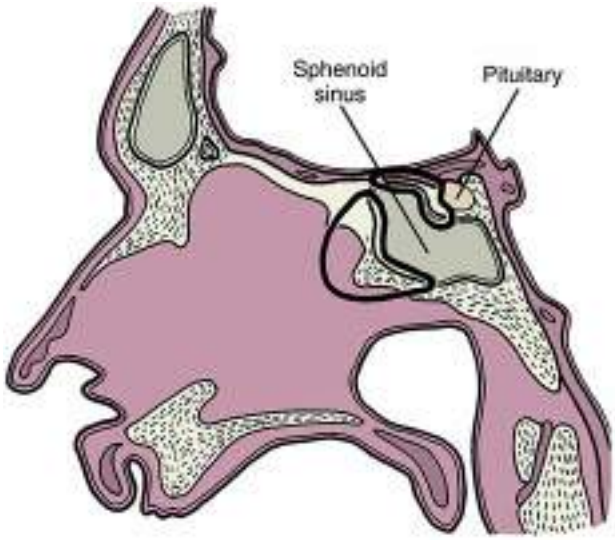

FIG. 117.7 The planum sphenoidale and sella may be removed in continuity to provide access to tumors with suprasellar extension.

FIG. 117.8 Coronal non-contrasted computed tomography of the sphenoid sinus demonstrating the lateral recess, the opening to which is bounded by the vidian nerve and V_2.

- Fig. 117.8 demonstrates the lateral recess, bounded by the vidian nerve and V_2 branch of the trigeminal nerve.

- If a nasoseptal flap is used in conjunction with a transpterygoid approach, the contralateral side is preferentially harvested due to the sacrifice of the SPA.
- The crista ethmoidalis is palpated with the Cottle elevator, and a mucosal flap is elevated superiorly and posteriorly to expose the SPA at the sphenopalatine foramen, which is cauterized and divided.
- A 1-mm Kerrison rongeur is used to remove the bone of the posterior wall of the maxillary sinus, starting from the sphenopalatine foramen. After it is enlarged, a larger rongeur may be used.
- The pterygopalatine fossa (PPF) contents are exposed after the posterior maxillary wall is removed. Lateral displacement of the contents reveals the Vidian artery and nerve entering the PPF from the pterygoid canal.

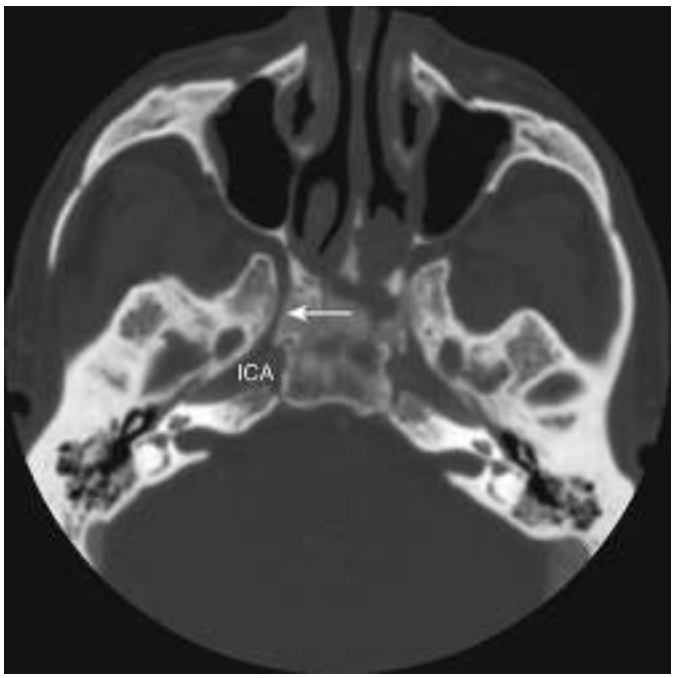

FIG. 117.9 The pterygoid canal *(arrow)* is a reliable landmark for locating the petrous internal carotid artery (ICA) at the second genu.

- Dividing the Vidian nerve allows further lateral retraction of PPF contents to reveal V2 superolaterally on its course through the foramen rotundum.

- The floor of the sphenoid and the base of the pterygoid may be drilled as needed for exposure to the lateral recess.
  - Following the Vidian nerve posteriorly leads to the foramen lacerum and the lacerum segment of the ICA (Fig. 117.9).
  - The Vidian nerve crosses superolaterally over the petrous segment of the ICA.
- If additional inferior exposure is required in the sphenoid, a medial maxillectomy may be performed. After a maxillary antrostomy is performed, the posterior 2⁄3 of the inferior turbinate is removed and the antrostomy is taken to the floor of the nose with hand instruments or the drill. Care is taken not to injure the greater palatine neurovascular bundle.

Reconstruction

- Pituitary surgery without significant vascular or arachnoid exposure may be reconstructed with a free mucosal graft from the harvested middle turbinate or the nasal floor.
  - Surgicel is placed around the edges of the graft to overlap with the remaining mucosa to hold it in place and is reinforced with Gelfoam.
  - Nasal packing with Merocel tampons or a balloon catheter inflated with saline is unnecessary after routine pituitary surgery.
  - If significant diaphragmatic herniation is noted and there is concern for benign intracranial hypertension, an adipose tissue graft may be placed in the defect for support. However, this makes revision surgery more difficult due to fibrosis.
- If the ICA is exposed, a significant dural defect is present, or significant cavernous sinus dissection is performed, the nasoseptal flap is used for coverage.
  - The flap should be rotated so that the entire length is in contact with the dura and bone.
  - Different arcs of rotation (oblique lateral orientation vs. a midline orientation) may be used depending on the bony anatomy and length needed.

FIG. 117.10 A right nasoseptal flap held in position by Surgicel covers the sellar defect. The pedicle containing the nasoseptal artery *(*)* is visible.

  - The distal (anterior) flap is the thickest portion of the flap and is best used at the site of greatest risk.
  - If there is doubt about which side is the mucosal side, restore the flap to its native position and mark with a surgical marker prior to reconstruction. Torsion of the pedicle should be avoided.
  - The edges of the flap are held with Surgicel and Gelfoam, as described above.
  - Fig. 117.10 demonstrates a right-sided nasoseptal flap reconstruction of a sellar defect.
- Dural defects should be closed in a layered fashion, with a collagen graft underlay, followed by the mucosal graft or nasoseptal flap.
  - Consider a three-layered closure for high-flow or very large defects.
  - Fascia lata, acellular dermis, porcine intestine, and other grafts have been used successfully as an interposed middle layer.
- When there is reconstruction of a dural defect, or when a nasoseptal flap is used, packing is left in place for 5 to 7 days.
  - Merocel tampons or a Foley balloon catheter may be used when there is an intraoperative CSF leak, concern for the development of a postoperative leak, or for a perceived high-risk reconstruction (carotid exposure).

- If the optic nerves are exposed, Merocels should be carefully placed and balloon packing avoided so that the optic nerves are not compressed. Vision checks should be performed regularly in the postoperative setting to ensure that optic nerve ischemia is not occurring.

- Doyle splints are sewn to the anterior septum and left for 3 weeks when a nasoseptal flap is used to promote healing.
  - A free mucosal graft (from a resected middle turbinate or nasal floor) to the anterior septum may speed septal mucosalization.

Common Errors in Technique

- A high trajectory to the sphenoid sinus may result in violation of the skull base and subsequent CSF leak.
- Opening the sphenoid sinus inferiorly may result in injury to the vascular pedicle of a nasoseptal flap.
- Inadequate superolateral exposure in the posterior ethmoids leads to poor visualization and fighting for space for the two-surgeon team.
- Failure to remove the sphenoid rostrum does not allow instrumentation in the clival recess or lower sella.
- Inadequate opening of the sella limits access to the medial cavernous sinus and margins of the tumor.

Postoperative Period

Postoperative Management

- Vision should be evaluated as soon as the patient is cooperative.
- Oral antibiotics should be continued as long as packing is in place.
- Pituitary function should be assessed with postoperative laboratory studies if the gland is manipulated.
- Nasal saline irrigations may be started as soon as a CSF leak is no longer a concern.

- Patients should return for scheduled in-office débridements after packs are removed.
  - These may need to be performed frequently in the first month and continued for up to 3 months when a nasoseptal flap is used.
  - Care should be taken not to disrupt the dural repair during débridement.
- If a CSF leak is suspected, fluid should be collected and tested for β_2 transferrin.
  - Postoperative CSF leaks should be repaired within 12 to 24 hours.

Complications

- Epistaxis: Mild epistaxis is usually secondary to mucosal trauma. Brisk, immediate postoperative bleeding can be secondary to arterial injury, usually from a branch of the SPA or the proximal stump of a resected middle turbinate. Significant delayed bleeding may be a sentinel bleed for a carotid pseudoaneurysm that would require emergent angiography.
- Nasal synechiae: Mucosal trauma is generally the cause of nasal synchiae and is diagnosed on postoperative nasal endoscopy. This can be minimized in the nasal cavity with the use of silastic splinting in the nasal cavity postoperatively. If the patient is symptomatic, lysis of synchiae can be performed in the office under local anesthesia.
- Septal perforation: This typically occurs in the setting of a nasoseptal flap harvest when a tear is created in the contralateral nasal mucosa.
- Iatrogenic chronic sinusitis: a rare complication that can generally be managed with medical interventions, such as topical nasal steroids. In some cases, a secondary functional endoscopic sinus surgery is warranted after a trial of maximal medical therapy as per the American Academy of Otolarynology—Head & Neck Surgery guidelines.
- CSF leak: Clear watery drainage that increases with straining or bending forward is the typical presentation of CSF rhinorrhea. Biochemical confirmation with β_2 transferrin can be obtained, but clinical history remains critical. We advocate emergent exploration

with repair of the CSF fistula rather than observant therapy with lumbar drainage.

- Meningitis: Meningitis occurs almost exclusively in patients with postoperative CSF rhinorrhea. Closure of the leak and treatment with broad-spectrum IV antibiotics are warranted.
- Diabetes insipidus/panhypopituitarism: Overmanipulation or injury to the anterior and/or posterior part of the pituitary gland can result in transient or permanent endocrinopathies and diabetes insipidus, respectively. Careful tumor resection with preservation of the native structures is critical. In some tumor pathology, such as craniopharyngioma, sacrifice of the pituitary stalk is indicated and will result in these postoperative outcomes.
- Optic nerve/orbital injury: Optic nerve injury can occur secondary to direct injury, adjacent thermal injury, or vascular injury. Direct injury is generally avoided by identifying the intrasphenoidal landmarks. Thermal injury is mitigated by drilling on the optic canal with constant irrigation. Vascular injury generally occurs in the suprasellar space with injury to a branch of the superior hypophyseal artery or, rarely, the ophthalmic artery.
- Cranial nerve injury: Precise identification of the cranial nerve is critical. This can be supplemented with neurophysiologic monitoring of potentially involved cranial nerves.
- Injury of the ICA: Care must be taken with removing the bone of the carotid canal. Inadvertent injury can occur with dissecting instruments or high-powered drills. Identifying and coagulating the inferior hypophyseal artery, rather than avulsion of this vessel, can prevent a significant arterial bleed that can mimic an ICA injury.

Alternative Management Strategies

- Medical management
  - Growth hormone (GH) receptor antagonist or somatostatin analogue
  - Dopamine agonists
- Stereotactic radiation

Discussion

Evidence-Based Medicine Question

How do outcomes of endoscopic endonasal pituitary resection compare with the microscopic approach?

No prospective, randomized trials have been performed to compare microsurgical approaches to the sellar and parasellar regions to the endoscopic endonasal approach (EEA). However, systematic review and meta-analyses of retrospective studies favor EEA over sublabial and microscopic approaches for completeness of tumor resection and septal perforation[3,4] and EEA over the sublabial approach for CSF leaks and epistaxis. Other complications, including meningitis, diabetes insipidus, and endocrine dysfunction were not significantly different between groups. Other retrospective studies comparing outcomes for adrenocorticotropic hormone (ACTH)-secreting tumors report equivalent biochemical cure rates between microscopic and endoscopic techniques.[5] GH-secreting tumors tend to be larger and have a higher degree of cavernous sinus invasion; therefore, one would postulate that endoscopy would provide better visualization and safer dissection. Direct comparison between microscopic technique and EEA is difficult because of a more stringent definition of biochemical cure, which was adopted in 2010. Evidence suggests that EEA is equal to or superior for GH-secreting tumors, although a significant number of patients will require medication and/or radiosurgery in addition to surgery.[6,7]

Sinonasal-specific quality of life appears to be equal or better in patients undergoing endoscopic sellar surgery compared to microscopic surgery according to a multicenter, prospective study.[8] However, expanded approaches necessitating Vidian nerve sacrifice, large septectomy, aggressive skull base drilling, or extended nasoseptal flaps lead toward prolonged recovery and decreased sinonasal quality scores, at least temporarily.

Editorial Comments

The endonasal approach to the sella has been greatly enhanced by

endoscopic visualization and multidisciplinary team surgery. Wide exposure provides direct visualization and instrumentation of tumor margins without the need for blind dissection. Wide exposure with improved visualization of critical structures can also minimize the risk of injury. Experience gained by the surgical team performing pituitary surgery (functioning as a team, hemostasis, dural reconstruction) can then be applied to other skull base surgeries outside the sellar area.

Review Questions

1. The following is a contraindication to an endoscopic approach to the sella:

   a. Secreting pituitary adenoma

   b. Cavernous sinus extension

   c. Suprasellar extension

   d. **None of the above**

2. What is the intracranial structure correlating to the lateral opticocarotid recess?

   a. Sella turcica

   b. Chiasmatic groove

   c. **Optic strut**

   d. Middle clinoid

3. The nasoseptal artery is a branch of which artery?

   a. Sphenopalatine

   b. Angular

   c. Internal carotid

   d. Posterior ethmoidal

Transcranial and Endonasal Approaches to the Anterior Cranial Base

Lee A. Zimmer

Introduction

Surgery of the anterior cranial base is often fraught with anxiety and concern because of the close proximity of major neurovascular structures. Often these tumors are extracranial; however, when tumors extend intracranially or invade into the brain parenchyma, a team effort of Neurosurgeons and Otolaryngologists is needed for surgical management. Most lesions of the anterior cranial base arise from the nasopharynx, nasal cavity, or paranasal sinuses, and a wide range of pathologic types are encountered (Box 118.1).[1]

Malignant tumors of the anterior cranial base are rare, accounting for only 3% of all tumors of the head and neck. A linkage between cigarette smoking and squamous cell carcinoma has been reported.[2] Well-known risks of developing sinonasal malignancy include exposure to wood dust (adenocarcinoma), nickel-refining processes, leather tanning, mineral oils, chromium and chromium compounds, isopropyl oils, lacquer paint, soldering and welding, and radium dial painting.

Key Learning Points

1. Because of the location of tumors of the anterior cranial base, the initial clinical symptoms may be subtle and are often very similar to chronic inflammatory sinusitis.

2. Preoperative confirmation of histopathology is critical because of the wide variety of pathology of the anterior cranial base and the treatment

options available.

3. Careful preoperative evaluation of imaging is important for planning the surgical approach (open, endoscopic, or combined).

4. Tumor invasion of the anterior table of the frontal sinus, orbital adipose tissue, floor of the nasal cavity, or carotid artery or gross parenchymal invasion precludes an endoscopic approach.

5. Care must be taken when elevating a bicoronal flap to preserve the blood supply from the supraorbital and supratrochlear vessels to the pericranial flap.

6. Elevation of the bicoronal flap must occur in a plane deep to the superficial layer of the deep temporal fascia in order to avoid injury to the temporal branches of the facial nerve.

7. Failure to preserve the superficial temporal vessels may forfeit the use of a temporoparietal flap for reconstruction.

8. A basal subfrontal approach is preferred to avoid excessive retraction of the frontal lobe.

9. If endoscopic resection of pathology of the anterior cranial base is being undertaken, oncologic principles should never be compromised, and the same resection must be achieved endoscopically as would be done through a traditional approach.

10. All frontal sinus mucosa should be drilled away to avoid late complications such as the formation of a mucocele.

11. Lack of a watertight barrier separating the intracranial contents from the paranasal sinuses may lead to cerebrospinal fluid (CSF) leakage or infection.

12. In the postoperative period, endoscopic manipulation can disrupt the reconstruction and cause an iatrogenic CSF leak.

Preoperative Period

History

1. History of present illness

a. Tumors often grow undetected and present late.

1) Subtle signs and symptoms are present.

a) Nasal obstruction, rhinorrhea, and epistaxis are often overlooked.

2) Tumor progression

b) Cranial nerve involvement leads to more alarming symptoms, such as anosmia, diplopia, vision loss, numbness of the face, dysarthria, and facial weakness. Invasion of the brain with frontal lobe involvement leads to subtle headaches and mood changes.

Physical Examination

1. Orbit

Proptosis, chemosis, and impairment of extraocular muscles suggest a space-occupying lesion in or invading the orbit.

2. Face

Widening of the nasal dorsum and swelling of the cheek indicate a lesion in the nasal cavity and maxillary sinus, respectively, with bone erosion by tumor.

3. Ear

Serous effusion in the middle ear with conductive hearing loss often occurs with obstruction or invasion of the lateral wall of the nasopharynx.

4. Oral cavity

Swelling of the gingiva or gingivobuccal sulcus and loose dentition suggest the presence of an advanced sinonasal tumor.

5. Nasal endoscopy

If the tumor is not obstructing the nasal cavity, nasal endoscopy may provide useful information as to the location and, in some cases, the suspected pathology. For instance, a tumor medial to the middle turbinate is often an esthesioneuroblastoma. Biopsy of intranasal masses in an office setting should proceed cautiously owing to the relative

inability to control bleeding from a highly vascular lesion or for fear of a CSF leak.

Imaging

1. Computed tomography (CT) with contrast

Thin-cut (1 mm) CT with contrast is preferred for evaluation of the bony confines of the sinonasal tract and relative vascularity of the tumor.

2. Magnetic resonance imaging (MRI) with and without contrast

Contrast-enhanced MRI can distinguish tumor from soft tissue and trapped mucus and also evaluate dural involvement. Furthermore, in some cases MRI can identify perineural extension.

3. CT or MR angiography is a helpful adjunctive imaging modality for tumors involving the cavernous sinus and intracranial components of the carotid artery and circle of Willis.

4. Positron emission tomography (PET)/CT

If biopsy reveals a malignant neoplasm, PET combined with CT is preferred to evaluate for regional or distant metastases.

Indications

1. Benign and malignant tumors of the anterior cranial base

   a. Prior to any intervention, it is recommended to review cases with a multidisciplinary tumor board. For the purpose of this chapter, most benign and malignant tumors of the anterior cranial base can be removed surgically.

   b. After treatment planning is finalized, approaches are determined by the surgical team.

2. Lateral rhinotomy (Fig.118.1)

The lateral rhinotomy incision is useful in combination with a bicoronal transcranial approach for tumors of the maxillary and ethmoid sinuses with extension into the anterior cranial fossa, orbit, and pterygoid fossa. It is limited though to unilateral tumors and includes a facial incision.

3. Midfacial degloving (Fig.118.2)

The midfacial degloving technique is appropriate for bilateral tumors of the nasal cavity and paranasal sinuses. Although limited in approach to the ethmoid roof and frontal sinuses, these limitations can be resolved with the addition of a bicoronal approach.

FIG. 118.1 The lateral rhinotomy incision affords excellent exposure of the ipsilateral nasal cavity and paranasal sinuses with a good cosmetic result.

FIG. 118.2 The midfacial degloving approach is useful for tumors involving the sinonasal cavity bilaterally.

4. Endoscopic transnasal techniques

With improved optics and high-definition resolution, endoscopic transnasal techniques may be appropriate for tumors involving the nasal cavity, paranasal sinuses, and cranial base with minimal intracranial involvement or in combination with the bicoronal approach.

Contraindications

1. Bilateral orbital involvement

2. Bilateral cavernous sinus or carotid artery involvement

3. Gross intracranial extension

4. Distant metastatic disease

5. The overall functional and health status of the patient must be considered.

Preoperative Preparation

1. Consent

After a review of tumor type, location, and choice of intervention, the patient is presented with the plan, in which the risks and benefits are defined. Risks discussed should include intracranial bleeding, stroke, diplopia, blindness, CSF rhinorrhea, meningitis, epistaxis, facial nerve weakness, facial parasthesias, epiphora, and nasal obstruction.

2. Medications

All medications and supplements with antiplatelet or anticoagulating properties should be discontinued a week prior to surgery.

3. Prophylaxis of deep venous thrombosis with pneumatic compression stockings is provided throughout the surgery and hospital stay.

Operative Period

Anesthesia

General

All procedures for the open and endoscopic resection of skull base tumors are performed under general anesthesia.

Positioning

Supine

With the patient in a lateral position, a lumbar drain is placed to remove CSF prior to intracranial exposure for open procedures. This relaxes the brain and limits the need for parenchymal retraction as well as the risk of encephalomalacia. Although the drain is usually removed after completion of the case, some surgeons may prefer to leave it in place for 48 to 72 hours to lower intracranial pressure as the reconstruction heals. The patient is placed supine on a Mayfield head holder without pins for ease of rotation and repositioning during the procedure. If a bicoronal approach is planned, the eye are protected with a suture tarsorraphy to prevent inadvertent injury to the corneas. The intranasal cavity, including the inferior and middle turbinates, basal lamella, and anterior wall of the sphenoid sinus medial to the middle turbinate are infiltrated with 1% xylocaine with 1:100,000 epinephrine, and 0.05% oxymetazoline-soaked pledgets are placed in the nasal cavity. The patient is then prepped and draped in routine fashion.

Perioperative Antibiotic Prophylaxis

Ceftriaxone

Antibiotics used for prophylaxis should have a broad spectrum and CSF penetrance.

Vancomycin if the patient is allergic to penicillin or cephalosporins

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Open cranial base set including vascular instruments
2. Basic endoscopic sinus surgery set
3. Nasal endoscopes (4 mm) with 0-, 45-, and 70-degree lenses

4. Basic endoscopic skull base surgery set

5. Variable high-speed drill with diamond and cutting attachments. Various handpieces and drill bit sizes are available for open, craniotomy, and skull base access.

6. Reciprocating saw for skull base bone cuts

7. Endoscopic, pistol- or pencil-grip bipolar electrocautery instruments

8. Endoscopic pistol-grip Hemoclip applier

Key Anatomic Landmarks

1. Bone: The anterior cranial fossa includes the frontal bone with orbital roof, the crista galli, cribriform plate, ethmoid bone, chiasmatic sulcus, and the lesser wing of the sphenoid bone including the anterior clinoid process.

   a. Tumors that arise in this region may extend into the orbit, paranasal sinuses, or nasal cavity (e.g., esthesioneuroblastoma). Conversely, tumors arising from the paranasal sinuses and nasal cavity may also extend or invade through the anterior cranial fossa to involve intracranial structures (e.g., sinonasal undifferentiated carcinoma or squamous cell carcinoma).

2. Nerves: When surgical resection of tumors in this region is being considered, one should be aware of the complex anatomy, including cranial nerves I, II, III, IV, VI, and the frontal branch of VII.

3. Orbit and extraocular muscles

4. Arteries: The anterior and posterior ethmoid arteries, the sphenopalatine and other distal branches of the internal maxillary artery, and foremost the carotid artery

Prerequisite Skills

1. Fellowship: The head and neck surgeon must be trained in both open and endoscopic approaches to the anterior cranial base. This requires detailed understanding of skull base and sinonasal anatomy. Although extra training in a head and neck surgical oncology or rhinology

fellowship is not required, it is highly recommended.

Operative Risks

1. Intraoperative hemorrhage: Care must be taken to control small to medium-size arteries early with vascular clips or bipolar cautery including the sphenopalatine artery (SPA) and anterior ethmoid arteries to avoid unnecessary blood loss. The team must be prepared to control massive bleeding, although rare, from the carotid artery.

2. Fluid resuscitation: Communication with anesthesiology on blood loss and length of surgery is mandatory for appropriate management of fluid and blood products during surgery to prevent hypotension and underperfusion of the brain.

3. Seizure: Stress from CSF loss, brain retraction, and tumor removal may cause seizures. Preoperative and scheduled dosing of antiseizure medications such as levetiracetam may be useful in certain cases.

4. Parenchymal damage

5. Scalp and flap necrosis: Protection of the supraorbital arteries and hydration of the pericranial flap with saline-soaked gauze will limit injury.

6. Facial nerve injury: The temporal branches are at risk with elevation of the scalp.

7. Orbital injury: Inadvertent injury to the ophthalmic artery can lead to blindness. Injury to the periorbita may cause enophthalmos and diplopia.

Surgical Technique

Bicoronal Approach

- Vasoconstriction

  The planned incision is infiltrated with 0.5% xylocaine with 1:200,000 epinephrine to allow large amounts (20 mL) of infiltration without toxicity.

- Skin incision

Allows access to the frontal lobes of the brain, orbital roof; frontal, ethmoid, and sphenoid sinuses; and cribriform plate. The planned incision site is marked at least 2 cm behind the hairline. It can be extended further to increase the length of the pericranial flap (Fig. 118.3). The incision is continued into a preauricular skin crease anterior to the helix.

- Pericranial flap and frontal bone exposure

Superiorly, the incision is carried down to the layer of loose areolar tissue without incising the pericranium. Dissection in the subgaleal plane posteriorly provides a longer pericranial flap. Using a curved hemostat to separate the tissue layers, the lateral incision is extended to the fascia of the temporalis muscle (deep temporal fascia). Careful attention is paid to the variable branching patterns of the superficial temporal artery. Preservation of the artery is important for maintaining the blood supply to the temporoparietal fascial flap and to the scalp in revision surgery and post-radiation therapy. Raney clips are placed on skin edges for hemostasis. The pericranial flap is incised in a U-shaped fashion based on the supraorbital and supratrochlear vessels. The flap may extend beyond the scalp incision depending on the length required. The pericranium is elevated from the cranium to the level of the brow; laterally, it is separated from the deep temporal fascia at the margin of the muscle (Fig.118.4A and B).

FIG. 118.3 The coronal scalp incision may be extended in a preauricular skin crease to provide additional lateral exposure.

At the medial half of the superior orbital rim, the supraorbital vessels and nerves are found (Fig. 118.5) and released from the bony foramina with a 2- to 3-mm osteotome in an inferior direction if surrounded by bone. If exposure of the lateral orbital rim is necessary, a horizontal incision is made in the outer layer of the deep temporal fascia several centimeters above the zygomatic arch. Elevation continues in this adipose layer to the zygomatic arch, thereby avoiding injury to the frontozygomatic branches of the facial nerve. If the orbital rim must be removed for a subfrontal approach, the periorbita is elevated in a subperiosteal plane medially to the frontoethmoid suture line and laterally to the inferior orbital fissure.

The temporalis muscle is elevated from the temporal bone toward the temporal fossa. A small cuff of periosteum is left at the margins to reapproximate the muscle during closure. Traction sutures or hooks are then used to reflect the scalp, pericranium, and temporalis muscle and secured to the surgical drapes for consistent exposure. A wet laparotomy towel is placed over these tissues to avoid desiccation and

loss of tissue.

- Frontal craniotomy

  A variety of craniotomy options are available to expose the anterior cranial fossa (Fig.118.6). Neurosurgical techniques for exposure of intracranial contents are beyond the focus of this chapter but may be found in various textbooks on neurosurgery.[3]

- Lateral rhinotomy or facial degloving

  Once the frontal craniotomy has been completed, further extracranial exposure of the tumor margins and anterior cranial fossa may be completed using a lateral rhinotomy or facial degloving approach (see Chapters 106 and 109). Exposure allows release of the septum from the anterior cranial base, and removal of the lamina papyracea detaches the lateral nasal wall and maxilla from the orbital roof. Bilateral sphenoidotomies and removal of the vomer with a high-speed diamond drill allows release of the specimen from the anterior wall of the sphenoid sinus. The large defect results in direct communication between the cranial cavity and the nasopharynx (Fig.118.7).

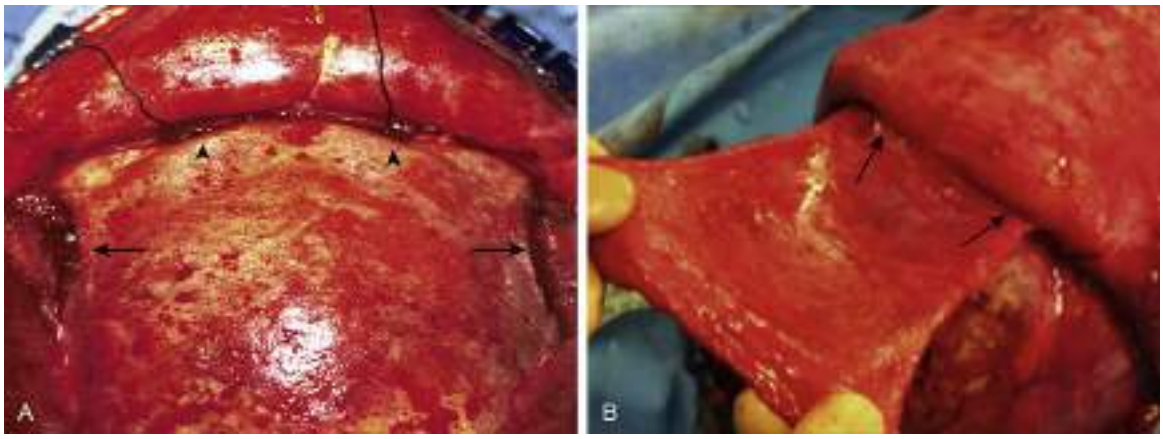

FIG. 118.4 The pericranial flap is dissected from the galea by sharp dissection to the level of the orbital rim. **A.** The scalp is elevated to the orbital rims with preservation of the supraorbital neurovascular bundle *(arrowheads)*. Laterally, the pericranium is separated from the temporalis muscles *(arrows)*. **B.** The vascular pedicle of the pericranial flap is dependent on the supraorbital vessels *(arrows)*.

- Reconstruction

A watertight closure is critical to decrease the chances of pneumocephalus, CSF leak, and meningitis. The most commonly used flap for this closure is the pericranial flap, as discussed earlier. The pericranial flap can cover the anterior skull base, including the cribriform plate, planum sphenoidale, fovea ethmoidalis, and orbital roof. The arc of rotation of the pericranial flap can be increased by using a unilateral blood supply or incising the base of the flap. The flap is then placed into the wound. The distal edge of the flap is secured to the edge of the intact dura at the posterior border of the skull base defect. Suturing is then performed from posterior to anterior along the cut dural edges or periorbita to form a watertight seal. The use of split calvarial bone grafts is not needed to support the reconstruction and could lead to osteomyelitis or osteoradionecrosis if radiation is planned. Skin grafts are not needed, as remucosalization will occur on the nasal side of the pericranium. Prior to replacement of the bone grafts, all remaining mucosa within the frontal sinuses must be removed in order to allow cranialization of the frontal sinus. Blunt stripping of the mucosa with a Freer elevator and then "polishing" all edges and crevasses with a 3- to 4-mm high-speed diamond drill with continuous irrigation are recommended. This will help to prevent postoperative mucocele formation. This dissection is carried into the frontal recess bilaterally, and temporalis muscle plugs are used to obliterate the recess.

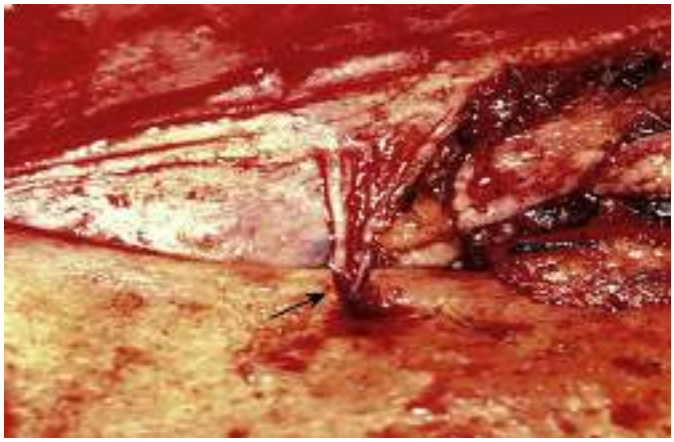

FIG. 118.5 Subperiosteal elevation of the frontal scalp reveals the supraorbital nerve exiting from a completely

enclosed bony foramen. The bone inferior to the nerve has been removed *(arrow)*.

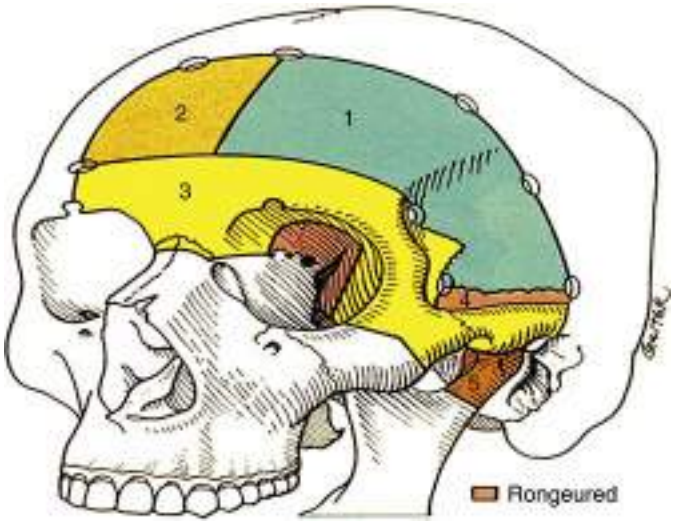

FIG. 118.6 Various segments of the frontal bone and supraorbital rims may be removed to provide adequate exposure of the anterior cranial base. *1*, frontotemporal craniotomy; *1 & 2*, bifrontal craniotomy; *3*, subfrontal approach with orbitozygomatic osteotomy; *4*, subtemporal craniectomy; *5*, mandibular condylectomy

The craniotomy and supraorbital bones are then replaced. Care must be taken not to compress the pericranial flap at the inferior edge of the supraorbital bone. It is recommended to remove an extra 2 to 3 mm of bone to avoid this complication. The bone flaps are secured with titanium microplates and 3- to 4-mm self-tapping screws. Burr-hole plates can be used to prevent postoperative cosmetic defects (Fig.118.8). Prior to closure, a 7-mm Jackson-Pratt drain is placed into the wound. The drain exit should be posterolateral to the bicoronal scalp incision and secured with a 2-0 Prolene suture. The drain should never be placed on wall suction in order to prevent excess removal of CSF fluid if there is a leak in the repair. The scalp is then repaired in layered fashion with 3-0 Vicryl sutures to reapproximate deep tissues and staples to reapproximate the skin edges.

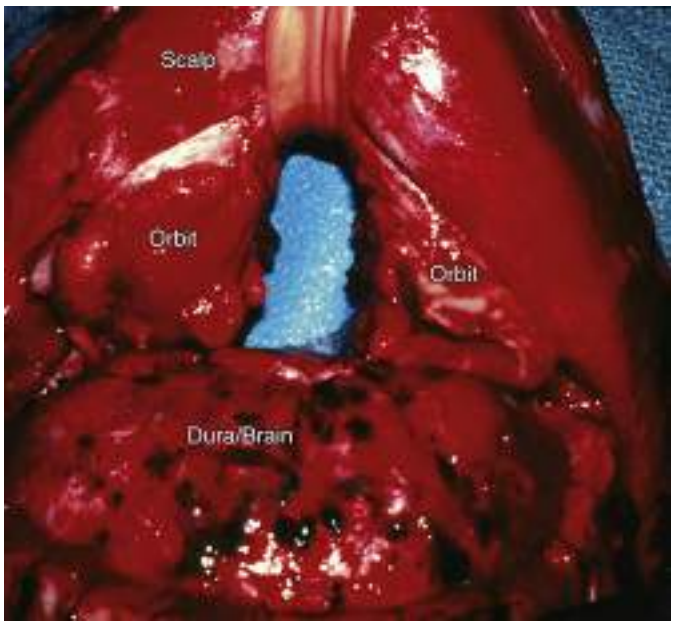

FIG. 118.7 After resection of the neoplasm, a large defect of the anterior cranial base remains and communicates with the paranasal sinuses.

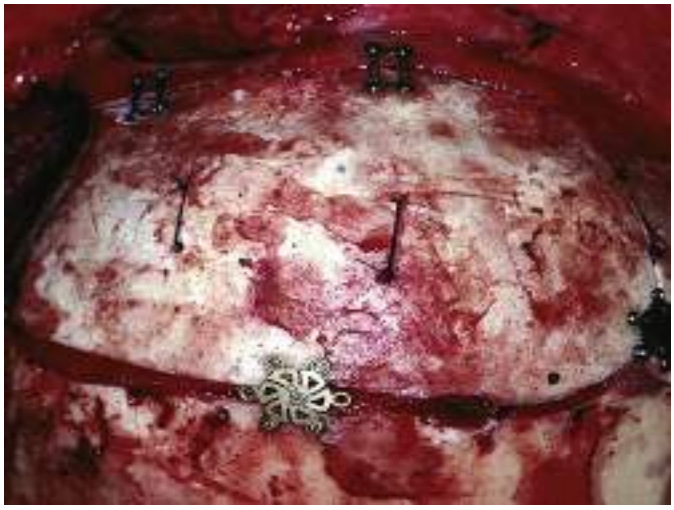

FIG. 118.8 Bone defects may be covered with titanium burr-hole covers to prevent a postoperative deformity.

Endoscopic Approach

Endoscopic techniques can be used to approach malignant and benign tumors of the ethmoid roof and cribriform region of the anterior cranial base.[4,5] Endoscopic techniques or corridors to other regions of the

anterior skull base have been described and are presented in other chapters (see Chapters 117, 119, 120, and 122). All of these techniques may be combined with open approaches per surgeon preference.

- Vasoconstriction

  After receiving three rounds of 0.05% oxymetazoline spray in the preoperative holding area, the patient is positioned in a supine position on the operating table. Using a headlight, approximately 10 mL of 1% lidocaine with 1:100,000 epinephrine is injected into the septum, middle turbinate, uncinate process, and the anterior wall of the sphenoid sinus. Pledgets soaked in 0.05% oxymetazoline are placed into the nasal cavity.

- Image guidance

  At this time registration is performed for image guidance, and the patient is draped in routine fashion without a skin prep.

- Nasal approach

  Pledgets are removed and a nasal endoscopy is performed to evaluate the extent of the tumor. A Cottle elevator is often used to discern tumor attachment to the septum or middle turbinates. This helps to determine whether intranasal tissues such as the septal flap or middle turbinate mucosa may be used for reconstruction at the end of the operation.

  Using a 0-degree endoscope and a 4-mm microdébrider, the tumor is quickly debulked to localize where it is attached in the nasal cavity. Epinephrine pledgets (1:1000) are then placed for rapid hemostasis. Exposure of noninvolved sinuses is performed as previously described, including maxillary antrostomy, total ethmoidectomy, and sphenoidotomy (see Chapters 103, 108, and 110) to identify the lateral and posterior margins. A Draf 3 frontal sinus approach (see Chapter 113) is performed to evaluate the anterior margins. If not involved by tumor, a nasal septal flap can now be elevated for use in closure of the defect (see Chapter 124Chapter 157). Detachment of the vomer from the sphenoid rostrum is performed with a 3-mm high-speed diamond drill. Through-cutting rongeurs may be used to detach the septum from the rostrum to the frontal sinuses anteriorly (Draf 3 exposure) (Fig.118.9A).

- Ethmoid arteries

  The anterior and posterior ethmoid arteries are exposed laterally where the fovea ethmoidalis attaches to the lamina papyracea and are either clipped or cauterized with bipolar cautery.

- Craniotomy

  Using a 30-degree endoscope and 3-mm high-speed diamond drill with continuous irrigation, the posterior table of the frontal recess is drilled anterior to the olfactory fibers in a horizontal fashion until the dura is exposed. This is repeated along the fovea ethmoidalis in a posterior-to-anterior fashion to connect the anterior craniotomy. Horizontal drilling of the planum sphenoidale anterior to the optic canals completes the craniotomy (see Fig.118.9B). This provides a rectangular craniotomy. The underlying dura may then be opened with a knife or fine scissors, allowing intracranial visualization of the tumor. Anteriorly, the crista galli is dissected free from the adjacent dura. Release of the specimen anteriorly requires transection of the falx cerebri in an anterior-to-posterior direction (see Fig.118.9C). Often the crista galli is thick, and meticulous thinning with a 3-mm high-speed diamond drill is needed to remove the crista and deliver the tumor (see Fig.118.9D). The olfactory bulbs and nerves can then be dissected from the surface of the brain and resected with the tumor-involved dura. It is recommended to obtain frozen section margins from the olfactory nerves because of "skip" lesions. Hemostasis is then obtained with endoscopic bipolar electrocautery, and the wound is reconstructed.

- Reconstruction

  Multiple reconstructive techniques are possible, including pedicled flaps, fascia lata, and free grafts, which are often placed in multiple layers: intradural, extradural but intracranial, and extracranial. This is discussed in another chapter (see Chapters 124 and 166).

Common Errors in Technique

1. Pericranial flap is too short

Inadequate length of the pericranial flap will not allow adequate closure and a watertight seal of the cranial base defect. Examine preoperative imaging to calculate the proper length of the flap.

2. Injury to the supraorbital artery

Loss of blood supply to the pericranial flap would lead to flap necrosis and failure to separate the nasal cavity from the intracranial contents.

3. Injury to the temporal (frontal) branches of the facial nerve

Dissection superficial to the temporalis muscle could lead to permanent paralysis of the upper third of the face.

4. Failure to identify and preserve the superficial temporal artery

This artery is the blood supply to the temporoparietal flap, which may be needed in revision surgery when a pericranial flap is not available.

5. Frozen sections

Frozen-section analysis of tumor margins is essential to perform gross total resection of disease.

6. Periorbita injury

Injury to the lining of the orbit may lead to herniation of adipose tissue, diplopia, and enophthalmos.

7. Anterior ethmoid artery

Unrecognized injury of the anterior ethmoid artery may cause a retro-orbital hematoma and loss of vision.

8. Frontal sinus cranialization

Removal of the posterior table of the frontal sinus with complete removal of mucosa from the frontal sinus is essential to prevent delayed mucocele formation.

9. Falx cerebri

Cutting the falx in a superior direction instead of posteriorly may cause intraparenchymal injury and bleeding.

Postoperative Period

Postoperative Management

1. Intensive care unit

After extubation, patients are transferred to the postanesthesia care unit (PACU) and then either the neurosurgical intensive care unit or a variable care unit.

2. Neurologic assessment

Close nursing care, including neurologic assessment every hour, is critical. Appropriate pain management without oversedation is important for neurologic examination.

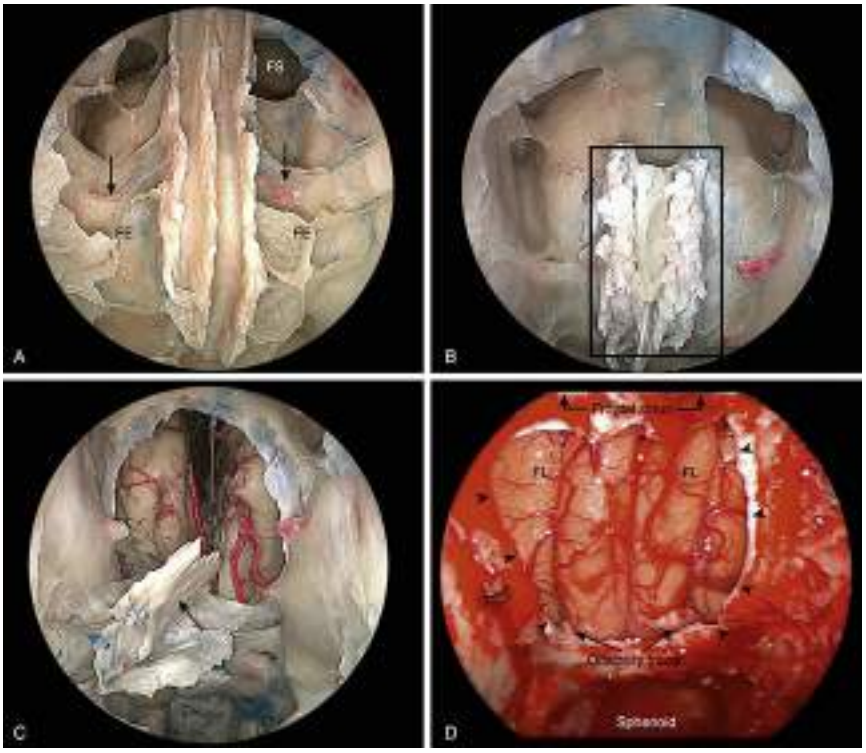

FIG. 118.9 **A,** Endoscopic visualization of the anterior cranial base in an anatomic specimen with a 30-degree endoscope. The ethmoid sinuses are broadly opened and the fovea ethmoidalis (FE) is exposed. A portion of the middle turbinates and septum remains (center). The anterior ethmoid arteries are identified *(arrows)*. **B,** A rectangular craniotomy is performed along the FE (lateral), planum sphenoidale, and frontal recess. **C,** Visualization of the attachment of the falx cerebri to the crista galli *(arrow)*. **D,** Intraoperative view of the cranial defect *(arrowheads)* during endoscopic surgery for esthesioneuroblastoma. Cut edges of dura *(arrowheads)*

FL, Frontal lobes; *FS,* frontal sinus.

3. Fluids and vital signs

Continuous monitoring of vital signs and volume shifts within the first 24 hours may lead to the identification of common metabolic disorders following surgery. Fluid replacement including blood products is not uncommon following skull base procedures.

4. Drain management

Hemovac drain management for open procedures is measured every 4 hours on the first postoperative day and every 8 hours thereafter. Drains should be placed only to self-suction to avoid inadvertent diversion of CSF. We aim to remove drains within 48 to 72 hours following surgery to avoid a CSF fistula. If a lumbar drain is used in cases of open or endoscopic surgery, 5 to 10 mL of CSF is released every hour. Often the drain is clamped 48 to 72 hours after surgery and removed 12 hours later if no CSF leak is noted.

5. Imaging

A CT or MRI scan is obtained on postoperative day 1 or 2 depending on the patient's acuity. This gives an objective measure of tumor clearance and aids in looking for intracranial complications such as hemorrhage or pneumocephalus.

6. General

Patients are advised not to blow the nose, sneeze with the mouth open, lift nothing heavier than 10 pounds, and avoid the use of straws for at least 4 weeks following surgery. Patients are advised to use oxymetazoline nasal spray every 8 hours in each nostril for 3 to 4 days to decrease postoperative nasal bleeding. Saline nasal spray is provided for nasal moisture; its use is recommended every 2 hours while awake. Routine follow-up in the office is scheduled for postoperative day 7 and after 1, 2, and 3 months to allow for endoscopic débridement of the nasal cavity and monitoring of nasal healing.

Complications

1. Intracranial hemorrhage

A rapid decrease in consciousness is concerning for an intracranial hemorrhage in the postoperative period. Careful manipulation of intravascular structures with sharp dissection of tumor without retraction prevents this complication. Immediate CT imaging of the head and operative exploration are warranted.

2. Facial nerve injury

The patient's inability to elevate the brow or crease the forehead skin is a sign of injury to the frontal branch of the facial nerve. Careful dissection of the bicoronal flap in the correct plane prevents injury.

3. Orbital injury

Diplopia, enophthalmos, or exophthalmos is concerning for an orbital injury. Preservation of the periorbita and careful cautery of the anterior ethmoid artery helps to prevent this complication. An immediate Ophthalmology consult is warranted to help identify the injury and provide possible interventions.

4. Visual loss

Postoperative examination of the patient with a basic vision examination is recommended. Loss of vision may be due to injury to the optic nerve, ophthalmic artery, superior hypophyseal arteries, or intracranial bleeding with optic nerve compression. A CT scan of the head without contrast can help to identify the cause. If there is concern for intracranial bleeding and compression, immediate operative exploration is warranted.

5. Olfactory loss

Loss of olfaction in some cases is unavoidable. However, aggressive resection of the septum for visualization of the planum sphenoidale or excessive superior mucosal dissection for a nasoseptal flap may cause permanent olfactory loss. When possible, care must be taken to preserve at least 1 cm of septal mucosa in the olfactory cleft to avoid this complication.

6. Syndrome of inappropriate antidiuretic hormone (SIADH)

Stress or retraction of the pituitary gland may lead to SIADH. Confusion and lethargy are common symptoms. Sodium levels should be checked frequently.

7. Diabetes insipidus

Although uncommon, decreased vasopressin production from the pituitary gland may follow brain retraction. Urine outputs are then measured, and appropriate fluid management is provided.

8. Deep venous thrombosis (DVT)

Operations on the skull base are inherently long, with decreased patient activity postoperatively. Prevention of DVT includes compression stockings and, in high-risk cases, subcutaneous heparin in the postoperative period.

9. Seizures

Intracranial manipulation increases the chance of postoperative seizures. Prevention includes minimizing trauma to normal parenchyma; perioperative prophylactic dosing of antiseizure medications such as levetiracetam may be useful.

10. Pneumocephalus

A meticulous, watertight closure of the dura after surgery lowers the risk of this life-threatening complication. A rapid decrease in patient responsiveness following surgery should be evaluated quickly with a CT scan of the head and immediate intraoperative repair.

11. CSF leak

As with pneumocephalus, a meticulous watertight closure prevents postoperative CSF leaks. If a patient shows signs of CSF rhinorrhea, bedside endoscopy may help to confirm the diagnosis and determine the site of the leak. Other causes include failure of free grafts, pedicled flaps, and microvascular free tissue flaps. Immediate identification with surgical repair is warranted.

12. Wound infections

As with any surgical approach, a wound infection is possible. Good sterile technique and the use of preoperative prophylactic antibiotics such as ceftriaxone or vancomycin are recommended. Erythema around the incision site with or without purulent exudate is highly suspicious for infection. Although antibiotics may resolve the infection, operative drainage and thorough irrigation of the infected site may be necessary.

13. Scalp necrosis

Decreased blood supply to the scalp after a bicoronal approach may lead to necrosis of the overlying skin. This complication can be avoided by preserving the vascular supply and not including the superficial layers of the scalp in the pericranial flap.

14. Chronic rhinitis

The removal of normal sinus and nasal cavity mucosa, particularly after radiation, may lead to chronic inflammation, mucous crusting, and nasal obstruction. Emollient nasal sprays and saline irrigations may improve sinonasal quality of life.

Alternative Management Plan

1. Induction chemotherapy and radiation

Some patients may choose nonsurgical therapies. Induction chemotherapy followed by radiation is an option in select malignancies squamous cell carcinoma (SCCa), sinonasal undifferentiated carcinoma (SNUC) and nasopharyngeal carcinoma (NPC). If nonsurgical management fails, surgery may be an option.

Discussion

Evidence-Based Medicine Question

Is there evidence for either equivalent or superior results with endoscopic resection of skull base malignancies versus traditional open approaches?

Despite aggressive surgical management, radiation, and in some cases chemotherapy, primary malignancies of the anterior cranial fossa remain difficult to cure. A low volume of primary cases prohibits high-volume, multiarmed, prospective trials to optimize overall care. The advent of endoscopic techniques does show promise, particularly in the case of early-stage tumors. A recent systematic review of the published literature for olfactory neuroblastoma and sinonasal adenocarcinoma has been published.[6,7] These results demonstrate equivalent if not superior results

with the endoscopic approaches in dealing with oncologic cases and postoperative complications. However, the limitations of these studies compared with prospective, multi-institutional trials must be understood before a final conclusion can be drawn.

Editorial Comment

The anterior cranial base may be resected using a completely transcranial approach, combined transcranial and transfacial/endoscopic approach, or completely endoscopic endonasal approach. Equivalent oncologic results for sinonasal malignancy can be achieved with all of these approaches, and the choice of approach depends on both the patient and surgeon.

For olfactory neuroblastoma, superior oncologic results have been noted with endoscopic endonasal surgery, even when adjusting for Kadish stage and Hyams grade.[6]

Review Questions

1. As the pericranial flap is extended to the root of the helix, arterial bleeding is noted. The artery is then sacrificed. Which pedicled flap has been lost for reconstruction?

   a. Pericranial

   b. Nasal septal

   c. Temporalis muscle

   d. **Temporoparietal**

2. Potential intraoperative complications of open anterior cranial base surgery include all of the following, except

   a. Seizure

   b. Facial nerve injury

   c. Blood loss

d. **Pneumocephalus**

3. After the completion of surgery, you are called to the PACU to evaluate your patient. His blood pressure is stable, postoperative hematocrit is 28, and he is somnolent. No pain medications have been given, and the nurse states that he was following commands until a few minutes ago. What is your next step in management, diagnosis, determination of cause, and intervention?

   a. Plain CT of the head, tension pneumocephalus, lumbar drain not clamped, clamp drain and wait

   b. MRI of the head, intracranial bleeding, pseudoaneurysm, interventional radiology with embolization

   c. **Plain CT of the head, tension pneumocephalus, lumbar drain not clamped, return to operating room to identify the source of reconstructive failure**

   d. MRI of the head, tension pneumocephalus, inadequate postoperative fluid management, burr hole in the PACU

4. Postoperative complications include all of the following, except

   a. Diplopia

   b. CSF leak

   c. Necrosis of the scalp

   d. **Hearing loss**

5. Common errors in intraoperative technique include all of the following, except

   a. **Injury to the supraorbital artery, leading to necrosis of the temporoparietal flap**

   b. Injury to the frontal branch of the facial nerve with paralysis of the frontalis muscle

   c. Failure to identify and preserve the superficial temporal artery

   d. Not checking multiple frozen sections to determine the extent of surgical resection

Endoscopic Endonasal Transpterygoid Approaches to the Middle Cranial Fossa

Ricardo Carrau, and Daniel M. Prevedello

Introduction

- Endoscopic endonasal approaches (EEAs) provide direct access to pathologies near the median and paramedian ventral skull base. A major principle of endoscopic endonasal surgery is the use of anatomical corridors to safely access skull base lesions with low associated morbidity. To access the middle cranial fossa, the maxillary sinus and the pterygopalatine fossa (PPF) are traversed to encounter and remove the pterygoid process, partially or completely; hence, the name transpterygoid approach.
- These approaches provide access to Meckel's cave with the trigeminal nerve and its associated foramina and branches, cavernous sinus, petrous and parasellar segments of the internal carotid artery (ICA), PPF, infratemporal fossa (ITF), and fossa of Rosenmüller (i.e., nasopharynx).[1-5]

The pterygoid process is a paired bony projection comprised of two plates (medial and lateral) that project posteriorly and a common anterior wall and base (Fig. 119.1). It extends inferiorly and perpendicularly from the junction of the body and greater wing of the sphenoid bone. At its anterior face, one can identify two prominent foramina: the foramen rotundum where the maxillary nerve exits and the Vidian canal that transmits the preganglionic parasympathetic fibers to the sphenopalatine ganglion as well as the postsynaptic sympathetic fibers from the deep petrosal nerve (Fig. 119.2).[5-10]

Key Operative Learning Points

- The pterygoid process is part of the surgical corridor to the middle cranial fossa, ITF, and nasopharynx.
- The Vidian canal and foramen rotundum are fixed anatomical landmarks that help with intraoperative orientation.
- The ICA and its relationship to the tumor will dictate the extent and direction of the approach.

Preoperative Period

History

- Mass effect or facial swelling
- Pain
- Trismus
- Double vision
- Dry eye
- Corneal ulcers
- Numbness
- Facial paralysis or weakness
- Medications:
  - Antiplatelet drugs
  - Herbal products
  - Vitamin E
  - Fish oil
- Prior surgery or radiation therapy

Physical Examination

- Thorough evaluation of cranial nerves (CN), specially CN 1–7;
- Ocular function
- Mouth opening
- Nasal endoscopy including nasopharynx
- Olfactory function

Imaging

- Computed tomography (CT)
- CT angiogram (CTA)
- Magnetic resonance imaging (MRI)
- Angiography
- An initial differential diagnosis is based on the appearance and site of origin of the lesion as demonstrated by MRI and/or CT. These imaging studies are considered complementary, as MRI is best in determining soft tissue relationships, whereas CT is best to show the bony architecture.
  - MRI demonstrates the interface between the tumor and the surrounding soft tissues, differentiating the tumor from secretions or inflammatory sinonasal disease, assessing the presence and extent of perineural spread, and the degree of involvement of the dural, brain, or orbit.
  - In addition, imaging studies allow the surgeon to estimate the extent of surgical exposure necessary. One may draw imaginary vertical lines in the coronal plane intersecting these foramina; thus, dividing the region into the sinonasal tract medially; the middle cranial and ITFe laterally; and the PPF in between. Imaginary horizontal lines, in the coronal plane, drawn through the lower level of foramen rotundum and the Vidian canal, approximate the locations of the middle cranial fossa, the lateral aspect of the petrous temporal bone (i.e., the petrous segment of the ICA), and the ITF. The spaces between the vertical lines are further divided by the horizontal line through the Vidian canal into two regions: the lateral sphenoid

recess above this horizontal line, and the PPF below it (see Fig. 119.2). Matching a lesion height and width in relation to these landmarks helps the surgeon to estimate the surgical corridor required to expose any particular lesion (Fig. 119.3A and B).[4]

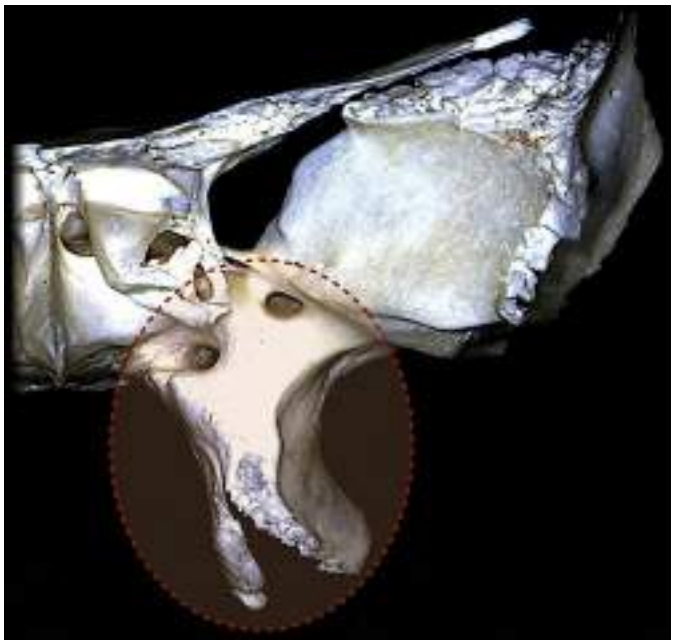

FIG. 119.1 Anterior view of the left sphenoid bone.

Shaded area corresponds to the pterygoid process. The term transpterygoid responds to the fact that these approaches have to transgress part or all the pterygoid process.

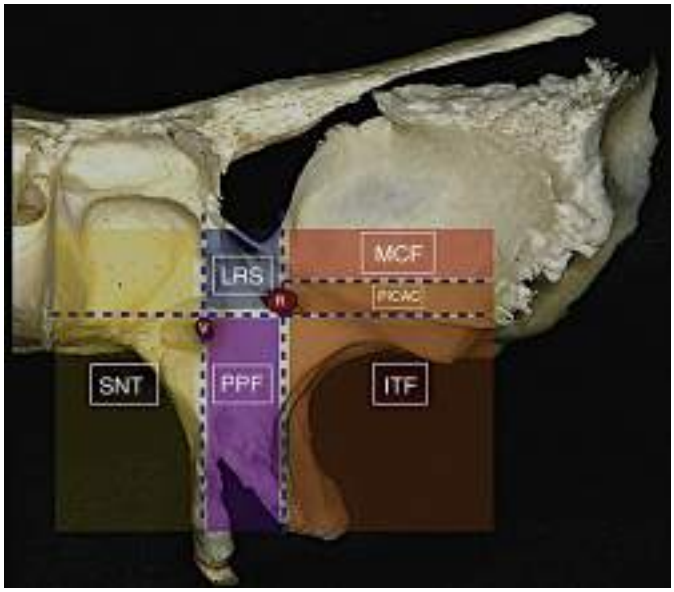

FIG. 119.2 Anterior view of the left sphenoid bone.

The foramen rotundum *(R)* and vidian *(V)* canal are useful landmarks in the anterior face of the pterygoid process. Horizontal lines, in the coronal plane, drawn through the lower level of foramen rotundum and vidian canal, approximate the locations of the middle cranial fossa (MCF), the lateral aspect of the petrous temporal bone (i.e., petrous segment of the ICA [PICAC]), and the infratemporal fossa (ITF). The spaces between the vertical lines are further divided by the horizontal line through the vidian canal into two regions: the lateral sphenoid recess (LRS), and the pterygopalatine fossa (PPF) and sinonasal tract (SNT).

- A full body positron emission tomography (PET) scan, or a fused PET/CT scan helps to identify the presence of regional or distant metastasis in patients presenting with a malignant tumor.
- Additionally, a high-resolution CTA appraises the course of the ICAs and their intracranial branches, evaluates the skull base bony anatomy, and may improve the accuracy of the intraoperative navigation.
- Using the intraoperative navigation software, MRI can be fused to the CT or CTA scan to plan the approach preoperatively.
- If there is involvement of the ICA, the patient must be assessed by one

of the various balloon occlusion tests to determine the degree of collateral flow and to evaluate the tolerance to the loss of one ICA. Areas of hypoperfusion on imaging mandate an extracranial-to-intracranial artery bypass or stenting of the vessel.

- Patients with benign lesions who can be operated on electively may benefit from ICA stenting as a protective measure. However, stenting requires antiplatelet therapy for 6 to 12 weeks; thus, ICA stenting is not a practical approach for patients with malignant tumors.

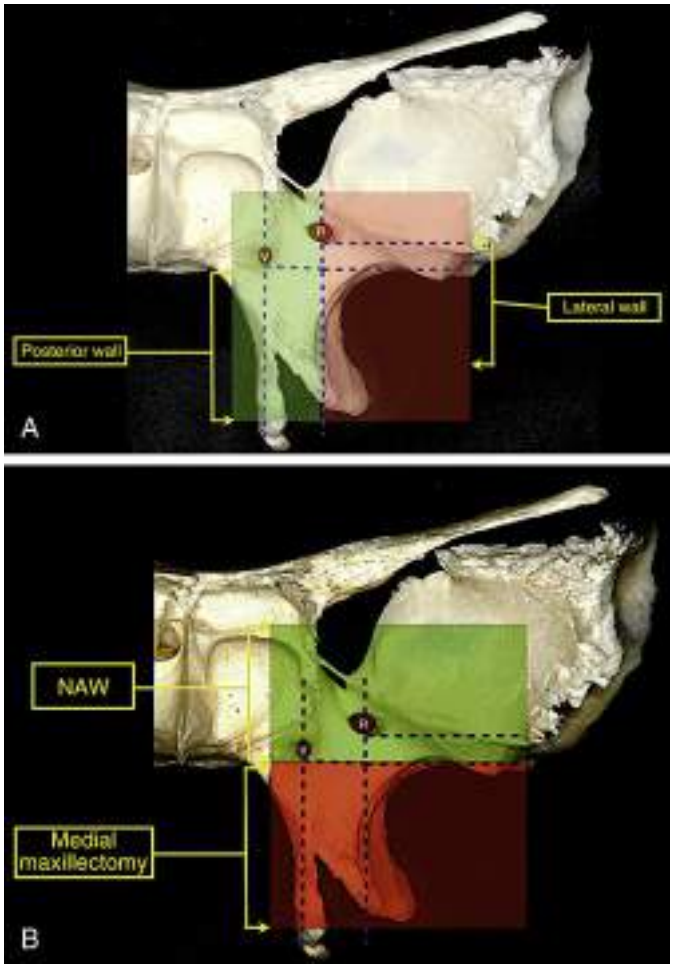

FIG. 119.3 **(A)** Lesions that are medial to a vertical line crossing the foramen rotundum *(R; green shaded area)* may be resected after removing the posterior wall of the antrum; however, lesions that are lateral to this line *(pink shaded area)* will need an extended approach including the resection of the lateral wall of the antrum. **(B)**

Lesions that are superior to a horizontal line crossing the vidian *(V)* foramen may be resected via a large nasoantral window (NAW); however, lesions that extend inferior to this line require a full medial maxillectomy.

Indications

- Endoscopic endonasal transpterygoid approaches (EETPA) were first used to access pathologies in the lateral sphenoid sinus such as bony defects associated with CSF leaks and meningo/meningoencephaloceles.[1]
- Multiple extensions and modifications of the EETPA followed, addressing select pathologies arising in the PPF, the petrous apex, the anterior aspect of Meckel's cave, the cavernous sinus, the ITF, and the medial aspect of the middle cranial fossa.[2-10]
  - Meningiomas, chordomas, chondrosarcomas, and trigeminal schwannomas, are tumors commonly affecting these regions.
  - Other less common pathologies that may be approached via a transpterygoid corridor include select sinonasal carcinomas, juvenile nasopharyngeal angiofibromas, aggressive pituitary macroadenomas, and metastatic neoplasms.
- One must consider the goals of surgery (cure vs. gross total resection vs. debulking or decompression), the relationship of the lesion to neurovascular structures (one must not cross a critical CN or vessel), expected sequelae, and the experience and expertise of the surgical team to decide whether to use an endoscopic endonasal technique or any other alternative approach.
  - Surgery for a benign tumor usually strives for a total resection; however, a partial resection may be preferred to avoid significant morbidity.
  - Even a malignant tumor involving critical structures may require compromising the resection and settling for just a gross total resection (as opposed to a wide resection) to be followed by adjuvant treatment.
- The use of multiple lesser approaches (concomitant or staged) may

produce less morbidity than a massive resection with a single approach.

Contraindications

- Despite its perceived minimally invasive nature, an EETPA yields a resection equivalent to that of an open approach, albeit through a smaller access; thus, any uncontrolled comorbidity that would preclude an open approach also applies to the EETPA. Cardiopulmonary, infectious, or other systemic comorbidities should be taken into consideration.
- One must use the approach that will achieve the most complete and safest resection adjusted according to the histopathology and extent of the tumor, but not the other way around; thus, the resection should not be compromised because the surgical approach is inadequate.
- The presence of an active bacterial infection in the sinonasal tract is a contraindication for an intradural approach, as it can seed the bacteria in the subarachnoid space.
- Tumor histopathology and goals of surgery (i.e., wide resection, gross total resection, or decompression) geographical extent (within the realm of the approach limits), and the relationship to neurovascular structures (the lesion should not be attached or posterior to the ICA or functioning CN) are important considerations in choosing a surgical approach.

When a tumor encases the ICA, the risk of intraoperative vascular injury is significant. If a surgical resection is mandatory, one should consider alternatives including the sacrifice of the ICA, the use of a different approach, or a partial resection followed by adjunctive therapy.

Preoperative Preparation

- The patient's symptoms and comorbidities, coupled with the histopathology and imaging characteristics of the lesion, are the most important determinants for establishing the goals of surgery and for estimating potential sequelae and risks.

- An informed consent should explain the risks involved, present clear goals, and set realistic expectations.
- Anticipate and plan for the social, financial, and psychological ramifications of the expected sequelae and potential complications of surgery.
- Skull base neoplasms frequently mandate a multimodal treatment. Evidence of perineural spread, aggressive bone, or dural invasion mandates adjuvant radiation therapy with or without chemotherapy. Occasionally, decompression of the orbit, the optic nerve, or the optic chiasm may warrant a palliative resection or debulking. Any remaining disease may have to be treated with adjuvant therapy. Therefore, it is important to discuss the clinical plan of management with radiation and medical oncologists in a multidisciplinary setting, such as a Tumor Board.

Operative Period

Anesthesia

- General
- Awake sedation
- Local

Positioning

- Supine
- Prone
- Lateral recumbent
- Following the induction of general anesthesia (preferably intravenous) and orotracheal intubation, the patient's head is placed in a horseshoe-type holder with the neck tilted slightly to the left and rotated slightly to the right.
    - We use a three-pin head holder for patients who require

electromyography (EMG; i.e., cannot be paralyzed) or when a lengthy surgery is anticipated.

Perioperative Antibiotic Prophylaxis

- Third- or fourth-generation cephalosporin
- Wide spectrum antibiotics, with adequate cerebrospinal fluid (CSF) penetration, are administered before the beginning of the surgery and are continued for 48 to 72 hours postoperatively.

Monitoring

- Somatosensory evoked potential (SSEP)
- EMG
- Electroencephalography
- Image guidance
- Doppler acoustic sonography
- Image guidance is an important adjunct during EEA and its need should be anticipated.
  - We prefer a CTA for intraoperative guidance for EETPA, as it provides a map of the bony structures as well as the vasculature.
  - In addition, a CTA can be fused with MRI to provide better definition of the soft tissue interfaces.
- Other adjuncts, like acoustic Doppler or diagnostic ultrasonography, can provide real-time and complementary information to that of the navigation system.
- Intraoperative neurophysiologic monitoring of SSEPs is prudent, as the ICA will be at risk with most EETPA. Similarly, electrophysiological monitoring of CN using EMG, and brain stem evoked responses (BSERs) are used according to the extent of the resection and the relationship to the neurovascular structures.

Instruments and Equipment to Have

Available

- Basic endoscopic sinus surgery set
- Extended insulated needle tip electrocautery
- Suction electrocautery
- Endoscopic bipolar electrocautery
- High-speed drill
- Microsurgical instruments

Key Anatomic Landmarks

- Sphenopalatine foramen
- Foramen rotundum
- Vidian canal
- Eustachian tube (ET)
- Lateral pterygoid plate (LPP)
- Foramen ovale and V3

Prerequisite Skills

- Sphenoidotomy
- Endoscopic sphenopalatine artery ligation
- Optic nerve decompression
- Repair of CSF leak
- Nasoseptal flap

Operative Risks

- Catastrophic hemorrhage from ICA
- Injury to the greater palatine nerve

- Injury to V1, V2, or V3
- Injury to the vidian nerve
- Injury to the ET
- Injury to the pterygoid muscles
- Injury to the orbital
- Injury to the brain

Surgical Technique

General Principles

- Considering the goals and anatomical intricacies of EETPAs, they can be classified in five main types[5]:
  - Type A: Partial removal of the medial and/or LPPs, indicated for the transposition of a temporoparietal fascia flap.
  - Type B: Removal of the medial aspect of the base of the pterygoid process, indicated for lesions (e.g., CSF leaks) at the lateral recess of the sphenoid sinus above the level of the Vidian canal.[1,2,4]
  - Type C: Dissection of the Vidian canal removing the base of the pterygoid plates to reach the petrous apex (infra- or retro-petrous), Meckel's cave, or cavernous sinus.[2,3,5,7,8]
  - Type D: Provides access to the ITF and requires a variable removal of the pterygoid plates.[2,5-7]
  - Type E: Removal of the medial pterygoid plate or even the entire pterygoid process, and medial third of the ET to expose the lateral nasopharynx (fossa of Rosenmüller) or the lateral aspect of the craniocervical junction.[3]
- EETPA begins with the expansion of the sinonasal corridor. All EETPA lateral to the vidian canal require traversing the maxillary sinus.
  - The degree of resection of the mucosa and the medial, posterior, and lateral walls is dictated by the extent of exposure necessary to address the pathologic process (see Fig. 119.3A and B).

- Endonasal access to the infratemporal or middle cranial fossae requires a substantial lateral extension of the maxillary sinus corridor, which may involve the addition of a Denker's or Sturman-Canfield's extension to the medial maxillectomy (anterior extension including the removal of the piriform aperture and an anterior maxillotomy). This latter modification provides an extended line of sight toward the structures within the ITF (Fig. 119.4).[3,5,7]

Nasal Preparation

- A povidone solution is applied to the perinasal and periumbilical areas (in the event that an autologous adipose tissue free graft is required for reconstruction).
  - If the tumor or corridor approaches the ICA, we also prep the lateral thigh for possible harvesting of muscle (i.e., to patch the ICA if injured).
- The nose is decongested using:
  - Topical adrenaline 1/10,000 solution applied with cottonoids.

FIG. 119.4 An endoscopic Denker's or Sturman-Canfield approach involves the anterior extension of a medial maxillectomy, including the removal of the piriform aperture and an anterior maxillotomy. This provides an extended line of

sight toward lateral structures within the infratemporal fossa.

- Injection of 1% lidocaine with epinephrine (1:100,000–1:200,000) in the anterior and inferior septum; and anterior middle meatuses.

Nasal Corridor

- The nasal corridor may be ipsilateral (e.g., CSF leak at the lateral recess of the sphenoid); however, both nasal cavities are more commonly used to allow for a two-surgeon, four-handed technique and to provide a cross-court approach that enhances the line of sight to the lateral aspect of the corridor.
- A zero-degree rod lens endoscope provides visualization for most of the surgery (Karl Storz, Tuttlingen, Germany) and may be coupled with straight instruments (the line of sight matches the geometry of the instruments).
  - Angled-lens endoscopes allow to "look around the corner"; however, they are more difficult to use, as they distort the view and require angled instruments to match their path to the visual field.
  - The endoscope is coupled to a high-definition (HD) endoscopic camera and monitor (Karl Storz Endoscopy; Tuttlingen, Germany).
  - Manual irrigation or an endoscope-irrigating sheath maintains a clean lens.
- Expansion of the sinonasal corridor starts with the out-fracturing of the inferior turbinates bilaterally, and out-fracturing of the contralateral middle and superior turbinates.
- Sinus surgery begins as an uncinectomy and is performed using a backbiting rongeur and microdébrider.
- The natural ostium to the maxillary sinus is identified and it is enlarged:
  - Posteriorly towards the posterior wall of the antrum (PWA)
  - Superiorly to reach the inferior and medial orbital walls
  - Inferiorly to reach the inferior turbinate
- A partial middle turbinectomy and complete anterior and posterior

ethmoidectomies augment the nasal corridor ipsilateral to the transpterygoid approach.

  - Removal of the ipsilateral middle turbinate also provides a mucosal free graft, which can be used for the reconstruction.

- At this point, a microdébrider is used to exenterate the anterior and posterior ethmoid sinuses, identifying and preserving the lamina papyracea and anterior skull base.

  - The cells of the ethmoid sinuses may be exenterated completely or partially to allow visualization of the surgical landmarks or to expand the space needed for instruments.

- Anticipating the possibility of a CSF leak and the need to expose and subsequently protect the ICA, a pedicled nasoseptal flap is harvested from the contralateral side, as the blood supply of the ipsilateral pedicle would be at risk during an EETPA.

- A "reverse" flap is harvested ipsilaterally to immediately cover the donor site of the nasoseptal flap (denuded septum).

  - The remaining septum and reverse flap are protected with silicone splints to avoid injury or avulsion during the passage of instruments.

- Bilateral wide sphenoidotomies facilitate bilateral and bimanual instrumentation, and the identification of anatomical landmarks for surgical orientation.

- The natural os of the sphenoid sinus is enlarged superiorly and laterally until the opening is in plane with the roof and the lateral wall of the sphenoid sinus.

  - Alternatively, the sphenoid sinus can be accessed at the junction of the nasal septum and the sphenoid rostrum.

  - Regardless of the technique, the goal is to achieve wide bilateral sphenoidotomies so there is sufficient space for the instrumentation, with satisfactory freedom of movement, and proper visualization of anatomical landmarks (sella, ICAs, optic nerves).

- The basopharyngeal fascia can be dissected from the inferior floor of the sphenoid sinus to allow the drilling of the floor posteriorly towards the clival recess, and laterally in the direction of the foramen lacerum.

- Once bilateral sphenoidotomies are completed, the ipsilateral sphenopalatine foramen (or foramina) and associated arteries are cauterized with bipolar electrocautery and divided.

Antral Corridor

- EETPAs to the PPF (Type A), lateral recess of the sphenoid sinus (Type B), petrous apex and Meckel's cave (Type C) target areas above the level of the vidian canal; therefore, only a wide nasoantral window (NAW) is required.
  - An adequate NAW should expose the superior half of the posterior wall of the maxillary sinus when using a zero degree endoscope.
  - A maximal NAW extends anteroposteriorly from the nasolacrimal duct to the posterior antral wall, and cephalo-caudally from the inferior orbital wall to the superior aspect of the inferior turbinate.
- Access to the ITF (Type D) and lateral nasopharynx (Type E) exposes a target that extends below the Vidian canal; thus, it requires a medial maxillectomy to expose the entire height of the PWA.
  - A medial maxillectomy should extend from the nasolacrimal duct to the PWA (anteroposteriorly) and from the inferior orbital wall to the floor of the nasal cavity (cephalo-caudally).
- Extended approaches to the ITF and/or middle cranial base or fossa may require an endoscopic Denker's approach (i.e., Sturman-Canfield approach; Fig. 119.4).
  - Maximal exposure includes the removal of the remaining inferior turbinate, anterior aspect of the inferior meatus, piriform aperture, ascending process of the maxilla, and sharp transection of the lacrimal duct to extend the medial maxillectomy anteriorly and laterally.

Pterygopalatine Fossa

- The anterior compartment of the PPF contains the internal maxillary artery and its terminal branches; whereas the posterior neural compartment contains neural structures, that is, sphenopalatine ganglion, Vidian nerve, greater and lesser palatine nerves, orbital

branches (sympathetic and parasympathetic fibers to the lacrimal gland) and a branch from the ganglion to the infraorbital nerve (Fig. 119.5).

- The sphenopalatine and posterior nasal arteries dominate the anatomy of the superomedial aspect of the PPF (Fig. 119.6).
  - These arteries should be identified and clipped/cauterized as they entered the nasal cavity at the level of the sphenopalatine foramen. It should be noted that the terminal branches of the internal maxillary artery are often more than two, and most commonly enter the nose through different foramina.
- Using a 1 to 2 mm Kerrison or Citelli rongeur, remove the anterior aspect of the sphenopalatine foramen for better exposure and control of the arteries.
- Removal of the PWA is extended as needed to expose the PPF (i.e., to the level of the superior aspect of the inferior turbinate after opening a NAW, or to the antral floor after a medial maxillectomy; Fig. 119.7). The periosteum is preserved to avoid injuring the vascular structures within the PPF.
  - Laterally, the resection of the PWA should be extended to reach the level of the inferior orbital fissure. The infraorbital nerve should be identified at the point where it exits from the PPF and before it enters the infraorbital canal (located in the roof of the maxillary sinus).
  - A meticulous dissection of the inferomedial aspect of PWA is necessary to avoid injury to the descending palatine artery and greater palatine nerve, which run together into the greater palatine canal, which is formed by the oblique junction of the posteroinferior aspect of the maxillary bone and the greater palatine groove.
    - The dissection should extend inferiorly to the greater palatine foramen, as this will facilitate the lateral mobilization of the soft tissues of the PPF (Figs. 119.8 and 119.9).
- Following a wide NAW or medial maxillectomy, the mucoperiosteum must be dissected off of the perpendicular plate of the palatine bone.

Resection of the Pterygoid Process

- Removal of the orbital process of the sphenopalatine foramen and anterior aspect of the perpendicular plate of the palatine bone provides access to the medial aspect of the PPF.
  - Inferiorly, the bony walls of the greater palatine canal are removed to expose and release the descending palatine artery and the greater palatine nerve (see Figs. 119.8 and 119.9).
  - Subsequently, the sphenoid process of the palatine bone is also removed to expose the palatovaginal canal.
  - The palatovaginal artery (i.e., pharyngeal artery) is identified and sacrificed to allow the lateralization of PPF soft tissue contents and expose the Vidian canal.
- The periosteum of the anterior aspect of the pterygoid plates may be dissected leaving the contents of the PPF enclosed in a periosteal sac formed by the periosteum of the posterior maxilla and that of the pterygoid plates.[8]

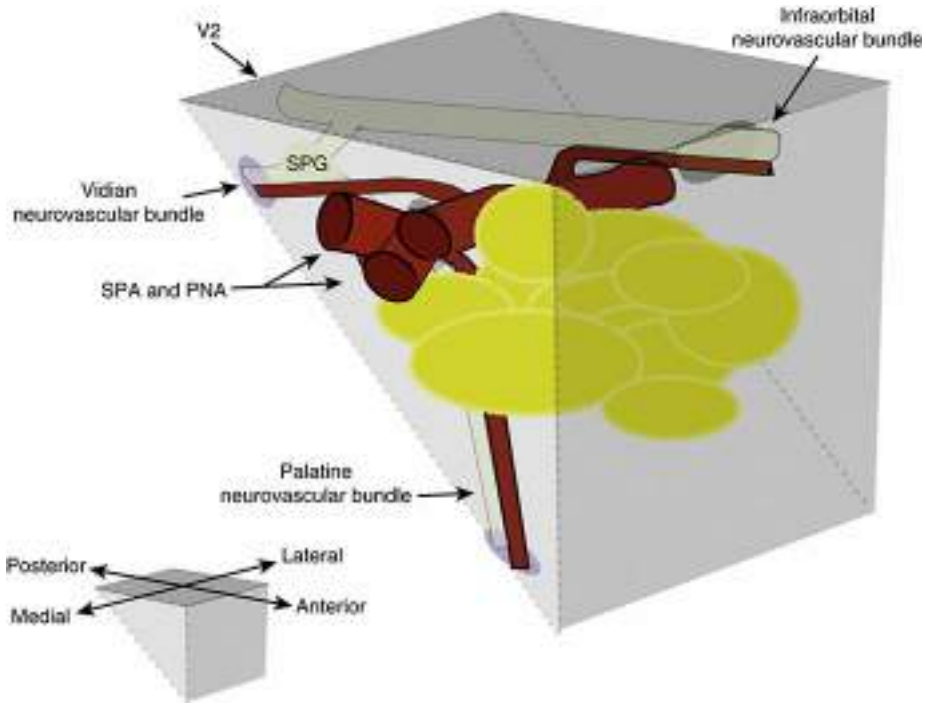

FIG. 119.5 Simplified schematic representation of the inverted pyramidal shape of the pterygopalatine fossa *(left)*. A vascular compartment is anterior to the neural compartment, both surrounded by adipose tissue and a

vascular plexus. *PNA,* posterior nasal artery; *SPA,* sphenopalatine artery; *SPG,* sphenopalatine ganglion.

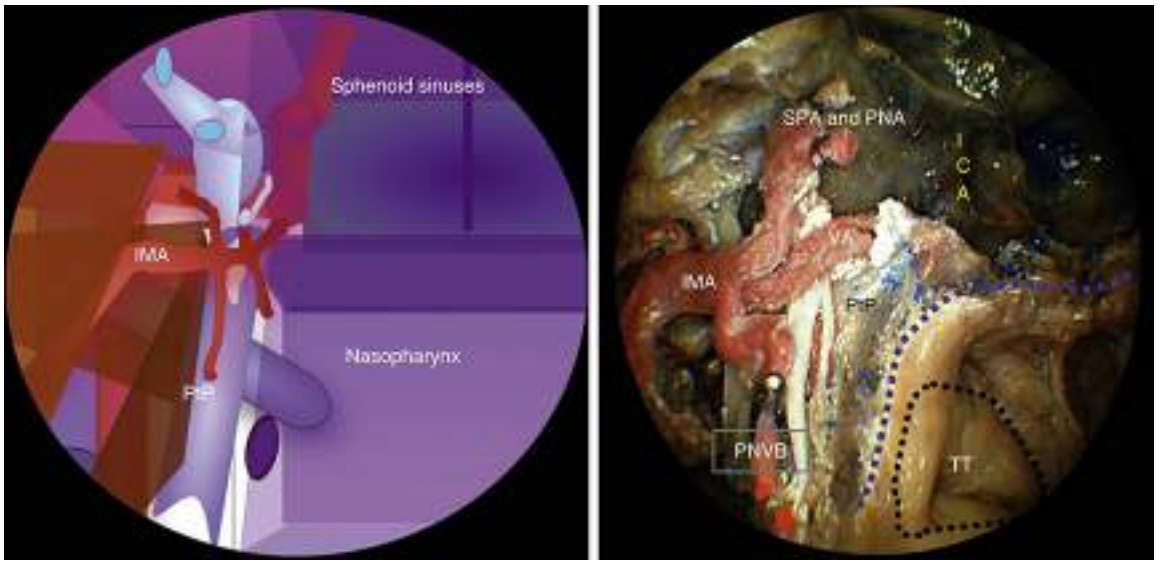

FIG. 119.6 Right pterygopalatine fossa with exposed vascular compartment (schematic representation *[left]*, and cadaveric dissection *[right]*). *ICA,* internal carotid artery; *IMA,* internal maxillary artery; *PNA,* posterior nasal artery; *PNVB,* palatine neurovascular bundle (includes the palatine artery anteriorly; greater and lesser palatine nerves posteriorly); *PtP,* pterygoid process; *SPA,* sphenopalatine artery; *SPG,* sphenopalatine ganglion; *TT,* torus tubarius; *VA,* vidian artery.

  - However, the vidian neurovascular bundle will tether the lateral mobilization of the fossa. Therefore, it must be cauterized and divided in most cases (see Fig. 119.9).
  - Preservation of the Vidian nerve is possible for select approaches to the infrapetrous ICA and Meckel's cave.
- Further lateral and superior dissection of the periosteum over the pterygoid process, exposes the base of the pterygoid process with the foramen rotundum and the maxillary branch of the trigeminal nerve (V2) (Fig. 5.10; see also Fig. 119.9).
- Exposure of the lateral aspect of the ITF in some patients requires

extending the medial maxillectomy anteriorly (endoscopic Denker's or Sturman-Canfield approach to obtain an adequate line of sight laterally) (see Fig. 119.4).

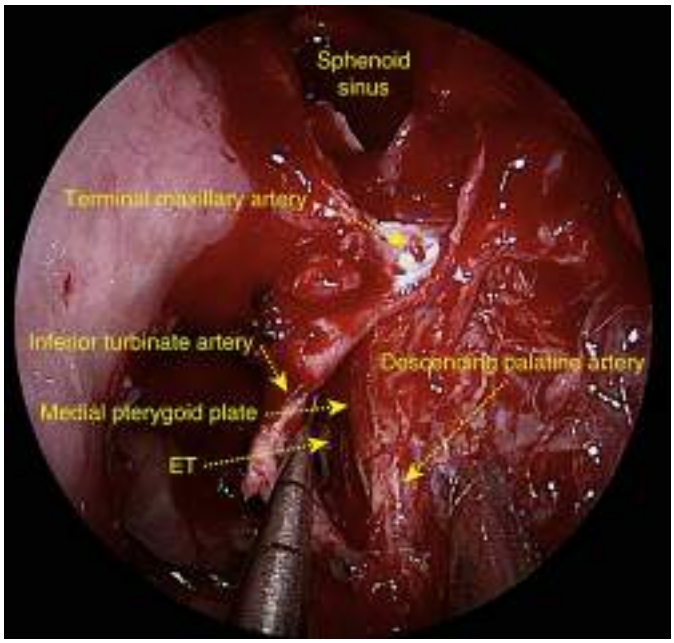

FIG. 119.7 Intraoperative photograph of the left pterygopalatine fossa.

The elevator is reflecting the mucoperiosteum over the remaining ascending process of the palatine bone and medial pterygoid plate to expose the Eustachian tube (ET).

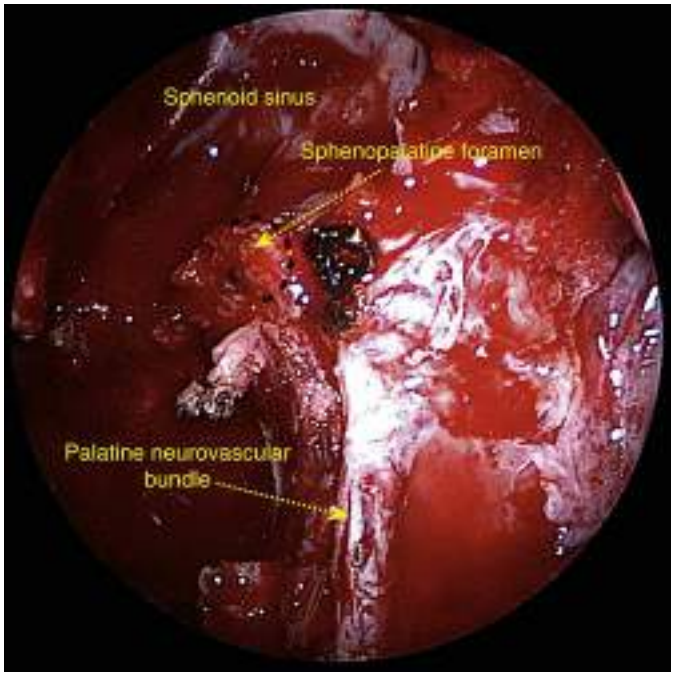

FIG. 119.8 Intraoperative photograph of the left pterygopalatine fossa demonstrating the palatine neurovascular bundle, which includes the palatine artery anteriorly, as well as the greater and lesser palatine nerves posteriorly.

- This includes removing the remaining inferior turbinate and anterior aspect of the inferior meatus with backbiting rongeurs, osteotomes, or drill.
- Exposure of the piriform aperture requires a vertical incision right on the edge of the aperture, which can be palpated just anterior to the head of the inferior turbinate.
- A full exposure requires removing the piriform aperture and ascending process of the maxilla, including the dissection and sharp transection of the lacrimal duct.

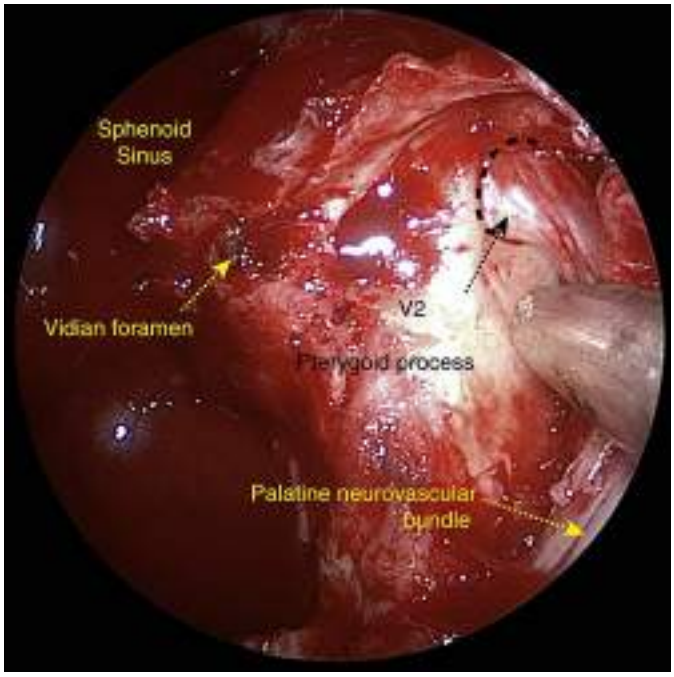

FIG. 119.9 Intraoperative photograph of the left pterygopalatine fossa demonstrating the lateral displacement of the palatine neurovascular bundle to expose the pterygoid process posteriorly. Notice the vidian and rotundum foramina (with V2).

- According to the surgical exposure requirements and the anatomy of the individual patient, the removal may be confined to the area inferior to the nasolacrimal opening.
- A subperiosteal dissection exposes the anterior maxilla, which is then removed to expose the entire lateral wall of the antrum.
- This modification allows a straight line of sight that encompasses the lateral aspect of the ITF.

- During a Type B approach (lateral recess of the sphenoid sinus), the sphenoidotomy can be extended laterally, removing the anterior wall of the lateral recess (i.e., pneumatized base of the pterygoid process) above the level of the Vidian canal.
  - Occasionally, if the pneumatization of the pterygoid process extends to the greater wing of the sphenoid, the Vidian neurovascular bundle needs to be sacrificed to allow further lateral mobilization of the soft tissues of the PPF.

- During a Type C approach (petrous apex or Meckel's cave approaches), it is usually sufficient to remove the medial aspect of the pterygoid process base.
  - The floor of the sphenoid sinus floor is removed, using a high-speed drill with a 4 mm hybrid or rough diamond burr, until it is flush with the clival recess.
  - The medial pterygoid plate is drilled using a coarse diamond 3 mm burr, and the Vidian canal should be followed to identify and preserve the horizontal segment of the petrous ICA.
  - The Vidian canal is dissected, drilling circumferentially around the Vidian canal to reach the foramen lacerum.
  - A lateral transposition of the vidian nerve may expose the base of the pterygoid process while preserving the neurovascular bundle.
    - To preserve the integrity of the Vidian nerve, the Vidian canal is drilled until it is eggshell thin. A dissector can be used to out fracture the thin residual bone while preserving the periosteum of the canal, as it protects the nerve during its manipulation.

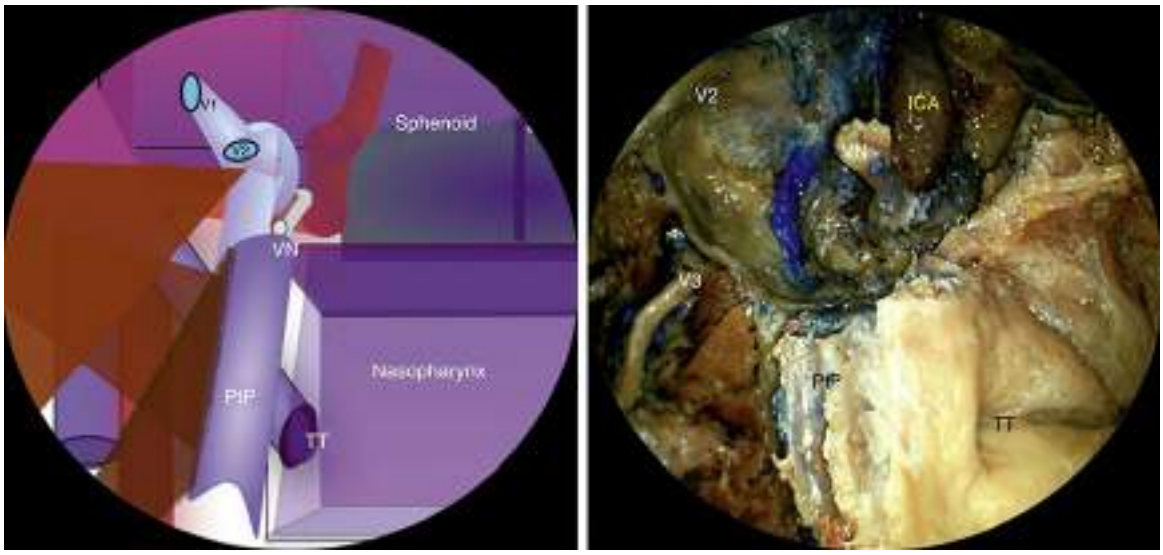

FIG. 119.10 Right pterygoid process after displacement of the soft tissues of the pterygopalatine fossa (schematic representation *left*, and cadaveric dissection *right*). *ICA,* internal carotid artery; *PtP,* pterygoid process; *TT,* torus tubarius; *VN,* vidian nerve; *V2,*

maxillary nerve; *V3,* mandibular nerve.

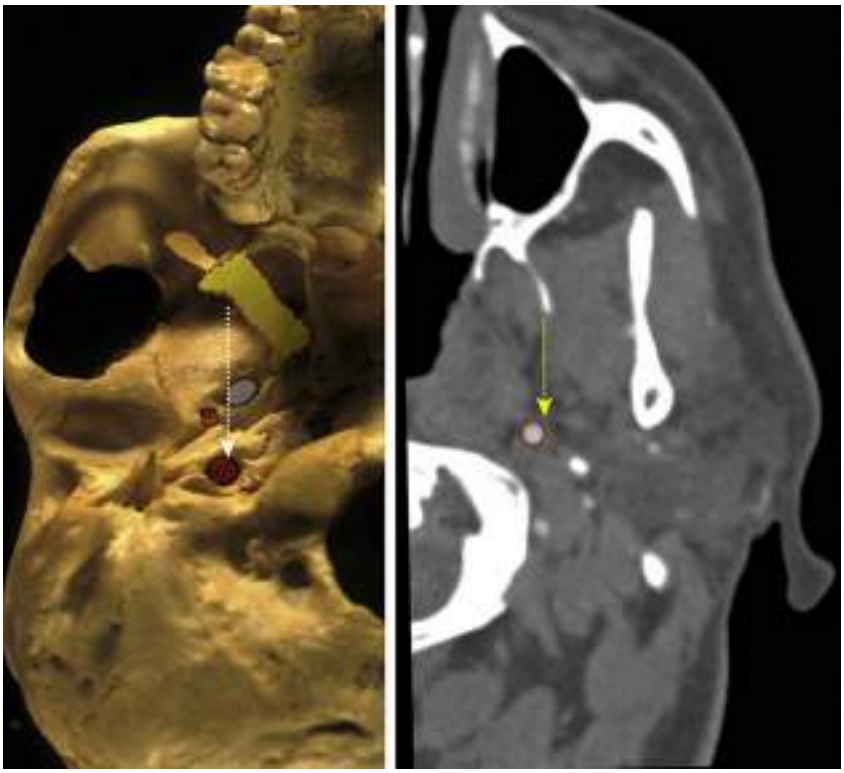

FIG. 119.11 Basal view of the skull base (left photograph) demonstrating the alignment (sagittal plane) of the lateral pterygoid plate, the foramen ovale (i.e., V3) and the carotid canal (i.e., internal carotid artery [ICA]). These structures mark specific depths and safety checkpoints during an endoscopic transpterygoid approach. The lateral pterygoid plate may serve as a proxy landmark to establish the position of the parapharyngeal ICA. However, this needs to be confirmed with imaging *(right photograph)*, as the parapharyngeal ICA can be very tortuous.

- During a Type D EETPA to the ITF, the internal maxillary artery should be divided at the level of the pterygomaxillary fissure. The Vidian neurovascular bundle and the branch of the sphenopalatine ganglion to V_2 are divided.
  - This allows the inferior and lateral displacement of the soft tissues of the PPF, and therefore exposes the entire height of the pterygoid

process (see Figs. 119.9 and 119.10).

- Surgical landmarks that are important to approach the ITF include V3 and foramen ovale (identified just posterior to the base of the LPP), and the tensor veli palatini muscle (at the interpterygoid fossa and just anterior to the ET). The petrous ICA is posterior to the foramen ovale (V3) and the ET (Fig. 119.11).[3-7]
- In select cases, one may continue drilling further laterally into the LPP until it is in plane with the middle cranial fossa and foramen ovale. This transpterygoid corridor can be extended or curtailed according to the needs of the surgery.

FIG. 119.12 Basal view of the skull base demonstrating the alignment of the Eustachian tube *(gray arrow)* and the petrous portion of the internal carotid artery *(red arrow)*. *Yellow shaded area*, lateral pterygoid plate; *white circle*, foramen ovale.

- Extensive lesions of the ITF, with or without involvement of the middle cranial base, may require the removal of the entire pterygoid

process (Type E EETPA).

- Access to the ITF requires cauterization, clipping, or division of the internal maxillary artery as it enters the pterygomaxillary fissure, detachment of the lateral and medial pterygoid muscles, and removal of the LPP.
  - It is important to follow a subperiosteal plane to avoid bleeding from the pterygoid plexus (Figs. 119.12–119.14).

- Removal of the ET in a lateral and superior direction, including its bony canal, directs the surgeon to the carotid canal, which is just posterior.

Common Errors in Technique

1. Inadequate exposure
2. Confusing the superior orbital fissure with the foramen rotundum
3. Inadequate instrumentation

Postoperative Period

Postoperative Management

- EEAs are associated with a shorter inpatient hospital stay and a lower incidence of surgical complications. However, close monitoring during the perioperative period is essential for the early identification of complications regardless of the approach.
  - Most patients spend the first 24 hours in the intensive care or step-down care unit.
  - Immediate mobilization and administration of chemoprophylaxis for deep venous thrombosis, unless there is an absolute contraindication.

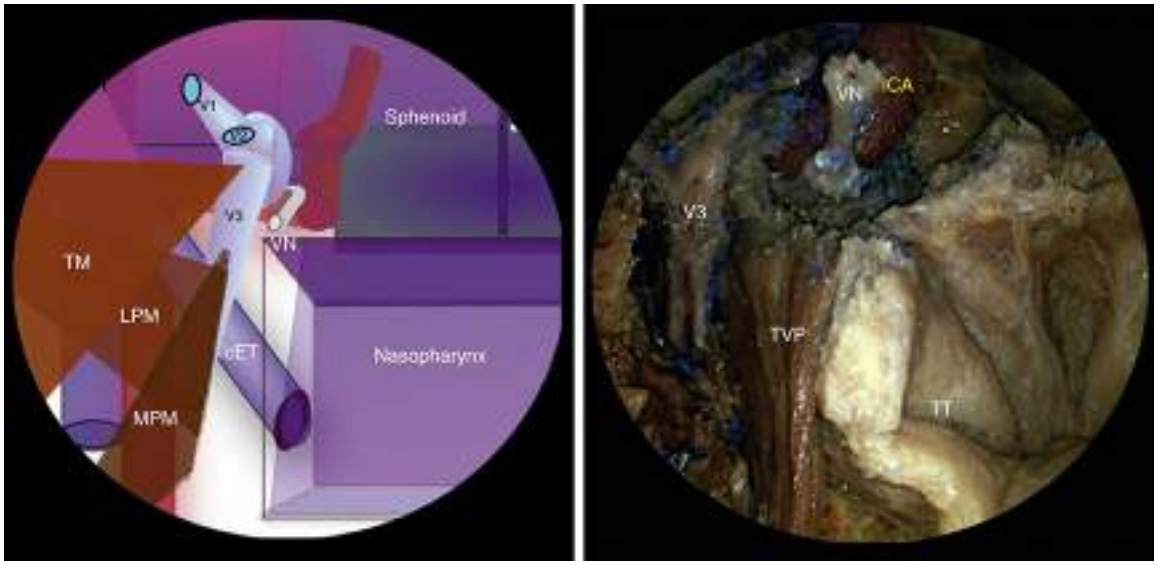

FIG. 119.13 Middle cranial fossa with exposed vascular compartment (schematic representation *left*, and cadaveric dissection *right*).

The right pterygoid process has been removed exposing the tensor veli palatine muscle (TVP) just anterior to the Eustachian tube. *cET,* cartilaginous Eustachian tube; *ICA*, internal carotid artery; *LPM,* lateral pterygoid muscle; *MPM,* medial pterygoid muscle; *TM*, temporalis muscle; *TT,* torus tubarius; *VN,* Vidian nerve; *V1,* ophthalmic nerve; *V2,* maxillary nerve; *V3,* mandibular nerve.

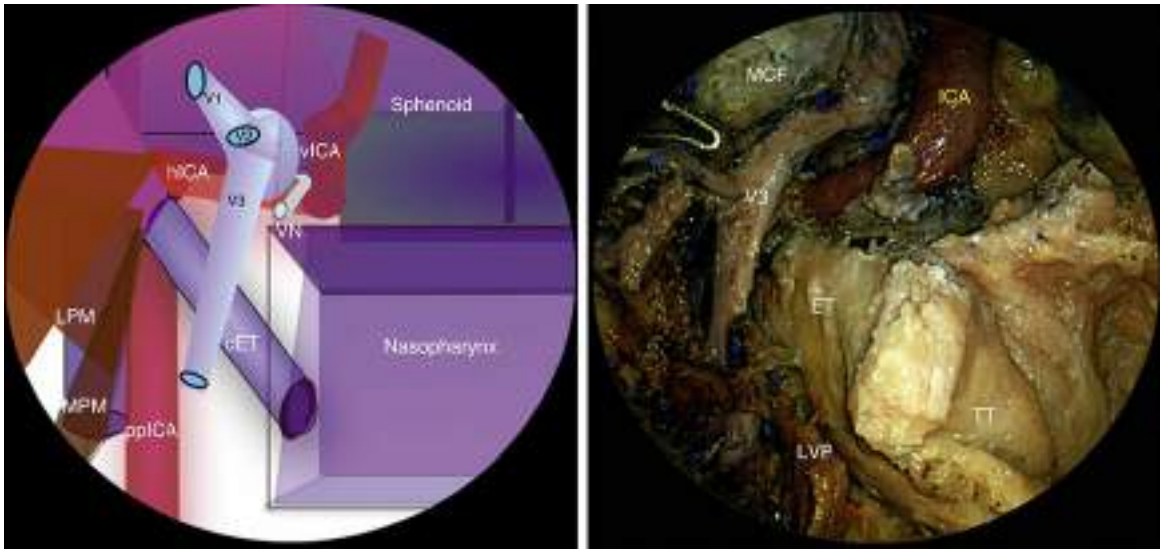

FIG. 119.14 This dissection is subsequent to Fig. 119.13. The tensor veli palatine muscle has been removed exposing the Eustachian tube and V3 in an alignment that follows that

described in Fig. 119.11. (schematic representation *left* and cadaveric dissection *right*). *cET,* cartilaginous Eustachian tube; *hICA,* horizontal internal carotid artery (petrous); *LPM,* lateral pterygoid muscle; *MPM,* medial pterygoid muscle; *ppICA,* parapharyngeal internal carotid artery; *TM,* temporalis muscle; *TT,* torus tubarius; *VN,* vidian nerve; *vICA,* vertical internal carotid artery (paraclival).

- Neurologic evaluation is required for patients with CSF loss, neurovascular manipulation, and electrolyte and acid-base disturbances.
- Maintaining the systolic blood pressure below 160 mm Hg (an arterial line is used as needed)
- Correcting endocrinopathies
  - For example, diabetes insipidus requires the monitoring of hourly fluid intake and output, serum sodium and osmolality, and urine-specific gravity at least every 6 hours.
- Patients with sleep apnea, requiring continuous positive airway pressure (CPAP) therapy at home, will only be able to have supplementary oxygen by facemask following a transdural surgery; therefore, cardiac monitoring and pulse oximetry is highly recommended in these patients.

- An immediate noncontrasted CT of the head allows early identification of intracranial complications. Although rare, tension pneumocephalus and acute intracranial hemorrhage can occur.
- Following oncologic resections, we also order an MRI of the brain, with and without contrast, within 24 hours after surgery to assess the degree of tumor resection.
  - As a secondary gain, one can ascertain the position and viability of the reconstructive flap.
- The rate of infection and CSF leak following EEA is less than 2% and 6%, respectively.[9-10]
  - To minimize these complications, patients are instructed to avoid any activities that increase intra-abdominal, intrathoracic, or intracranial pressure, thus avoiding bending, heavy lifting, straining, and squatting. Also, stool softeners should be taken to avoid

increased intra-abdominal pressure associated with constipation and straining to defecate. In addition, we ask our patients to cough and sneeze with an open mouth.

- Despite its relatively low incidence, patients are closely monitored for the presence of a postoperative CSF leak, which can be associated with significant morbidity, such as pneumocephalus and meningitis.
  - Clear nasal drainage, or a sensation of salty fluid in the throat, should prompt an immediate investigation.
  - The reservoir sign, where the patient tilts his or her chin toward the chest for at least 1 minute to observe for drainage of CSF, is a screening test that should be performed at least daily.
    - If "suspicious," a CT of the head should be obtained to assess the degree of pneumocephalus. Increased intradural air, compared with the immediate postoperative scan, strongly suggests the presence of a CSF fistula and calls for immediate intervention.
  - Testing for β-2 transferrin or beta trace may help to confirm the presence of a CSF leak but is not very practical, as the test for β-2 transferrin is time-consuming and not available at all sites, and beta trace protein assay is not available in the United States.
- Therefore, patients in whom a postoperative CSF leak is strongly suspected should be explored and repaired immediately.

- In addition to the administration of intravenous prophylactic antibiotics, such as a third-generation cephalosporin for 24 to 48 hours postoperatively, our practice is to continue wide spectrum oral antibiotics while nasal packing is in place.
- Patients who require dissection of the ITF frequently present with postoperative trismus or masticatory dysfunction. Early rehabilitation should be provided with active stretching exercises and devices.
- Barring complications, patients remain in the hospital for two to three nights prior to discharge.
- Normal saline solution sprays are initiated immediately after the surgery and nasal lavages with normal saline solution are started 3 to 5 days later.

- Nasal cavity débridements are performed every 1 to 4 weeks, as needed.

Complications

- Intraoperative bleeding from internal maxillary artery or pterygoid venous plexus.
- Significant bleeding is commonly encountered. It is most effectively controlled with bipolar electrocautery.
- Reduced lacrimation from the sacrifice of the sphenopalatine ganglion or the vidian nerve.
- Reduction of lacrimation is usually asymptomatic and requires no further attention. However, patients presenting with prior xerophthalmia and those with V1 or V2 cranial neuropathies may develop corneal ulceration requiring aggressive treatment.
- Facial hypoesthesia from V2, V3 injury.
- These deficits are usually temporary but can be permanent, and approximately 15% of patients develop deafferentation pain. The latter requires treatment with anti-seizure medications such as gabapentin or carbamazepine.
- During an approach to the petrous apex, Meckel's cave or nasopharynx, the ICA may be injured resulting in catastrophic and potentially fatal bleeding.
- Immediate control is best achieved with the application of a crushed muscle patch followed by endovascular stenting or occlusion.
- Postoperative CSF leak. The incidence of a CSF leak has significantly diminished since the adoption of pedicle flaps for the reconstruction. A postoperative CSF leak is best managed by immediate exploration and repair.
- CN V1 palsy. CN V1 is sensitive to manipulation. A permanent deficit requires management with prism lenses or strabismus surgery.

Alternative Management Plan

There are multiple open approaches to the middle cranial fossa and the nasopharynx. For example, the medial aspect of the middle cranial fossa may be accessed by temporal, frontotemporal, or temporal-subtemporal approaches. More recently described by Moe's study group, the transorbital approach seems to be a significant addition to the skull base armamentarium. Similarly, the ITF and nasopharynx may be approached from lateral (e.g., preauricular-subtemporal, postauricular-transtemporal) or anterior (e.g., LeForte I, facial translocation, maxillary swing) aspects. In addition, a multicorridor surgery combining an endonasal endoscopic approach with any of the aforementioned approaches or with lesser approaches, such as a transoral or transmaxillary approach to the ITF may yield an adequate resection while decreasing morbidity.

Discussion

Evidence-Based Medicine Question

Is a transpterygoid endoscopic approach equivalent to a traditional open approach?

Selecting a surgical approach is based on multiple factors that include the origin and histopathology of the tumor; the regional extent and invasiveness; the association with CN and ICA; the idiosyncratic patient needs; and the surgeon's training and bias. Taking these elements into account, it is difficult to compare adequacy of one approach over the other, even for similar lesions. However, Youssef and colleagues compared the exposure of the preauricular and transterygoid approaches to the ITF. The authors concluded that the endonasal endoscopic transpterygoid approach provides superior visualization and a more direct exposure of median structures, such as the nasopharynx, ET, sella, and clivus. Patients with benign lesions and some with select malignancies seem to be ideal candidates for the endonasal endoscopic transpterygoid approach. However, open approaches continue to play an important role, especially in patients with extensive malignant tumors. Similarly, Fahmy et al. and Kapucu et al. compared open and EEAs to the ITF and nasopharynx, respectively. Invariably, the EEA provided similar volumetric exposure compared to the open approaches with less sacrifice

of normal anatomy, suggesting the potential for less morbidity; however, the entry gate for instrumentation was limited and restricted the ease of motion. Shidoh and colleagues compared their results after the removal of clival chordomas via transoral-transpalatal (TO-TPA) and EEAs, concluding that the removal was more radical and less invasive in the EEA group than the TO-TPA group. However, tumors extending below the craniovertebral junction required using the transoral or combined approach.

Anatomically, the endoscopic approaches seem equivalent to the open traditional approaches for the median skull base. However, they require different instrumentation, skills, and institutional resources.

Editorial Comment

The transpterygoid approach is the surgical corridor to EEAs that involve the middle and inferior coronal planes. It is essential for surgical modules that involve the petrous segment of the ICA. As the authors demonstrated, the transpterygoid approach provides access to multiple areas, including the lateral recess of the sphenoid sinus; Meckel's cave, lateral cavernous sinus and middle cranial fossa; and the infrapetrous and infratemporal skull base. The classification of the transpterygoid approach into five types provides a useful construct for a graded approach to skull base tumors.

Carl H. Snyderman

Review Questions

1. Transpterygoid approaches provide access to:

a. Meckel's cave

b. Nasopharynx

c. Lateral recess of the sphenoid sinus

d. a and c

e **All of the above**

2. Identify the false statement regarding the anatomy of the pterygoid process:

   a. **The pterygoid process is part of the temporal bone**

   b. The pterygoid process contains the Vidian canal

   c. The pterygoid process contains the foramen rotundum

   d. The pterygoid process has two plates with a common base

   e. The pterygoid process is posterior to the terminal branches of the internal maxillary artery

3. The best imaging for lesions in the ITF is provided by:

   a. CT scan

   b. Water's view radiograph

   c. Scintigraphy

   d. MRI

   e. **a and d**

4. The following structures are contained in the PPF except for:

   a. Terminal branches of the internal maxillary artery

   b. Sphenopalatine ganglion

   c. Vidian nerve

   d. Greater and lesser palatine nerves

   e. **V3**

5. To locate the position of the ICA, one must consider the position of:

   a. V3

   b. LPP

   c. ET

   d. Foramen lacerum

   e. **All of the above**

Endoscopic Petrosal Approaches

Camilo Reyes, David Jang, and Arturo Solares

Introduction

The petrous portion of the temporal bone is a pyramid-shaped bone wedged between the greater wing of the sphenoid and the occipital bone. Its base is composed of the bony labyrinth (semicircular canals and cochlea); its anterosuperior surface makes up a large portion of the floor of the middle cranial fossa; its posterosuperior surface forms the anterolateral wall of the posterior cranial fossa; and its apex is joined to the clivus. The carotid canal, containing the petrous portion of the internal carotid artery (ICA), traverses the petrous pyramid anterior to the petrous apex. The internal auditory canal divides the petrous bone into anterior and posterior compartments (Fig. 120.1).

Most petrosal lesions are located in the petrous apex anterior and medial to the internal auditory canal. Moreover, lesions in the petrous apex often bulge medially into the sphenoid sinus and, therefore, are potentially amenable for an extended endonasal approach (EEA), as opposed to an external approach. The EEA can offer preservation of anatomic structures, less morbidity, improved cosmetics, and utmost control of the surgical target. Technological innovations, such as extended-length micro instruments, high-definition angled endoscopes, powered instruments, and image guidance systems, among others, allow for an EEA to the petrous apex.

Lesions of the petrous apex can be cystic or solid. The most common benign lesions of the petrous apex are cholesterol granulomas, followed by mucoceles and cholesteatomas, while chondrosarcoma and chordoma are the most common primary malignant tumors (Table 120.1). Because of its close proximity to the clivus, the sella, and the sinonasal cavity, lesions in these adjacent areas may involve the petrous apex secondarily.

The petrous apex may also be a site of metastasis from distant sites.

Key Operative Learning Points

- The petrous apex is deep to the paraclival segment of the ICA.
- The Vidian nerve is a key anatomic landmark to identify the second genu of the ICA.
- The abducens nerve is susceptible to injury in Dorello's canal during drilling or tumor removal deep to the paraclival ICA.
- The superior border of the petrous apex is the floor of the middle cranial fossa.

Preoperative Period

Preoperative evaluation of patients with petroclival lesions includes an extensive history and physical examination.

History

Many lesions of the petrous apex are small benign lesions that may remain asymptomatic for years and are often incidentally diagnosed on imaging done for other reasons. Therefore, symptoms can be vague, but larger lesions may cause the following symptoms:

1. Diplopia: most commonly due to lateral rectus palsy as a result of compression of cranial CN VI at the level of Dorello's canal

2. Headache: often retro-orbital

3. Hearing loss, imbalance

4. Facial pain or numbness: involvement of trigeminal ganglion in Meckel's cave

5. Lower cranial nerve neuropathies: dysphagia, dysarthria

6. Gradenigo's syndrome (otorrhea, diplopia due to ipsilateral lateral rectus palsy and retro-orbital headache)

7. Meningitis

8. Syncope, stroke, and amaurosis fugax: secondary to occlusion of the carotid artery

9. Unilateral nasal symptoms, such as persistent nasal obstruction, epistaxis, and/or rhinorrhea must raise the suspicion of a mass in the nasal cavity.

Physical Examination and Other Tests

1. Cranial nerve examination: While CN VI is affected most commonly (leading to lateral gaze palsy), any of the cranial nerves may be affected depending on the extent of the lesion.

2. The neck should always be examined to rule out metastases to the cervical lymph nodes in cases of malignancy.

3. Rigid or flexible laryngoscopy when lower cranial nerve compromise is suspected

4. An Ophthalmologist should evaluate any patient with visual symptoms to detect more subtle findings.

5. Nasal endoscopy: This is usually normal; however, it is important to assess for the presence of the following:

   a. Septal deviations, concha bullosa, and other anatomic variations that can hinder access

   b. Scarring or crusting from prior surgery and/or radiation

   c. Active sinusitis that can increase the risk of meningitis

   d. Viability of a nasoseptal flap: Prior surgery or septal perforation may obviate the use of the flap. In such cases, other reconstructive techniques need to be considered.

6. Examination of the ears and audiogram: Because of their close proximity to the middle ear, Eustachian tube, and hearing/vestibular apparatus, petroclival lesions can produce abnormalities in hearing and balance.

Imaging

1. Computed tomography (CT)
    a. Delivers information regarding bone erosion/remodeling, osteitis, and sinusitis
    b. High resolution CT (1 mm) with stealth protocol for image guidance
    c. CT angiography should be used to highlight the course of the ICA for image guidance navigation if CT/magnet resonance imaging (MRI) fusion is not being used.
    d. Contrast is typically not necessary if concurrent MRI with contrast will be performed.
2. Videofluoroscopy

If dysphagia is present preoperatively, videofluoroscopic evaluation of swallowing function should be performed.

3. MRI with gadolinium
    a. Best delineates tumor size, extent, and the intrinsic characteristics of the tumor
    b. CT and MRI are used in complementary fashion.
4. Vascular and interventional radiology
    a. Angiography, angio-MRI, or angio-CT has a cardinal role in outlining vascular anatomy and ruling out aneurysm, thrombosis, or compromise to adjacent arteries or veins.

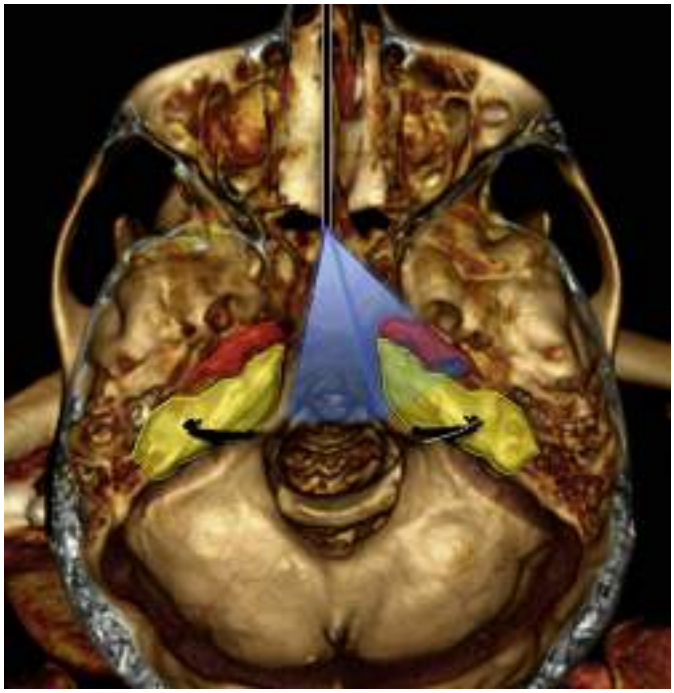

FIG. 120.1 Axial 3D reconstruction of the skull base viewed from above. Marked in yellow is the petrous portion of the temporal bone; the internal carotid artery (ICA) is anterior to it, in red. The image shows an endoscopic approach and the anterior relationship of the ICA to the petrous apex. A line through the modiolus of the cochlea and the internal auditory canal *(dashed white line)* divides the petrous bone into an anterior and posterior compartment. Most lesions are located anterior to this line because about 10%–30% of patients have anterior compartment pneumatization; in contrast, the posterior petrous bone (osseous labyrinth) rarely pneumatizes.

b. Although not common for petrous apex pathology, preoperative embolization of specific pathology can decrease intraoperative bleeding.

5. Balloon test occlusion (BTO)

A BTO can be done if the scans are suspicious for carotid invasion. Following a standard angiogram, a temporary balloon is placed in the ICA to be tested. A neurologist evaluates the patient for the next 20–25 minutes. Some centers, in the effort to enhance the prognostic validity of a BTO with clinical surveillance, use additional evaluations, such as hypotensive challenge to mimic physical activity, stump pressure measurements, electroencephalography and evoked potentials, cerebral

oximetry by using near-infrared spectroscopy, blood velocity measurements applying transcranial Doppler ultrasonography (TCD), evaluation of cerebral blood flow with xenon-enhanced CT, positron-emission tomography (PET), xenon-enhanced CT, and/or MR perfusion imaging. While a normal BTO reduces the morbidity and mortality associated with permanent ICA occlusion, unfortunately, it does not eliminate it. With BTO there is a risk of 0.4%–1.2% transitory and permanent complications, respectively. The incidence of stroke after permanent ICA occlusion is between 17% and 30%.

6. PET is often necessary for staging malignant lesions that are prone to regional and distant metastasis.

Indications

1. It is fundamental to adapt the surgical approach to the patient and not the other way around. Individual risks and benefits based on symptoms, extent of disease, and natural history of the disease must be considered. Small lesions in asymptomatic patients can be followed up every 6 months with serial imaging.

2. A multidisciplinary team with an experienced Otolaryngologist and Neurosurgeon is necessary.

3. The EEA is ideal when lesions are located medial to and below important neurovascular structures, namely the ICA (Figs. 120.2 and 120.3).

4. Compared to lateral approaches, the advantages of EEA are better access to deeply seated lesions, better exposure of the midline, preservation of hearing, and no manipulation of the facial nerve.

5. Lesions with lateral extension and those with involvement of critical neurovascular structures should be analyzed for an open or combined approach. Lateralization of the ICA is an option, but it should be reserved only for experienced skull base surgeons.

6. Stereotactic radiosurgery (SRS) or image-guided intensity modulated radiotherapy are options for patients who are poor surgical candidates or are at high risk for a vascular complication.

TABLE 120.1

Imaging Characteristics of Petrous Apex Pathology

Pathology	MRI (T1)	MRI (T2)	Contrast
Cholesterol granuloma*	Hyperintense	Hyperintense	None
Cholesteatoma	Iso or hypointense	Hyperintense	None
Petrous apicitis	Iso or hypointense	Hyperintense	Peripheral enhancement
Chordoma	Iso or hypointense	Hyperintense	Heterogeneous
Chondrosarcoma†	Iso or hypointense	Hyperintense	Heterogeneous
Meningioma	Iso or hypointense	Hypointense	Strong
Schwannoma	Iso or hypointense	Hypointense	Strong
Nasopharyngeal carcinoma	Isointense	Isointense to hyperintense	Heterogeneous

MRI, Magnetic resonance imaging.

* Most common cystic lesion.

† Most common solid lesion.

Contraindications

1. If the tumor is encasing vital vascular structures (i.e., ICA or perforating vessels), nonsurgical therapy (i.e., SRS) or an open approach, which allows for better vascular control, should be considered, especially if the tumor is of a hard consistency.

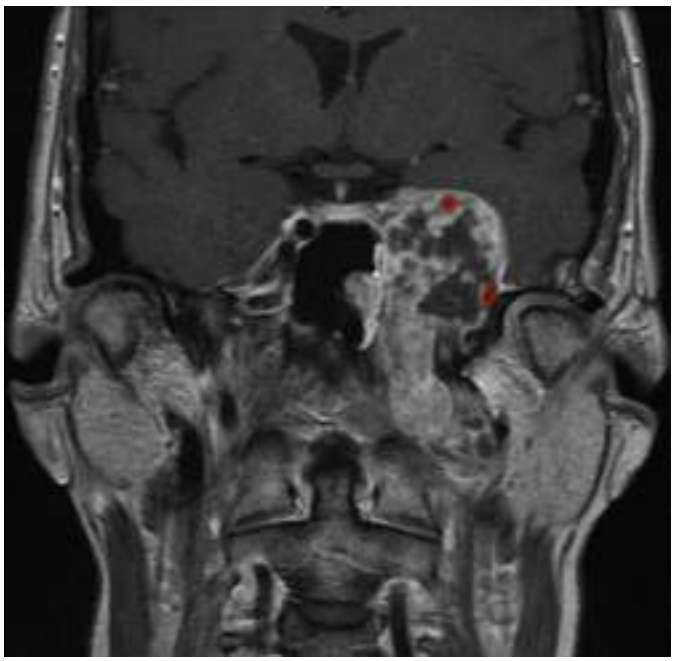

FIG. 120.2 Magnetic resonance imaging of a left

petroclival chondrosarcoma. Note how the lesion eroded the bone over the carotid and displaced from its location the paraclival and petrous segments of the internal carotid artery superiorly and laterally *(red circles)*, making an endonasal endoscopic approach ideal for this type of case.

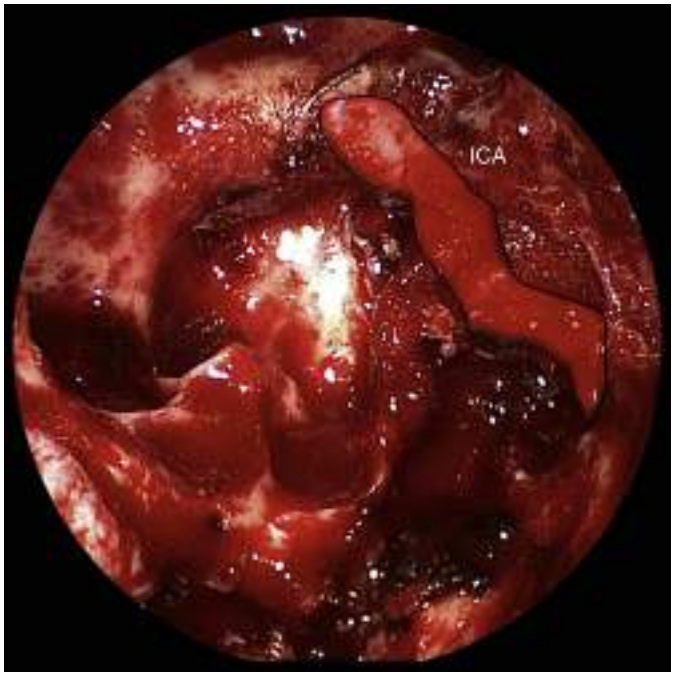

FIG. 120.3 Endoscopic view post-resection of a left petroclival chondrosarcoma. Surgical cavity with left internal carotid artery (ICA) outlined in red. Note how the lesion displaced the paraclival and petrous segments of the ICA superiorly and laterally.

2. In cases where neurovascular shunting is necessary, an open or combined endoscopic-assisted approach is favored.

3. A lateral component of the lesion may be better accessed through a lateral approach.

Preoperative Preparation

1. Patients should be informed about the risks associated with tumor excision, including vascular and neural injury, as well as the possibility

of skull base reconstruction and the need to convert to an open procedure.

2. Concomitant rhinosinusitis should be optimally treated before an EEA is done.

3. If there is risk of vascular injury, a neurointerventionalist must be available.

4. Preoperative angiography with BTO should be considered for cases with high risk of ICA injury.

5. Antiplatelet therapy and anticoagulants should be discontinued prior to surgery at the discretion of the patient's medical team. Low-molecular-weight heparin can be used as a bridge if indicated. Dietary supplements such as vitamin E, fish oil, Echinacea, aloe, and garlic extract also can be a source of bleeding disorders, and their use should be discontinued.

Operative Period

Anesthesia

The knowledgeable anesthesiologist provides optimum conditions that will minimize bleeding yet maintain hemodynamic stability of the patient.

1. Controlled hypotension
   a. Mean arterial pressure of 65–70mmHg
   b. Caution must be used for intradural lesions. Adequate blood pressure is needed to maintain perfusion through the circle of Willis and the collateral circulation.
2. Ventilation
   a. Hypercapnia produces vasodilatation, while normocapnia or mild hypocapnia minimizes bleeding and optimizes the surgical field during endoscopic endonasal surgery.[1]

3. Pain, nausea, emesis, and Valsalva during emergence can cause bleeding or cerebrospinal fluid (CSF) leak.

Positioning

1. Meticulous care with positioning is important to avoid pressure ulcers or traction on the brachial plexus with head positioning.

2. A reverse Trendelenburg position improves hemostasis of the surgical field when compared to the supine position.[2]

3. If a Mayfield skull clamp system is used, it should be positioned at the level or above the temporal line.

4. For the right-handed surgeon standing on the patient's right side, the patient's head should be slightly flexed, turned to the right, and tilted to the left. This allows the surgeon to operate comfortably in an ergonomic position.

Perioperative Antibiotic Prophylaxis

The risk of meningitis following EEA surgery can be as low as 1.8%, especially if there is no CSF leak.[3] Nonetheless, cefazolin 1–2 g IV is routinely given in the perioperative period. This can be re-dosed every 8 hours. For patients who are allergic to penicillin, clindamycin and vancomycin are reasonable alternatives. For patients with a history of chronic bacterial rhinosinusitis, prior culture results should guide perioperative antibiotic use.

Monitoring

1. Blood loss must be accurately monitored, as underestimating blood loss may result in poor fluid resuscitation with subsequent shock and organ damage.

2. Neurophysiologic monitoring (somatosensory evoked potentials): early detection of ischemia/hypoxia before irreversible damage occurs. This may also indicate the need for operative intervention (i.e., carotid shunt).

3. Electrophysiologic monitoring of cranial nerves, especially the abducens nerve

Instruments and Equipment to Have Available

1. Advanced endoscopic sinus surgery and endonasal microsurgery instrument set

2. Two flat panel monitors for a four-hand technique

3. Microdébrider with 4 mm blade

4. Radiofrequency ablation (i.e., Coblator with tonsillectomy tip) allows for hemostasis with minimal thermal injury.

5. High-speed extended length drill. An ultrasonic bone aspirator is also an option, but cost may be prohibitive.

6. Monopolar suction electrocautery

7. Extended length needle-tip Bovie for dissection of the nasoseptal flap

8. Image guidance system: optical or electromagnetic image guidance system with stealth merge capability

9. Intraoperative Doppler probe: helpful for identifying the ICA[4]

10. Hemostatic material, such as Surgicel (Johnson & Johnson, New Brunswick, New Jersey), thrombin-soaked gelatin foam (Floseal Baxter International Inc., Deerfield, IL, USA)

11. Reconstructive materials:

   a. DuraGen (Integra Lifescience Corporation, Plainsboro, New Jersey) and Alloderm (Lifecell Corporation, Branchburg, New Jersey) can be used for dural reconstruction.

   b. Fibrin glue, such as DuraSeal (Confluent Surgical, Inc., Waltham, Massachusetts) is also commonly used.

Key Anatomic Landmarks

1. Sphenoid sinus

   a. Intersinus septum: may insert posteriorly on the ICA or optic nerve (ON)

b. Bone covering the ICA or ON can be dehiscent.

c. Ethmoid-sphenoidal cell (Onodi cell) must be identified on imaging and endoscopy to avoid injuries to the ON.

d. Categories of sphenoid sinus pneumatization: sellar, presellar, conchal. A well-pneumatized sphenoid sinus (i.e., sellar) facilitates identification of important anatomic landmarks. However, conchal pneumatization makes this difficult. In such cases, dissection should proceed from a medial to a lateral direction, starting at the anterior margin of the floor of the sphenoidal sinus with identification of the Vidian canal and foramen rotundum laterally.

2. Pterygoid plates

a. The pterygoid process is closely associated with three foramina that must be identified prior to the drilling of the pterygoid plates:

1) Palatovaginal canal

2) Vidian canal

3) Foramen rotundum

b. Drilling and resection of the base of the pterygoid plates allow access to the inferior aspect of the petrous bone.

3. Vidian artery—nerve

a. Located at the junction of the sphenoid floor and the medial pterygoid plate

b. It is deep to the sphenopalatine and palatovaginal/palatosphenoidal vessels.

c. The Vidian nerve "protects" the ICA, as it runs along the floor of the sphenoid sinus.

d. The ICA will be reached with drilling superior to the pterygoid canal, which contains the Vidian nerve. Drilling inferior to the canal exposes the lacerum synchondrosis.

4. ICA

a. Review preoperative imaging, and rule out bony dehiscence of the ICA.

b. The anterior genu of the ICA is located at the foramen lacerum,

where the petrous segment of the ICA turns superiorly to form the paraclival segment.

c. If an expanding lesion does not remodel the petrous apex medially, the anterior genu of the ICA guards access to the petrous apex.

d. The horizontal petrous portion of the ICA is covered by thin bone.

e. The petrous segment of the ICA is located approximately 4.3–4.8 mm anterior to the foramen ovale.[5]

f. The most lateral limit of dissection is the horizontal petrous segment of the ICA, which cannot be retracted laterally.

Prerequisite Skills

1. Septoplasty

2. Functional endoscopic sinus surgery

3. Endonasal endoscopic approach to the pituitary using the four-handed technique

4. Nasoseptal flap or other reconstructive technique

Operative Risks

1. CSF leak: may be unanticipated

2. Meningitis and other intracranial infection

3. Hemorrhage: ICA, sphenopalatine artery

4. Cranial nerve injury: most commonly CN VI

5. Injury to the contents of the pterygopalatine fossa (greater palatine nerve, infraorbital nerve, vidian nerve)

6. Injury to the orbit (i.e., extraocular muscles, optic nerve)

Surgical Technique

The surgeon must select the ideal surgical corridor for each individual lesion. Basic and advanced sinonasal and skull base anatomy must be

mastered. For complex procedures, anticipation and preparation are critical. All surgical instruments must be ready before the procedure begins.

1. The nasal mucosa is topically decongested with 0.05% oxymetazoline, 4% cocaine or 1:1000 epinephrine-soaked pledgets before the sterile drapes are positioned.

2. The image guidance system is set up, calibrated, and accuracy confirmed. A stealth merge between the CT and MRI can be used for the entire procedure, especially to verify complete excision of tumors.

3. A 0-degree, 4-mm, rigid nasal endoscope attached to a high-definition video system is used for the majority of the operation. Thirty-, 45-, 70-, and 90-degree endoscopes should be available for evaluation of laterally extending lesions.

4. Sterile normal saline irrigations tempered between 40°C and 42°C

   a. Prevents fogging of the endoscope

   b. Aids in hemostasis as it activates the coagulation cascade

   c. Temperature above 48°C may predispose to mucosal tissue damage.

5. If a large surgical defect is anticipated, a vascularized nasoseptal flap based on the posterior nasal branch of the sphenopalatine artery is raised via electrocautery. The flap should be harvested from the contralateral side, if the ipsilateral sphenopalatine artery is clipped during a transpterygoid approach.

6. The petrous apex can be approached through a bilateral paraseptal approach or a transpterygoid approach.

Bilateral Paraseptal Transphenoidal Approach

Allows for access to the medial aspect of the petrous apex

1. Bilateral sphenoidotomies with 1–2 cm posterior septectomy are performed. This allows for a binostril approach with a four-handed technique. A more extensive septectomy can be considered for larger lesions.

2. The entire anterior wall of the sphenoid sinus along with the intersinus septum, sphenoid rostrum, and vomer is removed with Kerrison rongeurs and high-speed drill with a 3- or 4-mm coarse diamond burr. Incomplete removal of bony edges of the anterior wall of the sphenoid and within the sphenoid may limit the mobility of the instruments.

3. To reach the petrous apex, the medial aspect of the pterygoid process and the medial pterygoid plate are exposed superior to the Eustachian tube, and the Vidian canal is identified.

4. Drilling begins medially and inferiorly along the vidian canal back to the level of the ICA and the posterior wall of the sphenoid sinus. The palatovaginal artery can be cauterized where it exits the pterygopalatine space.

5. For inferior extension, a transclival approach can be performed in conjunction with this approach. For lateral extension, a transethmoidal-sphenoidal or a transethmoidal-pterygo-sphenoidal approach can be used.

Transethmoidal-Pterygo-Sphenoidal Approach

This allows for additional access laterally to the inferior aspect of the petrous bone (infrapetrous approach). In addition to the bilateral transphenoidal approach, the following steps are taken:

1. Unilateral middle turbinate resection may facilitate access.

2. Unilateral total ethmoidectomy and maxillary antrostomy are performed.

3. The antrostomy is extended posteriorly to the level of the pterygoid process, and the posteromedial wall of the maxillary sinus is removed.

4. The contents of the pterygopalatine fossa are exposed, and the sphenopalatine artery and its branches are cauterized or ligated.

5. The contents of the pterygopalatine space are displaced laterally, and CN V2 and the Vidian nerve are identified exiting the foramen rotundum and the Vidian canal, respectively. The greater palatine nerve and artery are also identified entering the greater palatine foramen.

6. This exposes the pterygoid process and both medial and lateral pterygoid plates. The pterygoid plates are then removed inferior to the Vidian canal.

7. Dissection along the posterior edge of the lateral pterygoid plate exposes V3 as it exits the foramen ovale.

8. The inferior surface of the petrous apex is reached by drilling the bone between the horizontal segment of the petrous ICA and the Eustachian tube, medial to V3 and staying inferior to the Vidian canal.

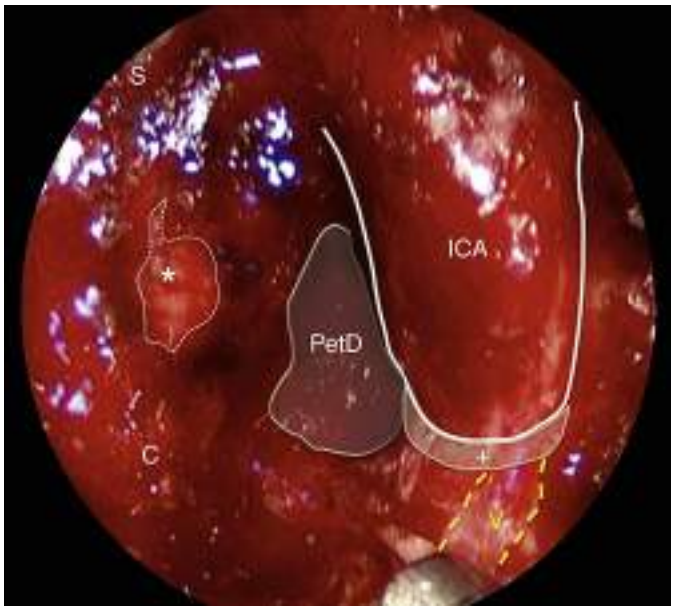

FIG. 120.4 Left petrous apex adenocarcinoma post-resection viewed with 30-degree angle scope. ∗, Bony erosion by tumor with exposed dura; *C,* clivus; *ICA,* internal auditory canal; *PetD,* petrous apex defect; *S,* sella; +, foramen lacerum cartilaginous portion; *V,* vidian nerve.

9. To positively identify the ICA, one can consider exposing the paraclival segment of the ICA and following it inferiorly to the anterior genu and the petrous portion. It may be necessary to transect the dense fibrocartilage between the foramen lacerum and the eustachian tube with scissors.

Lateralization of the Carotid Artery

1. After performing the transethmoidal-pterygo-sphenoidal approach, the vidian artery and nerve are traced posteriorly to the anterior genu of the ICA.

2. The bone of the vertical paraclival segment of the ICA is thinned with a 3-mm diamond burr and removed to the anterior genu.

3. The bone lateral to the ICA is also removed (Meckel's cave region), allowing up to several millimeters of lateral translocation of the vessel without compressing it.

4. Once the ICA is lateralized, lesions posterior to the paraclival and petrous ICA can be accessed (Fig. 120.4).

Tumor Removal and Reconstruction

The suspected pathology and surgical access required would dictate how much bone is removed over the lesion. The bone is "egg-shelled" with a diamond burr, and small pieces are removed with a small Kerrison rongeur or dissector (e.g., 1 or 2 mm). For cystic lesions, such as cholesterol granulomas and mucoceles, a sharp sickle knife is used to open the wall of the cyst and drain the contents. The cavity is irrigated with saline to remove any additional debris. A stent or mucosal graft can be positioned through the opening to help maintain patency. For solid lesions, such as chondrosarcoma and chordoma, removal with a ring curette and suction is often feasible, as these tumors are typically gelatinous. An ultrasonic aspirator is also an option. For fibrous tumors, such as meningioma, the use of dissectors and scissors, along with careful hemostasis, should be considered.

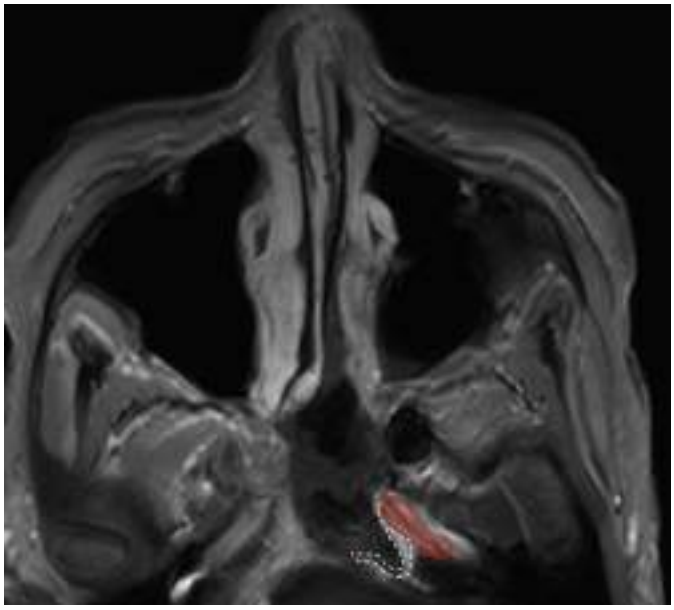

FIG. 120.5 Left petrous apex adenocarcinoma. Postoperative T1-weighted magnetic resonance imaging with gadolinium shows complete resection. The dotted white line shows nasoseptal flap covering the petrous apex defect. The internal carotid artery is highlighted in red.

For large surgical defects with or without CSF leak, a nasoseptal flap with or without an abdominal adipose tissue graft is an excellent reconstructive option (Fig. 120.5). The surgeon should anticipate this ahead of time so the flap can be raised and safeguarded in the nasopharynx or maxillary sinus. The nasoseptal flap must be elevated on the contralateral side, as the sphenopalatine artery is often ligated on the ipsilateral side. A small nasoseptal flap also can be inserted into the cavity of a marsupialized cholesterol granuloma as a substitute for a temporary silastic stent to keep the opening of the cyst patent.

Common Errors in Technique

1. Small exposure from a unilateral approach
2. Small opening for cholesterol granulomas
3. Inability to differentiate the vidian artery from the palatovaginal artery
4. Inadequate hemostasis that can compromise visualization

5. Inability to identify and expose the ICA may prevent optimal exposure of the lesion.

6. Careful ligation of internal maxillary artery branches will help to prevent postoperative epistaxis.

7. For extradural lesions, preserving the dura of the middle and posterior cranial fossae can prevent a CSF leak.

Postoperative Period

Postoperative Management

1. Antibiotics should be administered while nasal packing is in place.

2. Imaging should be considered 24 hours after surgery when an intraoperative CSF leak is encountered to rule out complications, such as pneumo-encephalus or intracranial hemorrhage.

3. Patients should have at least 24-hour neurosurgical intensive care unit (ICU) observation.

4. Pain medication: Patients would not be expected to have much pain following this operation. Avoid opioid-derived medications, especially in patients prone to sensitivity to these medications, so they do not develop nausea and emesis.

5. High-volume saline irrigations on postoperative day 1 if no CSF leak is seen. If a CSF leak is repaired and packing is placed, irrigations can begin as soon as the packing is removed on postoperative days 6–7.

6. Nasal splints placed during the procedure to avoid synechia can be removed in about 3 weeks.

7. Resumption of anticoagulants/antiplatelet drugs on postoperative days 3–5

8. Normoglycemia should be achieved. Insulin and glucose infusions should be used to titrate the patient to a near-normoglycemic level.

9. Nasal débridement is typically performed at weeks 3, 6, and 12.

Complications

1. CSF leak
2. Cranial nerve injury, in this case CN VI
    a. Resolution of CN VI palsy depends upon whether the lesion was caused by manipulation vs. section of the nerve. When the palsy is caused by manipulation, observation can be an option, and spontaneous resolution usually can be seen after 6 months. Patients with CN VI palsy can benefit from consultation with a neurologist, ophthalmologist, or neuroophthalmologist, especially if the lesion does not resolve.
3. Dry eye due to vidian nerve injury/sacrifice
    a. The incidence of dry eye syndrome is 12%–30% after vidian nerve neurectomy. When the sphenopalataine ganglion is preserved, the risk of dry eye syndrome is reduced; those patients that are symptomatic usually improve 30 days postoperatively. For symptomatic patients, treat with sodium hyaluronate eye drops.
4. Epistaxis
    a. Careful ligation of posterior nasal arteries will avoid this complication.
5. Intracranial hemorrhage
    a. Intracranial hemorrhage must be treated in conjunction with neurosurgery and the ICU.
6. ICA injury
    a. Carotid artery injury remains one of the most devastating complications in endoscopic skull base surgery. A well-defined protocol should be in place in the event of such a complication. Immediately following injury, the bleeding site should be tamponaded with focal packing if identified, and the nose should be packed bilaterally. Compression of the ICA in the neck may help to minimize blood loss. The blood bank should be mobilized, and the neurointerventionalist should be called. Hypotension should be avoided to maintain cerebral perfusion pressure. If the injury site is identified and bleeding initially controlled, repair with a crushed

muscle graft can be attempted. The patient must then be transferred to the angiography suite for possible BTO and permanent occlusion if definitive repair is still required. If BTO leads to electroencephalogram changes, stenting or a carotid bypass must be considered. For unstable patients, intraoperative angiography is an option.

Evidence-Based Medicine Question

Which is the best approach for petrous apex cholesterol granulomas?

Over the years, several authors have researched the feasibility of the EEA for drainage of cholesterol granulomas of the petrous apex. In a recent systematic review of surgical outcomes after endoscopic management of cholesterol granulomas, Eytan et al.[6] included a total of 53 patient cases from 1996 to 2013, where a symptom resolution or improvement was reported in 84.4% and 13.3% of cases, respectively, at a mean follow-up of 20 months. Recurrence rate in stent versus no stent use was also analyzed. Although the recurrence rate was higher in the nonstent group (10.7%) compared to the stent group (4.3%), the difference was not statistically significant. In the same study, the complication rate in open approaches (n = 134) ranged from 0% to 60% (mean 24.3%), where the most common was hearing loss and CSF leak; in contrast, the most common complication in the EEA group was epistaxis (13.2%). Success and complication rate, poor or inadequate reporting, and selective outcome reporting could be potential biases for their results. In addition to this, Scopel et al.[7], in an anatomic and radiologic study, showed how the EEA provided a wide surgical field with the preservation of important otologic structures. They showed how the EEA provided a large drainage window (3 times bigger) when compared to a transcanal infracochlear approach. Also, their results showed how the EEA to the petrous apex was more consistent, as it provided exposure to all the petrous ICA. As previously stated in this chapter, it is fundamental to adapt the surgical approach to the patient and not the other way around. The petrous apex is one of the least accessible areas of the skull base. Some pathology can be approached by one modality independently or by a combination of both. Each of us should critically analyze and acknowledge our own reach, limitations, and surgical skills for the benefit of our patients.

Editorial Comment

This chapter demonstrates the evolution of surgical approaches for the management of benign and malignant disease involving the petrous apex. The modern skull base surgeon must consider all approaches (transtemporal, middle fossa, and endonasal) and choose the approach that is best suited for the pathology and the patient. Close communication with colleagues in otology and neurosurgery is essential.

Although the risks and morbidity of other approaches are avoided with an endonasal approach, this approach has its own unique set of risks and morbidities. The most serious risk is injury to the ICA. Expansile lesions of the petrous apex, such as a cholesterol granuloma, provide a larger window for exposure, and the risk of carotid injury is minimal. Lesions that are less accessible require lateralization of the carotid artery or a combined medial and infrapetrous approach. With good exposure and knowledge of anatomic relationships, surgery can be safely performed in such situations. Dissection of the carotid artery is best performed by a team of skull base surgeons.

Review Questions

1. Which is the most common solid lesion of the petrous apex?

   a. Meningioma

   b. **Chondrosarcoma**

   c. Chordoma

   d. Cholesterol granuloma

2. Which of the following statements is incorrect?

   a. A clival chordoma is a destructive midline tumor centered on the clivus with high T2 signal intensity.

   b. Chondrosarcomas are seen along the lateral aspect of the clivus.

   c. Cholesterol granulomas are cystic lesions with high T1 and T2 signals.

d. **The T2 signal intensity of chondrosarcomas is low to intermediate.**

3. Which statement regarding the vidian nerve is correct?

a. The Vidian nerve is a motor nerve.

b. **The Vidian canal is located at the junction of the sphenoid floor and the medial pterygoid plate.**

c. The Vidian canal is lateral to the foramen rotundum.

d. The Vidian canal is an important landmark for the cavernous carotid artery.

Surgical Approaches to the Infratemporal Fossa

Neal M. Jackson, Meghan N. Wilson, and Daniel W. Nuss

Introduction

A variety of surgical approaches to the infratemporal fossa (ITF) have been developed to address pathologies in specific areas while attempting to preserve the function of key neurovascular structures.[1-5] Indeed, intimate knowledge of the anatomy and a multidisciplinary evaluation are of foremost importance when considering a surgical approach to this complex area. The boundaries of the ITF are shown in Table 121.1. Tumors may arise in the ITF or invade it by direct extension from surrounding structures, such as the parotid gland, the upper aerodigestive tract, the temporal bone, and the parapharyngeal space. A multidisciplinary approach, including review at a tumor conference, is important for proper evaluation and treatment, ensuring both effective treatment of disease and acceptable function and cosmesis.

Key Operative Learning Points

- The surgeon must have detailed knowledge of key structures in the ITF.
- There are a variety of approach options (open vs. endoscopic; preauricular vs. postauricular) to the ITF.
- Tumor location within ITF, benign versus malignant pathology, and the potential risk to neurovascular structures should all guide multidisciplinary treatment planning, including the choice of surgical approach.

Preoperative Period

History

History of Present Illness

1. Ask about any neurologic deficits, emphasizing dysfunction of any cranial nerves.

   a. Dysfunction of the trigeminal nerve is common for tumors in the ITF. This may present as localized numbness or dysesthesia in V1, V2, or V3 distribution and/or dysfunction of mastication, including malocclusion or deviation of the jaw due to mass effect or weakness/atrophy of the masticator muscle.

   b. Weakness of the face suggests tumor involvement either by compression or by direct invasion. However, it is important to counsel patients that intact preoperative function does not assure sparing of the nerve, and some approaches may lead to permanent weakness after manipulation or transposition of the nerve.

   c. Tumors approaching the jugular foramen may result in deficits of the lower cranial nerves (IX–XII), and tumors invading the temporal bone or posterior fossa may lead to sensorineural hearing loss and vestibular dysfunction.

   d. Patients with preoperative dysphagia and aspiration should be counseled that surgery may worsen these problems, and consideration may be given to placement of a feeding tube and/or tracheostomy.

   e. Conductive hearing loss due to unilateral Eustachian tube (ET) dysfunction with middle ear effusion may indicate compression of the ET by a tumor.

2. Ophthalmologic history is important, including any visual loss or diplopia.

Past Medical History

1. Any history of prior lesions, cancers, or other tumors in the head and

neck or distant locations is important, particularly the details of management including head and neck surgery or radiation.

2. The medical health and functional status of the patient are important, as surgery of the ITF may be a significant physiologic stress, depending on the pathology and reconstructive needs.

3. If the patient smokes, counseling and cessation are important for both perioperative healing and long-term survival.

Physical Examination

1. The infratemporal space is relatively inaccessible to direct visualization and palpation on physical examination. Subtle swelling of the temporal area above the zygomatic arch may be evident. It is essential to perform a thorough examination of the head and neck, with special attention to cranial nerve function, to assess both the tumor extent and the existing dysfunction.

2. Evaluate for trismus, as this may provide information about possible spread into the pterygoid musculature or the temporomandibular joint (TMJ). Preoperative airway planning is essential as some patients with significant trismus may need fiberoptic intubation or even tracheostomy if a major resection and reconstruction are planned.

3. Evaluate visual function and document visual acuity; evaluate hearing and document audiometric testing.

4. If considering an endonasal endoscopic approach, perform nasal endoscopy to assess the anatomy and adequacy of the surgical corridor.

Imaging

1. Because direct physical examination of the ITF is limited, radiographic imaging plays an essential role in precise tumor location and may suggest the type of pathology. Computed tomography (CT) and magnetic resonance imaging (MRI) are complementary, and often both are needed. The demonstration of bone involvement and widening of foramina is best seen on CT, while the evaluation of soft tissue planes and tumor extension along neural structures is best seen on MRI.

2. It is critical to evaluate the functional status of the internal carotid artery (ICA) and its precise anatomic relationship to tumors of the ITF as these influence the selection of the approach. If there is any concern for ICA involvement following CT and MRI imaging, a magnetic resonance angiogram (MRA) or angiogram should be considered. If intraoperative manipulation of the ICA is likely, the team should consider preoperative evaluation of collateral cerebral blood flow with a balloon occlusion test. Consultation with a Neurovascular Surgeon may be warranted if intraoperative vascular bypass is a possibility.

3. Evaluation of regional and distant metastatic disease is dictated by the histology and stage of the tumor.

TABLE 121.1

Boundaries of the Infratemporal Fossa

	Superior	Medial	Lateral	Anterior	Posterior
Bone	Temporal bone, greater wing of sphenoid	Lateral pterygoid plate, pterygopalatine fissure	Mandible, zygoma	—	Articular tubercle of the temporal bone, glenoid fossa, and condyle, styloid process
Muscle	—	Superior constrictor, pharyngobasilar fascia	Masseter, temporalis	Medial and lateral pterygoids, masseter	Prevertebral fascia
Foramina	Carotid canal, jugular foramen, foramen ovale, foramen spinosum, foramen lacerum	—	—	—	—
Nerves	Mandibular division of trigeminal nerve (V3), Part cervicalis of jugular foramen	—	—	—	CN IX, X, XI; sympathetic plexus
Arteries	Internal carotid artery	Internal maxillary artery	—	—	Internal carotid artery
Veins	Internal jugular vein	Pterygoid venous plexus	—	—	Internal jugular vein
Other	—	—	Parotid gland	—	—

Indications

1. A wide variety of conditions can affect the ITF, including benign and malignant tumors, infections that arise from the dentition, paranasal sinuses and salivary glands (which may be fungal, bacterial, or polymicrobial), and other destructive or infiltrative pathologies (e.g., fibromatosis, soft-tissue radionecrosis). Not all lesions of the ITF require surgery, and the "radicality" of surgery will be different depending on the pathology at hand. Surgery for infectious problems of the ITF is reserved for those cases in which appropriate, culture-directed antimicrobials have not resolved the problem.

2. Common neoplastic indications for ITF surgery include benign lesions, such as schwannomas, pleomorphic adenomas, vascular lesions (arteriovenous malformations, paragangliomas), and meningiomas (which may or may not have intracranial origin) and malignant tumors, such as rhabdomyosarcoma, malignant salivary tumors (from

aerodigestive tract, parotid, or microscopic minor salivary rests), and extensions of mucosal cancers from the oral cavity, sinuses, or nasopharynx.

3. Tissue biopsy with pathologic confirmation of the biologic behavior (benign vs. malignant) is necessary prior to any major extirpative surgery and may guide the degree to which aggressive measures (e.g., nerve sacrifice) are indicated. Open or transnasal endoscopic biopsy is often possible, but if the tumor is limited to a deep location, an image-guided fine-needle aspiration biopsy should be considered. Biopsies are usually not indicated for highly vascular lesions with characteristic imaging findings, such as glomus tumors. Open/invasive biopsy may be necessary to diagnose certain lesions, justified by noting that some pathologic processes (e.g., hematologic proliferative disorders, such as lymphoma, plasmacytoma, and metastasis from distant sites) will not benefit from surgical resection.

4. If imaging reveals skull base or intracranial invasion, neurosurgical consultation is essential.

5. When assessing the indications for tumor removal, also assess the medical fitness of the patient to have the surgery and the reconstructive needs and options.

Contraindications

1. Medical comorbidities with a high risk for general anesthesia

2. ICA involvement with failed balloon occlusion test

3. Extensive invasion of brain parenchyma by a malignant lesion

4. Lesions whose biologic behavior deems them not to be appropriate for surgical therapy (e.g., lymphoma, plasmacytoma)

Preoperative Preparation

1. Depending on the approach, image-guided navigation based on high-resolution, thin-cut CT images and/or MRI may be used to assist with the confirmation of anatomic landmarks and tumor boundaries and may assist in planning the surgical trajectory.

2. Blood products should be available, especially for highly vascular lesions, as the internal maxillary artery traverses the ITF, and the ICA is in close proximity. Preoperative embolization of the internal maxillary artery may be considered to minimize blood loss, although this may compromise reconstructive options.

3. If a large defect is anticipated after extirpation, preoperative consultation with a microvascular reconstructive surgeon is essential. Additional testing (Allen's test, vascular studies) may be necessary.

4. A lumbar drain should be inserted if a significant intradural dissection with risk of cerebrospinal fluid (CSF) leak is anticipated.

Operative Period

Anesthesia

1. General anesthesia is required. Preoperative evaluation of the airway is critically important to the safe induction of anesthesia. Depending on the patient, traditional induction and laryngeal exposure may be possible. In patients with trismus, preoperative aerodigestive abnormalities, or anticipated postoperative airway compromise, fiberoptic intubation or tracheostomy may be necessary.

2. If neurophysiologic monitoring will be performed, it is important to communicate with the anesthesia team regarding the need for avoidance of paralytic agents.

Positioning

1. The patient should be positioned supine. The head should be supported on an appropriate head holder or in Mayfield pins if intracranial neurovascular work is anticipated, depending on the needs of resection and the preference of the Otolaryngologist and Neurosurgeon.

2. Access to the neck for vascular control is important if the ICA/internal jugular vein (IJV) are at risk.

Perioperative Antibiotic Prophylaxis

1. Antibiotic prophylaxis should provide coverage against flora of the skin and upper aerodigestive tract. If intracranial surgery is anticipated, the use of an antibiotic with good penetration of the blood–brain barrier should be considered. Our patients without drug allergies receive intravenous cefazolin and metronidazole.

Monitoring

1. Facial nerve electromyography (EMG) is helpful for all preauricular and postauricular approaches.

2. Select cranial nerve monitoring (e.g., vagus nerve via laryngeal EMG endotracheal tube) is indicated in some cases.

Instruments and Equipment to Have Available

Open Approaches

1. Rainey clips

2. Drill, saw, osteotome

3. Midface/cranial plating system

4. Vascular instrument set if the carotid artery is at risk

5. Head and neck surgical set

Endoscopic Approaches

1. Stereotactic navigation system (recommended)

2. Standard O-degree and angled endoscopes, endoscopic sinus surgery instruments, and video camera with monitor

3. Endoscopic bipolar and suction monopolar electrocautery

4. Vascular clip appliers

5. High-speed surgical drill with extended-tip burs to reach depth of surgery

6. Cottonoid pledgets and additional hemostatic agents including absorbable gelatin sponge (Gelfoam) with thrombin, oxidized regenerated cellulose (Surgicel), or Floseal (or comparable hemostatic gelatin/thrombin matrix)

Key Anatomic Landmarks

Preauricular Subtemporal Infratemporal Approach

1. Frontal (temporal) branch of the facial nerve (See Table 121.1): During elevation of the scalp flap, one must incise to the deep temporalis fascia at a level above the superior orbital rim and follow this plane inferiorly to prevent injury to this nerve (Fig. 121.1D).

2. Main trunk of facial nerve (as in standard parotidectomy)

3. Vascular anatomy, including the internal maxillary artery and the carotid artery

4. Lower cranial nerves IX–XII

5. The lateral pterygoid plate can be followed posteriorly to identify the foramen ovale, foramen spinosum, and the spine of the sphenoid bone. These structures are valuable landmarks for guiding the surgeon to V3, middle meningeal artery, and carotid canal, respectively.

Postauricular (Transtemporal) Approach

1. Spine of Henle for mastoidectomy (See Table 121.1)

2. Facial nerve through intratemporal course and at stylomastoid foramen

3. Bony-cartilaginous junction of external auditory canal (EAC) (if EAC is to be closed permanently)

4. Vascular structures (common, internal, and external carotid arteries; IJV) are identified in the neck.

5. CN X, XI, and XII are identified in the neck.

Prerequisite Skills

For open approaches, proficiency with the following skills is necessary:

1. Bicoronal scalp incision and flap elevation

2. Parotidectomy and facial nerve dissection

3. Craniomaxillofacial plating

4. Harvest of abdominal adipose tissue

5. Otomicroscopy with standard microsurgical temporal bone dissection

6. Ligation of great vessels at the skull base or inferiorly in the neck

Endonasal Endoscopic Approach

1. Extended maxillary antrostomy and visualization of the orbital floor

2. Exposure of Sphenopalatine artery (SPA), internal maxillary artery, and V2 nerve branches after removal of the posterior wall of the maxillary sinus

For endoscopic approaches, proficiency with the following skills is necessary:

1. Advanced endoscopic sinus surgery including functional endoscopic surgery of the maxillary, ethmoid, and sphenoid sinuses

2. Septoplasty, if needed for access

3. Endoscopic medial maxillectomy and/or Caldwell-Luc approach

4. Endoscopic vessel control and ligation

5. Endoscopic and/or open reconstruction techniques including nasoseptal flap, free grafts, and temporalis muscle flap

Operative Risks

1. Temporary or permanent dysfunction of cranial nerves

2. CSF leak

3. Injury to the orbit

4. ICA injury or other vascular injury with resultant cerebrovascular accident, death

Surgical Technique

Preauricular Approach (Infratemporal Subtemporal Approach)

- This approach is suitable for many tumors arising in the ITF and intracranial tumors that arise in the greater wing of the sphenoid or anterior temporal bone (see Fig. 121.1)[1,2].
- It does not allow safe resection of the entire temporal bone or control of the infratemporal facial nerve or jugular bulb.

Steps

1. Make a hemicoronal or bicoronal incision across the vertex of the scalp. Ipsilateral preauricular incision is extended inferiorly. The scalp incision can be extended contralaterally to enable broader rotation of the flap (see Fig. 121.1A–D).

2. Extend the incision through the subcutaneous tissue, galea, and pericranium, and elevate the flap anteriorly in a subpericranial plane. Raney clips can be applied to the edges of the scalp to decrease bleeding according to the surgeon's preference. Preserve the anterior branches of the superficial temporal artery, as these supply the frontal scalp flap.

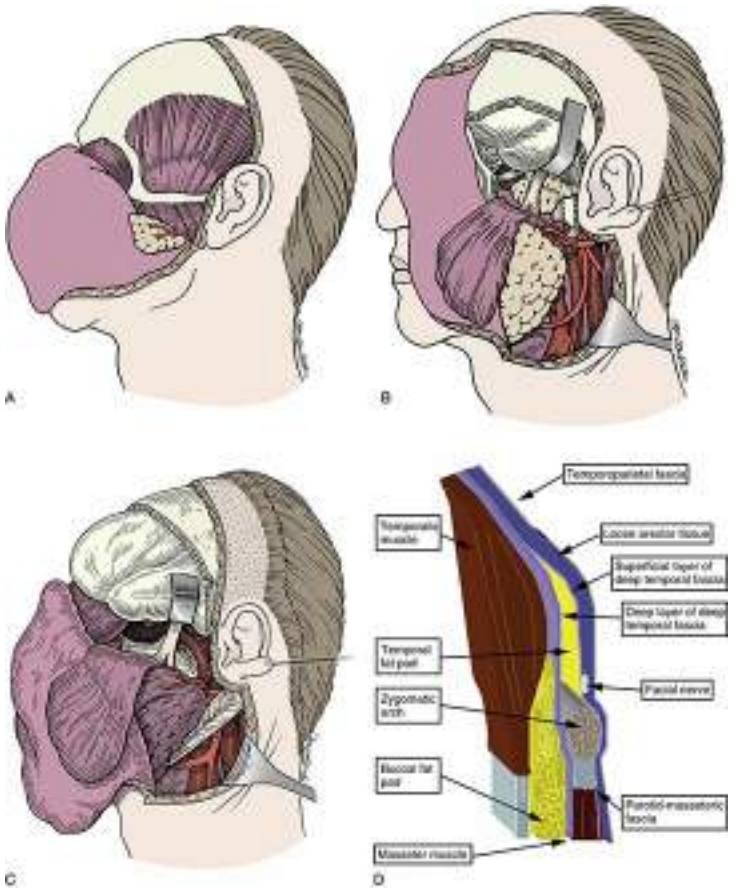

FIG. 121.1 Preauricular subtemporal infratemporal approach.

A, Bicoronal incision extended preauricularly reveals temporalis muscle and orbitozygomatic (OZ) bone. The facial nerve can be identified entering the parotid tissue in the standard parotidectomy technique. **B,** The reflection of the temporalis muscle anteriorly, the removal of the OZ bone, and temporal craniotomy enhance superior access, while extension of the incision into the mid-neck allows the dissection to reach the internal jugular vein, hypoglossal nerve, and internal carotid artery. Under the brain retractor, a beige-colored tumor is seen deep to V3. **C,** Further dissection reveals the petrous carotid (visualized just left of the auricle from this perspective) passing behind V3. The two cut ends of the transected V2 are seen. **D,** The coronal cut-through view of the temporal region. The temporal adipose tissue pad lies between the two layers of the deep temporal fascia. Note the temporal branch of the facial nerve,

which lies in the superficial layer of the deep temporal fascia. From: Carrau R, Vescan A, Snyderman C, Kassam A: Surgical approaches to the infratemporal fossa. In: Myers EU (ed). Operative Otolaryngology: Head and Neck Surgery, 2nd ed. Philadelphia: Saunders Elsevier; 2008, specific figures: Figure 101-106, Figure 101-120, Figure 101-121, Figure 101-105.

3. As the temporalis muscle is exposed from posterior to anterior, an incision is made in the superficial layer of the deep temporal fascia (the *interfascial incision)* to deepen the plane of dissection to include and elevate the temporal adipose tissue pad.

4. Further dissection anteriorly-inferiorly should proceed deep to this adipose tissue pad in order to protect the frontal branch of the facial nerve, which runs in the superficial layer of the deep temporal fascia (see Fig. 121.1D).

5. The temporal adipose tissue pad and superficial layer of fascia are reflected anteriorly with the scalp flap until the orbitozygomatic (OZ) complex is exposed sub-periosteally.

6. To access the anatomy deep to the OZ complex, first elevate the periosteum off both sides of the zygoma and elevate the periorbita from the lateral orbit to expose the area from the orbital roof to the inferior orbital fissure. A reciprocating saw is used to make beveled cuts at the root of the zygoma, zygomaticofrontal suture, and zygomaticomaxillary buttress to free the OZ bone segment. The bone is saved in saline for later reattachment with plating. Many advocate prebending and drilling screw holes before detachment to facilitate replacement and securing of the graft at the end of the procedure.

7. Identify and preserve the main trunk of the facial nerve with a standard parotidectomy technique. Other soft tissue structures anterior to the temporal bone can be transected to increase the rotation of the flap for better exposure.

8. The temporalis muscle is elevated off the temporal fossa, still attached at its inferior pedicle. (The temporalis is supplied by deep temporal artery branches of the internal maxillary artery on its deep surface near the attachment to the coronoid process of the mandible. Care is taken to preserve these vessels.) If it will be reattached, leave a rim of fascia on the

cranium at the superior attachment of the temporalis muscle for suturing during closure.

9. The ITF is now exposed, and resection of the tumor can begin.

A subtemporal craniectomy can be performed to aid in the identification and exposure of the foramina.

10. If access to the petrous portion of the ICA is required, the glenoid fossa must be accessed by either dislocating or resecting the condyle of the mandible. A temporal craniotomy may be needed for exposure of the superior aspect of the glenoid fossa. Remember, the ICA is located medial to the glenoid fossa (see Fig. 121.1C).

11. Closure must ensure that dead space is obliterated and there is no communication to the aerodigestive tract. The temporalis muscle, either in full or its anterior portion, may be transposed into the defect. If a portion of the temporalis muscle remains free, it should be placed in the anterior temporal defect to preserve cosmesis.

12. The OZ bone complex is now reattached with a midface plating system.

13. Free tissue transfer with microvascular anastomosis may be required if the temporalis muscle is not viable or if there is a large defect, such as when maxillectomy with or without orbital exenteration is performed in conjunction with the ITF resection.

14. Standard closure of soft tissue is performed. A suction drain is left in place under the scalp flap.

Other Considerations

In children, the distance from the mandibular body to the infratemporal skull base is less than in adults, and the infratemporal skull base can sometimes be adequately exposed using a transcervical approach with identification and preservation of the facial nerve.

Postauricular (Transtemporal) Approach

- Suitable for lesions involving the temporal bone primarily but extending into the ITF (see Fig. 121.2)[1,2]

Steps

1. A C-shaped or question-mark-shaped postauricular incision is started superiorly in the temporal area, brought over the mastoid region, and extended inferiorly into a natural crease in the mid-neck to allow access to the great vessels and lower cranial nerves.

2. The EAC may be transected and sewn closed (as depicted in Fig. 121.2A) if pathology dictates sacrifice of the middle ear and there is risk of CSF leak. Otherwise, the auricle may be reflected anteriorly, and incisions around the tragus and conchal bowl will allow anterior rotation of the auricle and preauricular tissues while leaving the EAC on the temporal bone. These incisions will facilitate closure of the soft tissue without incisions in the EAC that risk canal stenosis.

3. The cervicofacial flap is elevated in a subplatysmal plane in the cervical area, superficial to the superficial muscular aponeurotic system (SMAS) over the parotid and along the deep layer of the deep temporal fascia over the cranium. The cervicofacial flap can then be reflected anteriorly.

4. The main trunk of the facial nerve is identified by standard parotidectomy methods. It is advisable to leave a cuff of soft tissue around the facial nerve to minimize direct traction on the nerve. Parotid tissue may be resected if needed for exposure or if dictated by a malignant epithelial parotid pathology.

5. Mastoidectomy and dissection of the intratemporal facial nerve can allow mobilization of the nerve for wider access to the ITF, the jugular bulb, and the lower cranial nerves.

6. Attention is directed next at the midlevel of the neck to obtain vascular control of the common, internal, and external carotid arteries and IJV.

7. The sternocleidomastoid muscle and posterior belly of the digastric muscle are separated from the mastoid bone.

8. The styloid process is identified by palpation, the stylohyoid and stylopharyngeus muscles are transected, and the styloid process is removed. CN IX may now be subtly visible crossing over the exposed ICA.

9. Temporal craniotomy and OZ osteotomy can be performed as described previously, exposing the rest of the infratemporal skull base (see Fig. 121.2B).

10. Tumor removal as dictated by tumor borders can then proceed with reconstruction as described in the previous section.

Fisch Lateral Infratemporal Fossa Approaches

Professor Ugo Fisch described multiple transtemporal approaches (types A–C) that focus on drilling through the temporal bone and re-routing the intratemporal facial nerve for enhanced subtemporal dural exposure (See Fig. 121.3)[3]. These three approaches were primarily otologic, microsurgical procedures for which detailed descriptions can be found in otologic texts. Their general uses are as follows:

Fisch type A is often used for glomus jugulare surgery or other tumors limited to the middle ear cleft. Type B includes reflection of the zygomatic arch and temporalis muscle inferiorly, extensive temporal bone dissection (referred to as a subtotal petrosectomy), and disarticulation of the TMJ to provide complete exposure of the ICA and foramen ovale.

Type C extends type B by resection of the pterygoid plates to provide access to the ET orifice, nasopharynx, and posterior maxillary sinus. A later "type D" described a modification, which is essentially a preauricular approach that does not remove middle ear/ET structures, reroute the facial nerve, or fully expose the ICA.

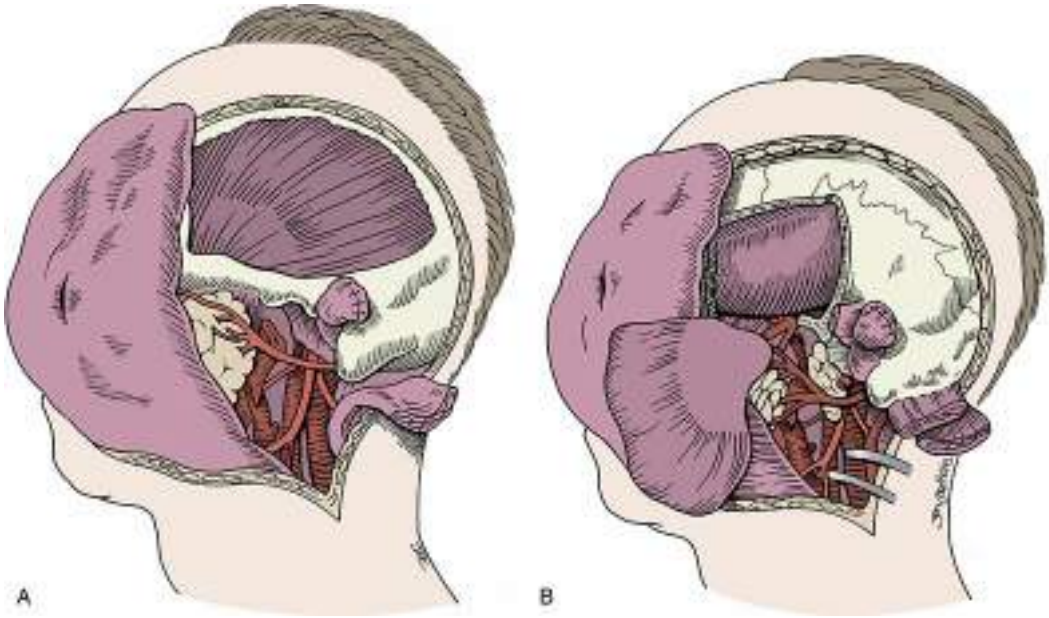

FIG. 121.2 Postauricular approach to allow temporal bone dissection.

A, The cervicofacial flap has been reflected forward to expose the temporalis muscle, the orbitozygomatic (OZ) bone, the closed external auditory canal, the main trunk of facial nerve entering parotid gland, the hypoglossal nerve, and the great vessels (deep). **B,** The temporalis muscle has been reflected forward, the OZ bone removed, and the temporal bone craniotomy reveals the extent of the approach to the infratemporal fossa. From: Carrau R, Vescan A, Snyderman C, et al. Surgical approaches to the infratemporal fossa. In: Myers EU (ed). Operative Otolaryngology/Head and Neck Surgery. 2nd ed. Philadelphia: Saunders Elsevier; 2008, specific figures: Figure 101-133, Figure 101-135.

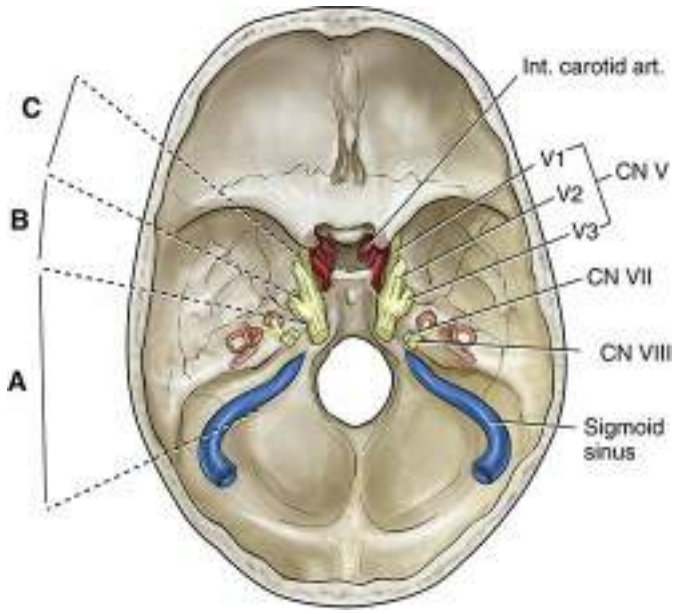

FIG. 121.3 Diagrammatic representation of Fisch infratemporal approaches, showing the approximate degree of cranial base access each provides. See text for details. From Persky M, Manolidis S. Vascular tumors of the head and neck. In: Johnson J, Rosen C (eds). Bailey's Head and Neck Surgery—Otolaryngology, 5th ed, Chapter 127, Philadelphia: Lippincott Wolters Kluwer; 2014.

Facial Translocation Approach

This is the dedicated topic of Chapter 44 and will only briefly be discussed here. This approach is generally reserved for very extensive lesions of the ITF, masticator space, pterygomaxillary fossa, and paraclival region and certain tumors of the nasopharynx extending into the ITF (See Fig. 121.4)[4].

Steps

1. Hemicoronal incision with preauricular extension is made on the affected side. The elevation of the scalp proceeds as described in the preauricular approach section (see Fig. 121.4A).

2. A modified Weber-Ferguson incision is made and extended down to the periosteum; lip-split is not usually needed but may be added to provide access.

3. A horizontal incision connects the previous two incisions, extending

from the lateral canthus aspect of the Weber-Ferguson incision posteriorly to the preauricular/scalp incision at the superior attachment of the auricle.

4. In making this incision, frontal branches of the facial nerve will be identified, tagged, and transected. EMG stimulation/monitoring is helpful in this pursuit. These nerves will be reapproximated at the end of the case.

5. The middle and lower face flap is reflected inferiorly.

6. The infraorbital nerve (V2) is transected and tagged. If not involved in the tumor, it can be reapproximated at the end of the procedure.

7. The frontotemporal scalp flap is elevated in a subpericranial plane as previously described, and the OZ osteotomies are performed (see Fig. 121.4B). In addition, unilateral maxillary Le Fort I or II osteotomies are completed as needed to free the anterior face of the maxilla with the OZ complex (see Fig. 121.4C and D).

8. The temporalis muscle is reflected inferiorly. Osteotomy of the coronoid process can be performed to increase the arc of rotation, taking care to protect the nearby deep temporal arteries.

9. At this juncture, the anterior, medial, and lateral boundaries of the ITF should be completely exposed, and tumor removal can proceed. If further access to the medial ITF or nasopharynx is needed, the pterygoid plates can be removed.

10. If intracranial access is needed, a temporal/subtemporal craniotomy can be performed (see Fig. 121.4E).

11. For reconstruction, the temporalis muscle may be used to obliterate the defect (see Fig. 121.4F), versus additional free tissue transfer.

12. A temporary tarsorrhaphy for 10–14 days may be placed to prevent lower lid ectropion.

13. Soft tissue is carefully closed in layers. If the lacrimal system was transected, the lacrimal canaliculi should be stented with silicone stents secured in the nasal cavity.

Endoscopic Endonasal Approaches

This minimally invasive technique may be used for biopsy and/or resection of tumors in the medial ITF (see Fig. 121.5A-H)[5].

We use 3D stereotactic navigation based on thin-cut CT images obtained immediately prior to surgery.

Steps

1. After the face is prepped with betadine solution (with the eyes lubricated but accessible for monitoring of the pupils and globes), the nasal cavity is prepared with pledgets saturated with a topical decongestant.

2. The navigation system is calibrated using reliable external surface anatomy.

3. The endoscopic procedure is begun with bilateral diagnostic endoscopy. Lidocaine with epinephrine can be injected at this time to minimize bleeding. If a septal deviation impairs surgical access to the ITF, a septoplasty can be performed first.

4. A generously wide maxillary antrostomy is created endoscopically to access the posterior wall of the maxillary sinus, which is then gently removed to reveal the pterygomaxillary fissure.

5. The sphenopalatine artery is then identified and ligated with either a vascular clip or bipolar cautery. Dissection continues to the pterygopalatine fossa.

6. The mandibular division of the trigeminal nerve (V3) is the next key structure to identify, and stereotactic navigation is helpful in identifying its neural foramen (ovale) and in navigating to the lesion in a safe, precise way.

7. If additional lateral exposure or better 3D access is needed, consider a traditional, sublabial Caldwell-Luc antrostomy.

8. Removal of the posterior portion of the inferior turbinate or medial maxillectomy may provide additional visual access or space for instrumentation.

9. Dissection can proceed posteriorly to the pterygoid plates and the ET.

Common Errors in Technique

- Adequate exposure is essential in both open and endoscopic techniques.
- Careful attention to tissue planes while elevating the flap is essential to prevent inadvertent injury to the branches of the cranial nerves (e.g., frontal branch of the facial nerve).
- Preservation of reconstructive tissues and their blood supply during exposure is important to maintain reconstructive options.
- Similarly, careful attention to re-establishing these tissue planes in reconstruction is essential for restoring form and function.
- Vascular control is essential in all cases.

Postoperative Period

Postoperative Management

Monitoring in an intensive care unit is recommended for at least the night following surgery due to the proximity of dissection to the skull base and neurovascular and intracranial structures.

In all open approaches, the facial nerve is at risk, and postoperative surveillance of the nerve function is essential. If volitional eye closure is incomplete (lagophthalmos), keratoconjuntivitis and even blindness may occur. Moisturization techniques including lubrication, humidity chambers, and taping of the eyelids should be initiated as needed. Tarsorrhaphy or gold/platinum weight placement also may be considered in these patients to prevent chronic exposure.

In endoscopic techniques, patients should be monitored for epistaxis, and nasal bleeding should be evaluated carefully to rule out bleeding from the internal maxillary artery or its branches. Consideration should be given to packing the nasal cavity to reduce the risk of epistaxis and to stabilize any endoscopically placed tissue grafts if used.

In open or endoscopic approaches in which the dura is opened, early recognition of CSF leak is important. Lumbar drainage or re-operation may be indicated.

Complications

- A significant morbidity relates to dysfunction of the trigeminal nerve. Sacrifice of V2 and/or V3 may be required for tumor resection; facial anesthesia puts the patient at risk for self-injury, especially when chewing food and shaving. V1 anesthesia carries a high risk of corneal ulcer and must be managed aggressively. Loss of V3 motor function will lead to malocclusion and mandibular drift but usually does not negatively affect the diet unless numbness is also present.
- Injury to the main trunk of the facial nerve may be caused by transection or excessive traction. It is essential to protect the eye from exposure keratitis in these cases to prevent further morbidity.
- Trismus is common postoperatively, both immediately due to pain and chronically due to pterygoid musculature scarring/fibrosis. Patients should regularly perform jaw-opening exercises to prevent permanent trismus.
- Vascular complications can be severe, especially during or following dissection along the ICA. Bleeding is a risk and can be challenging to control. In cases of ICA injury, ischemic brain injury is possible even with a satisfactory preoperative balloon occlusion test. These patients must be managed diligently to minimize complications.
- Dissection in proximity to the dura places the patient at risk of immediate or delayed postoperative CSF leak.
- Cosmetic deformities may arise even with careful planning of incisions and reconstruction. If the temporalis muscle is sacrificed or transposed, this leads to a depression in the temple that should be reconstructed

with a free graft or implant at the time of surgery or at a later date.

Alternate Management Plan

Some neoplasms in this area are susceptible to treatment with external beam radiation with or without chemotherapy. Discussion at a multidisciplinary tumor board will assist in deciding the best and alternate treatment plans.

Discussion

We emphasize that every patient with a lesion involving the ITF deserves an individualized and comprehensive evaluation by a multidisciplinary team, as the biologic behavior and precise extent of the tumor determine the appropriate management. Unless the imaging and clinical picture are pathognomonic (as in glomus tumor cases), it is imperative to attempt to obtain a biopsy-proven pathologic diagnosis prior to undertaking major open or endoscopic surgery.

Evidence-Based Medicine Question

What is the optimal surgical treatment of schwannomas in the infratemporal and parapharyngeal space?

Schwannomas are some of the most common tumors affecting the ITF and parapharyngeal space (PPS). Historically there have been varied philosophies of how schwannomas should be resected; these range from radical resection (of the tumor and the nerve of origin) to partial resection and nerve-sparing techniques. Intuitively, radical resection would seem to have the advantage of a lower likelihood of tumor recurrence but often leads to major morbidity, especially when the nerve of origin is functionally complex, as in the case of the high vagus nerve, the facial nerve, or the trigeminal nerve.

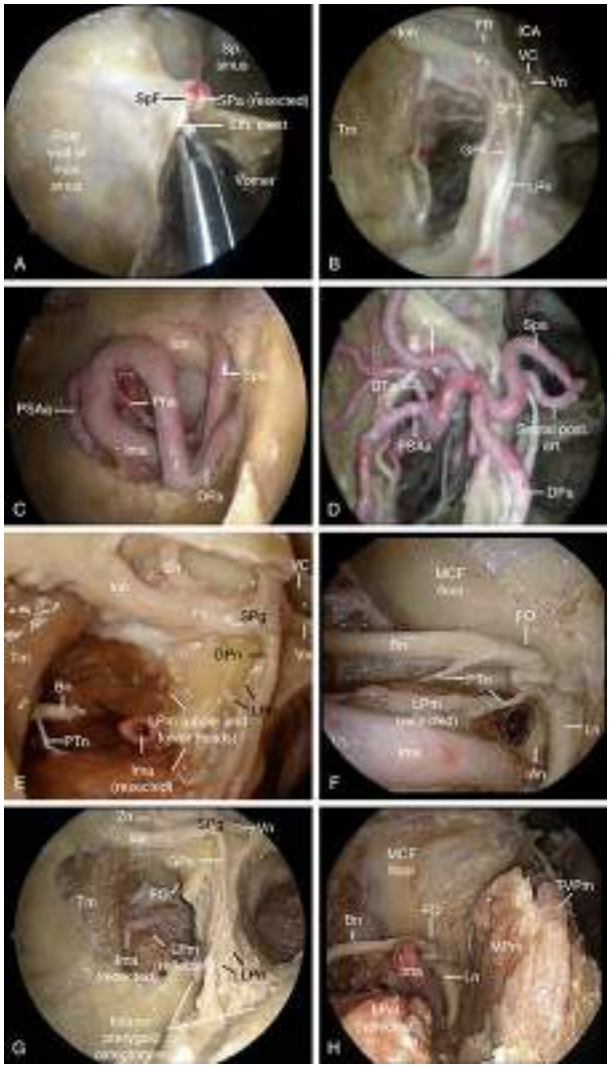

FIG. 121.5 Endoscopic endonasal approach to the infratemporal fossa *(right side)*.

A, The posterior wall of the maxillary sinus and sphenopalatine foramen (SpF) seen after wide antrostomy. The resected sphenopalatine artery is also visualized. **B,** View of the infratemporal fossa (ITF) after removal of the internal maxillary artery and branches. **C,** After removal of the posterior wall of the maxillary sinus, the pterygopalatine fossa is viewed with prominent blood vessels. **D,** The view of the distal third of the internal maxillary artery branches seen after further removal of bone and fat. **E,** The right ITF seen with the transected internal maxillary artery as well as the upper and lower heads of the lateral pterygoid muscles. **F,** V3 is seen exiting from foramen ovale and dividing into the lingual

nerve, the inferior alveolar nerve, the buccal nerve, and the lateral pterygoid nerves. The internal maxillary artery is prominently seen. **G,** The view from the nasal cavity into the ITF is enhanced with the removal of the pterygoid plates and the reflection of the lateral pterygoid muscles. **H,** The perspective with the endoscope in ITF showing the transected internal maxillary artery, V3 exiting the foramen ovale with early branching of the buccal nerve and the lingual nerve. Reproduced from Falcon RT, Rivera-Serrano CM, Miranda JF, et al. Endoscopic endonasal dissection of the infratemporal fossa. Anatomic relationships and importance of eustachian tube in the endoscopic skull base surgery. Laryngoscope, 2011 121:31–41. http://dx.doi.org/10.1002/lary.21341. This composite figure, labeled A–H, is borrowed from the following eight figures: Figure 2A, Figure 2B, Figure 3A, Figure 3B, Figure 6A, Figure 6B, Figure 7A, Figure 7B.

Netterville and Groom[6] reviewed their experience with 43 schwannomas, including cervical and parapharyngeal tumors, and reported improved outcomes using a "function-sparing intracapsular enucleation" technique.

The technique involved enucleation of bulky tumors, with sparing of the functionally significant portions of the involved nerve. This was accomplished using EMG in cases of vagal tumors. In such cases, careful

EMG mapping allowed the sparing of functionally significant fibers, which were often located near the surface of the tumors, while still achieving adequate resection. The majority of those patients had normal or nearly normal voice outcomes, and no recurrences were observed with 36 months of follow-up. The authors advocated this technique for cervical plexus schwannomas as well.

The authors concluded that "intracapsular enucleation of cervical schwannomas appears to be an effective long-term oncologic treatment while providing significant improvement in functional outcomes. Neural monitoring of motor function provides guidance in neural mapping of the location of the motor nerve fibers on the surface of the tumor. This provides further accuracy in preventing injury to the primary nerve during enucleation. One should consider function-sparing intracapsular enucleation as the treatment of choice for cervical schwannomas in which the primary nerve of origin still has significant neural function."

Whether this approach can be extrapolated, with comparable outcomes, to patients who have high infratemporal or parapharyngeal schwannomas is unclear, but the argument for function-sparing is compelling. Additional considerations for decision making in schwannoma treatment have been summarized by other authors.[7]

Editorial Comment

This chapter captures the complexity and variety of approaches to the ITF. As with most complex areas, there is no single best approach; therefore, a combination of approaches may provide the best exposure with the least morbidity. Although some of these approaches are less familiar, surgeons should be aware of all approaches and be prepared to enlist other surgeons with complementary expertise. The development of endoscopic techniques has had a major positive impact on the management of tumors in the ITF and allows histologic confirmation of most tumors before planning a major operation.

Carl H. Snyderman

Review Questions

1. Which of the following structures is in the ITF?

   a. V2

   b. V3

   c. Internal carotid artery

   d. All of the above

   e. **b and c only**

2. Which of the following are important considerations in choosing a surgical approach to the ITF?

   a. Exact location of the tumor

   b. Involvement of the internal carotid artery

   c. Involvement or dysfunction of cranial nerves V, VII, IX–XII

   d. Biologic behavior of the tumor

   e. **All of the above**

3. You have just taken down the posterior wall of the maxillary sinus. What space is now exposed and which important vascular structure should be identified next?

   a. ITF, anterior ethmoid artery

   b. ITF, sphenopalatine artery

   c. Pterygopalatine fossa, anterior ethmoid artery

   d. **Pterygomaxillary fissure, sphenopalatine artery**

   e. ITF, internal maxillary artery

Juvenile Angiofibroma

Carl H. Snyderman, Harshita Pant, and Paul A. Gardner

Introduction

Juvenile angiofibroma (JNA) is a rare, benign tumor that is found almost exclusively in adolescent males.[1] The pathogenesis of JNA remains undefined, although hormonal and genetic factors have been implicated. JNA arises in the lateral nasopharynx near the sphenopalatine foramen and can spread in multiple directions to the nasal cavity, oropharynx, paranasal sinuses, orbit (via inferior orbital fissure), and infratemporal fossa (via pterygomaxillary fissure). Intracranial extension occurs through the skull base foramina and by the erosion of bone. Early symptoms include unilateral nasal obstruction and recurrent unilateral epistaxis. Large tumors can displace normal structures, resulting in facial swelling, proptosis, diplopia, visual loss, and facial hypesthesia. The primary treatment is surgical excision, with endoscopic surgery replacing open approaches for most tumors. The greatest challenge in surgery is bleeding caused by the hypervascular nature of JNA. Treatment options for recurrent tumor include surgery or radiation therapy (RT).

Key Operative Learning Points

- Unilateral nasal obstruction and recurrent epistaxis in an adolescent male is suggestive of angiofibroma.
- Diagnosis can be established radiographically without biopsy in most cases.
- Staging and surgical planning should consider residual vascularity following embolization.
- Preoperative embolization of the tumor's blood supply reduces

intraoperative bleeding.

- The base of the pterygoid plate is a frequent site of recurrence and should be drilled to remove all remnants of the tumor.
- An anterior endoscopic approach can be augmented with a transmaxillary approach.
- A lateral infratemporal approach can be combined with an anterior approach to provide access to the middle cranial fossa.
- Large tumors should be divided into vascular segments and may require multiple staged surgeries.
- Residual tumor on follow-up scans should be observed for growth; not all residual tumors require additional treatment.

Preoperative Period

History

- Nasal obstruction (unilateral or bilateral)
- Recurrent epistaxis
- Facial swelling
- Diplopia
- Numbness of the face (V2 distribution)
- Pain in the face/sinus pressure
- Hearing loss.

Physical Examination

- Nasal endoscopy: reddish, smooth lobulated mass occupying the posterior nasal cavity
- Swelling of the cheek or temporal area
- Proptosis or displacement of the globe

- Middle ear effusion with conductive hearing loss
- Hypesthesia of the maxillary division of the trigeminal nerve.

Imaging

- Computed tomography (CT) with contrast (Fig. 122.1)

  CT is the preferred initial imaging modality since it demonstrates the vascular nature of the tumor and the bony architecture of the sinuses, orbit, and skull base. A characteristic feature of JNA is widening of the pterygopalatine space with remodeling of the posterior wall of the maxillary sinus. For surgical planning, a CT angiogram is obtained (skull base protocol with navigation protocol) for demonstration of the carotid artery and bony landmarks.

- Magnetic resonance imaging (MRI) (Fig. 122.2)

  MRI shows the interface of tumor with soft tissues (orbit, masticator space, dura) when there is bony erosion or extension of the tumor through the foramina. It can also differentiate the tumor from obstruction of a sinus with retained secretions. Without MRI, CT can be misleading, suggesting an aggressive neoplasm, such as a sarcoma.

- Angiography

  Angiography is not necessary in most cases but helps to confirm the diagnosis (characteristic hypervascularity of JNA) and demonstrates the blood supply of the tumor. The blood supply is usually derived from branches of the external carotid artery (internal maxillary and ascending pharyngeal arteries) and is often bilateral in larger tumors. Advanced tumors also receive blood supply from the internal carotid artery (ICA) via the vidian artery and cavernous branches (Fig. 122.3). For advanced tumors with skull base involvement and proximity to the ICA, angiography is important to assess collateral intracranial circulation (competency of the circle of Willis).

FIG. 122.1 Computed tomography (CT) scan of juvenile angiofibroma (JNA) (UPMC stage V) demonstrates bony erosion with extension of tumor to the orbits and cranial cavity. CT is superior for the visualization of bone and for estimating the vascularity of the tumor.

Indications

- Surgery is the treatment of choice for all JNA, even advanced tumors with intracranial extension.

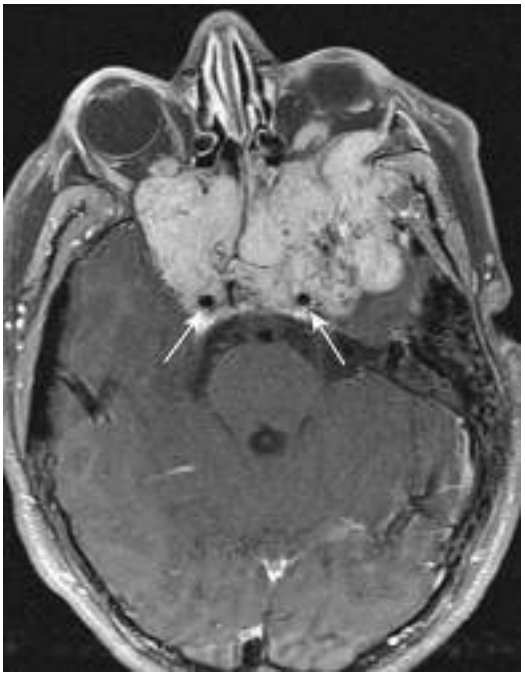

FIG. 122.2 Magnetic resonance imaging (MRI) of juvenile angiofibroma (JNA) (UPMC stage V) is superior for the interface of the tumor with soft tissue planes. The internal carotid arteries *(arrows)* and tumor vasculature appear as flow voids.

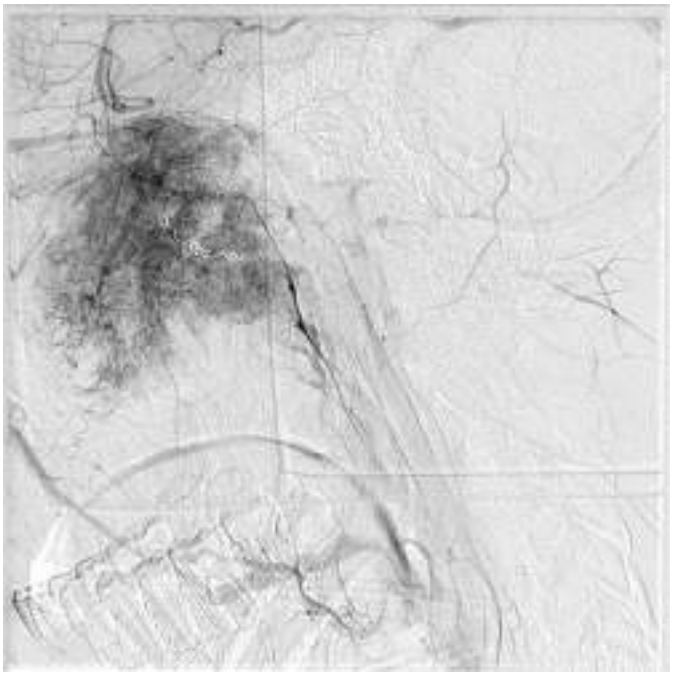

FIG. 122.3 Angiography demonstrates a large amount of

residual vascularity from the internal carotid artery following embolization of the internal maxillary artery (see coils in proximal trunk).

Contraindications

- Residual or recurrent tumor that is not growing can be observed.
- A prohibition against blood products (Jehovah's Witness) is a relative contraindication for an advanced tumor with residual vascularity following embolization.
- Medical condition that precludes surgery.

Preoperative Preparation

- Biopsy

  Histologic confirmation is not necessary unless there are atypical radiological features suggestive of malignancy (sarcoma). If a biopsy is necessary, it should be performed under general anesthesia with control of the airway.

- Embolization of the tumor

  Bilateral angiography is performed the day before surgery to identify and embolize the blood supply to the tumor. We prefer to use Onyx due to its superior penetration of tissues.[2] Coils are placed in the proximal internal maxillary arteries. For small tumors, an alternative to embolization is surgical ligation of the internal maxillary artery lateral to the tumor margin at the beginning of the operation.

- Staging

  A variety of staging systems have been proposed over the years for JNA. Only one staging system considers the vascularity of the tumor (University of Pittsburgh Medical Center (UPMC) staging system).[3,4] There are five stages based on tumor extent and residual vascularity following the embolization of blood supply from the external carotid artery (Table 122.1). Bleeding from the tumor is the greatest risk factor for complications during surgery, and the UPMC staging system provides superior prediction of intraoperative blood loss and risk of

residual/recurrent tumor.

- Balloon test occlusion of ICA

  If there is tumor encasement of the ICA, assessment of the adequacy of collateral circulation can be done with balloon test occlusion with neurological monitoring. This knowledge can guide the management of the patient in case there is injury to the ICA during surgery. Fortunately, most young patients can tolerate sacrifice of the ICA if necessary.

- Perioperative blood loss

  Despite adequate embolization, packed red blood cells should be available for transfusion. If desired, directed donors can be used for homologous transfusions. In older patients, surgery can be delayed for several weeks to allow banking of autologous blood for transfusion. When a large amount of blood loss is anticipated, a cell-saver device may be used to recycle the patient's own blood collected during surgery.

Operative Period

Anesthesia

- General anesthesia with oral intubation.

Positioning

- Supine
- Mayfield headholder

  If intraoperative navigation is used for skull base involvement, the head can be fixed in a Mayfield head holder to maintain accuracy of navigation, to stabilize the head for the drilling of bone, and to improve positioning.

Perioperative Antibiotic Prophylaxis

- Second-generation cephalosporin
- Third-generation cephalosporin if there is a risk of opening the dura.

TABLE 122.1

UPMC Staging System for Juvenile Nasopharyngeal Angiofibroma

Stage	UPMC Staging System
I	Nasal cavity, medial pterygopalatine fossa
II	Paranasal sinuses, lateral pterygopalatine fossa No residual vascularity
III	Skull base erosion, orbit, infratemporal fossa No residual vascularity
IV	Skull base erosion, orbit, infratemporal fossa Residual vascularity
V	Intracranial extension, residual vascularity M: medial extension L: lateral extension

Monitoring

- Somatosensory evoked potentials (SSEPs)

  SSEPs provide a measure of cortical function and are a sensitive indicator of ischemia due to changes in blood pressure. SSEPs are measured when dissection of the ICA is anticipated.

- Electromyography (EMG)

  EMG of the cranial nerves, most commonly III, IV, VI, and V_3, aids in identification and preservation of function.

Instruments and Equipment to Have Available

- Endoscopic sinus surgery set
- Maxillofacial instruments for transmaxillary approach
- Doppler probe for identification of ICA

- Nerve stimulator for EMG
- Endoscopic bipolar electrocautery
- Endoscopic drill
- Harmonic scalpel
- Navigation system.

Key Anatomic Landmarks

- Pterygoid canal

  The pterygoid base is the site of origin of JNA and must be drilled to prevent recurrence from the tumor infiltrating the spaces in the bone (Fig. 122.4). The pterygoid canal containing the vidian nerve and artery is located inferomedial to the lateral recess of the sphenoid sinus and is immediately behind the sphenopalatine foramen. The pterygoid canal with the vidian nerve is an important landmark for exposure of the petrous segment of the ICA.[5]

- Greater palatine nerve

  The greater palatine nerve contains sensory branches of the maxillary nerve and parasympathetic fibers from the pterygopalatine ganglion. It descends in a bony canal just deep to the sphenopalatine foramen. The nerve is often stretched over the surface of the tumor and the contents of the pterygopalatine space must be dissected from the surface of the tumor in a medial to lateral direction to preserve this nerve. Injury to the greater palatine nerve results in ipsilateral numbness of the palate.

- Infraorbital nerve

  The infraorbital nerve is often displaced superiorly by the tumor eroding the floor of the orbit. This sensory nerve is a terminal branch of the maxillary nerve and must be preserved to prevent numbness of the cheek.

- Foramen rotundum

  The maxillary nerve exits foramen rotundum superolateral to the lateral recess of the sphenoid sinus.

- Foramen ovale

The mandibular nerve exits the foramen ovale inferior to the foramen rotundum and posterior to the lateral pterygoid plate.

FIG. 122.4 Coronal computed tomography (CT) demonstrating characteristic tumor invasion of the base of the pterygoid *(black circle)* around the pterygoid canal. The normal relationship of the pterygoid canal and foramen rotundum are visible on the contralateral side.

Prerequisite Skills

- Endoscopic sinus surgery
- Caldwell Luc approach
- Medial maxillectomy.

Operative Risks

- Numbness of the palate (greater palatine nerve)
- Facial hypesthesia (infraorbital nerve) of the middle third of the face
- Injury to the mandibular nerve resulting in facial hypesthesia of the

lower third of the face and weakness of the muscles of mastication

- Acute anemia due to blood loss
- ICA injury
- Dry eye (loss of emotional tearing) due to sacrifice of the vidian nerve
- Cerebrospinal fluid leak.

Surgical Technique

The choice of surgical approach depends on the stage of the tumor (extent and vascularity). UPMC stage I and II tumors can be removed using a completely endoscopic endonasal approach. Larger tumors with residual vascularity will require augmentation with a transmaxillary approach. Tumors with lateral extension to the middle cranial fossa or infratemporal area may benefit from a combined anterior and lateral (infratemporal) approach. Palatal incision, LeFort I osteotomy, lateral rhinotomy, and facial translocation are approaches that have been largely supplanted by endoscopic techniques. The choice of approach also depends on the characteristics of the patient (age, size) and the experience of the surgeon with different approaches.

Endoscopic Endonasal Approach

- The nasal cavity is decongested with cottonoid pledgets soaked in 0.05% oxymetazoline.
- Nasal endoscopy is performed to assess the extent of the tumor.[6] (Video 122.1)
- A large middle meatal antrostomy is performed on the side of the tumor.
- The antrostomy is enlarged posteriorly and the sphenopalatine foramen is identified. Overlying bone is removed with Kerrison rongeurs (1 to 2 mm) to expose the pterygopalatine space. The bone is often remodeled by the tumor and is very thin. The removal of bone extends lateral to the margin of the tumor and superiorly toward foramen rotundum.

- An ethmoidectomy is performed on the side of the tumor. The inferior portion of the middle turbinate is resected with sinus scissors or thru-cutting ethmoid forceps. Removal of ethmoid air cells continues posteriorly with exposure of the roof of the ethmoid and the medial wall of the orbit. If possible, the anterior wall of the sphenoid sinus is opened superior to the tumor. Care is taken to avoid any instrumentation of the tumor, although its surface can be bluntly dissected from the anterior cranial base and gently displaced inferiorly.
- If there is bleeding from the surface of the tumor, it is best controlled with bipolar electrocautery.
- On the contralateral side, the mucosa of the posterior septum is cauterized and transected to expose the sphenoid rostrum. A sphenoidotomy is performed with removal of the rostrum to provide binarial access.
- Mucosal margins in the nasopharynx are incised with needle-tip monopolar electrocautery. This facilitates final detachment of the tumor as it is delivered into the nasopharynx.
- Now that there is circumferential access to the tumor, the pterygopalatine space is dissected to expose the lateral margin of the tumor. The overlying tissues are dissected from medial to lateral in order to preserve the greater palatine nerve, which is often displaced anteriorly by the tumor. Dissection proceeds on the surface of the tumor with delivery of nodules of tumor from the masticator space and posterior to the maxilla.
- The sphenoid component of the tumor is separated from the walls of the sphenoid sinus using blunt dissection. It is important to have good visualization of the optic canal and the course of the ICA.
- The last area of attachment is the pterygoid base where there is often infiltration of the tumor into the spaces of the bone, and there may be some blood supply from the vidian artery. The tumor is bluntly dissected from the bone and the vidian artery (and nerve) is cauterized using bipolar electrocautery.
- The entire tumor can then be delivered transorally or cut into smaller pieces. Large tumors can be divided into vascular segments using ultrasonic (Harmonic scalpel, Ethicon) and radiofrequency (Coblation,

Smith & Nephew) ablation.

- The last step is to drill the bone of the pterygoid circumferentially around the pterygoid canal to remove all vestiges of the tumor. If necessary, the bone can be drilled to the plane of the petrous ICA.
- Hemostasis is obtained with bipolar electrocautery, topical application of absorbable gelatin powder (Surgifoam, Ethicon), and warm saline irrigation. Exposed surfaces are covered with fibrin glue (Tisseal).

Transmaxillary Approach

- A medial maxillectomy is performed endoscopically (see Chapter 106). The inferior turbinate is cauterized and transected with straight sinus scissors. The posterior stump is cauterized with suction electrocautery.
- The medial wall of the maxillary sinus is resected with backbiting forceps and drilled to the level of the floor of the nose. The nasolacrimal duct is preserved anteriorly.
- If additional lateral access is necessary, an anteromedial maxillotomy is performed. The soft tissues at the pyriform aperture are incised with electrocautery and the periosteum is elevated with a Cottle elevator from the edge of the bone and the anterior wall of the maxilla.
- The vertical edge (1 to 2 cm) of the anteromedial maxilla is removed by drilling or the use of a bone rongeur. Bone removal extends across the anterior wall of the maxilla.
- An alternative to an anteromedial maxillotomy is an anterior maxillotomy (Caldwell Luc approach—see Chapter 104).
- Additional bone is removed from the posterolateral wall of the maxilla to gain access to the masticator space and the lateral limit of the tumor. The tumor can be dissected off the infraorbital nerve and the floor of the orbit.

Infratemporal Skull Base Approach

- A hemicoronal scalp incision is made with extension to the pre-auricular area (see Chapter 121).

- The scalp is elevated superficial to the deep temporal fascia with preservation of the temporal branches of the facial nerve.
- The periosteum is incised along the lateral orbital rim and zygomatic arch. The masseter muscle is separated from the inferior margin of the zygomatic arch with electrocautery. The periorbita is elevated from the lateral wall of the orbit and the inferior orbital fissure is identified.
- A reciprocating saw is used to make an osteotomy in the zygomatic arch posteriorly and the lateral wall of the orbit. The final osteotomy across the malar eminence, connecting to the inferior orbital fissure, releases the orbitozygomatic bone segment for removal as one unit.
- The temporalis muscle is reflected inferiorly.
- A subtemporal craniectomy is performed to gain access to the middle cranial fossa. Foramen ovale and V3 are identified and preserved.
- The infratemporal extension of the tumor is identified and a plane of dissection is developed deep to the temporalis muscle and pterygoid muscles.
- If coverage of the ICA or dura is needed following the removal of the tumor, the anterior half of the temporalis muscle can be transposed into the defect (see Chapter 168).

Common Errors in Technique

- Inadequate exposure

  Exposure is enhanced with a medial maxillectomy and bilateral sphenoidotomies. A Caldwell Luc approach provides added room for instrumentation, especially the introduction of bipolar electrocautery forceps.

- Early violation of the tumor capsule

  Dissection of the tumor before the margins have been completely exposed results in troublesome bleeding.

- Failure to find a plane of dissection in the pterygopalatine space

  In order to preserve the sensory branches of V2, it is necessary to find the plane of dissection medially and to dissect the contents of the

pterygopalatine space from the surface of the tumor in a medial to lateral direction.

- Incomplete drilling of pterygoid base

  It is easy to miss small remnants of tumor hidden in the spaces of the pterygoid base.

- Missing tumor nodules behind the maxilla

  Small tumor nodules may extend inferior to the plane of the maxilla in the pterygopalatine space and must be delivered into the surgical field with grasping forceps. It is sometimes helpful to manually palpate the soft tissues intraorally to help to deliver the tumor into the surgical field.

Postoperative Period

Postoperative Management

- Nasal packing can be removed after 1 to 2 days if there is no bleeding.
- Antibiotics are continued as long as nasal packing is in place.
- Silastic septal splints are removed at 1 week.
- An oral diet is resumed on the first postoperative day. If a Caldwell Luc approach was used, oral hygiene with a chlorhexidine rinse is prescribed.
- Saline nasal sprays are instituted immediately postoperative and are continued until healing is complete. Saline rinses are started 1 week later.
- Patients are seen in the office at 1 week and then at increasing intervals for debridement of intranasal crusts.
- If trismus is present, patients are encouraged to do gentle stretching exercises.

Complications

- Intraoperative hemorrhage[6]

  Advanced-stage tumors with residual vascularization (UPMC stage IV/V) can bleed briskly. Bipolar electrocautery is more effective than monopolar electrocautery. Vascular segments of the tumor should be addressed sequentially to control blood loss. If intraoperative blood loss is excessive, the surgery may need to be staged by packing the surgical cavity.

- ICA injury

  The greatest risk for vascular injury is poor visualization due to bleeding. When the tumor is in close proximity to the ICA, avulsion of tumor vessels should be avoided since this may cause a perforation on the surface of the ICA. A small hole on the surface of the ICA can be controlled with bipolar electrocautery. The vidian nerve within the pterygoid canal is an important landmark for the petrous ICA.

- Cerebrospinal fluid (CSF) leak

  Dural invasion is rare and most tumors are easily separated from the dura. If a dural tear occurs, this can be repaired using inlay and onlay fascial graft techniques with the placement of an adipose tissue graft to provide support.

- Postoperative hemorrhage

  Postoperative hemorrhage is usually due to unembolized branches of the external carotid artery and can be controlled with nasal packing. A sentinel bleed from the ICA should be ruled out with angiography if there was intraoperative injury to the ICA.

- V2 injury

  Hypesthesia of the midface and palate is the most common complication of surgery. The greater palatine and infraorbital nerves should be identified early and protected to avoid injury.

- V3 injury

  Injury to V3 results in hypesthesia of the lower face and weakness of the muscles of mastication. The nerve is at risk with large tumors that invade the middle fossa or extend posterior to the pterygoid plates.

- Orbital injury

The extraocular muscles may be injured when dissecting tumors that involve the infraorbital nerve canal or extend into the inferior orbital fissure.

- Visual loss

  The optic nerve is at risk when there is erosion of the optic canal within the sphenoid sinus or tumor extension into the orbital apex. Electrocautery should be avoided in proximity to the nerve, and the drilling of bone over the optic canal should be done with constant irrigation.

- Dry eye

  Sacrifice of the vidian nerve decreases emotional tearing from that eye. Although most patients will not notice a difference, dryness of the eye may result in patients with decreased tearing due to other causes.

- Trismus

  Dissection of the pterygoid muscles will cause transient trismus from inflammation. Late trismus due to scarring can be overcome with stretching devices (Therabite).

- Residual tumor[7]

  The risk of residual tumor is associated with stage. Most common sites for residual tumor include the cavernous sinus, middle cranial fossa, and masticator space. Risk factors include inadequate exposure, poor visualization due to bleeding, failure to dissect on the plane of the tumor, large multilobulated tumors, and prior treatment (surgery or RT).

Alternative Management Plan

- Surgery is the preferred treatment due to the benign nature of the disease and the long-term sequelae of RT in a young population. If a complete resection is not possible due to proximity to critical structures, a subtotal resection may be entertained. Small remnants of tumor may not grow and can be monitored until significant growth is observed.

- RT is rarely indicated for JNA. It may be considered for a poor surgical

candidate due to medical co-morbidities or refusal of surgery. Patients with advanced-stage tumors who refuse transfusion of blood products may be offered RT. Tumors that are considered unresectable due to intracranial extension or involvement of critical structures may be candidates for RT, but subtotal resection with RT for the residual component may be a strategy to limit the field and dose. However, resectability is a subjective judgment, and patients should be referred to Centers of Excellence that have extensive surgical experience with the management of JNA.

- Chemotherapy and hormone therapy are not effective.

Discussion

Evidence-Based Medicine Question

Are surgical outcomes better with endoscopic surgery for JNA?

Boghani Z, Husain Q, Kanumori VV, et al: Juvenile nasopharyngeal angiofibroma: a systematic review and comparison of endoscopic, endoscopic-assisted, and open resection in 1047 cases. Laryngoscope 2013;123:859–869.

This is a systematic review of treatment outcomes for JNA that compared endoscopic, endoscopic-assisted, and open surgical approaches. Endoscopic resection had decreased blood loss and a lower recurrence rate compared with open resection. However, after adjusting for tumor grade (Radkowski/Sessions tumor stage), there was no difference in recurrence rates.

Editorial Comment

The greatest challenge of surgery for JNA is dealing with intraoperative hemorrhage, especially for advanced-stage tumors with residual vascularity from the ICA following embolization of the external carotid artery system. These tumors are best treated by a team of skull base surgeons so that one surgeon has two hands free for tumor dissection while the second provides endoscopic visualization. Experience with treating other skull base tumors in proximity to neurovascular structures

is valuable in translating expertise to the management of JNA.

Eric W. Wang

Review Questions

1. The most important prognostic factor for the staging of JNA is:

   a. Size of the tumor

   b. Erosion of the skull base

   c. **Vascular supply from the ICA**

   d. Bilateral extension

2. Which of the following are absolute indications for RT?

   a. Blood supply from the ICA

   b. Intracranial extension

   c. Patient refusal of blood products

   d. Residual tumor in the cavernous sinus

   e. **None of the above**

3. Strategies for minimizing blood loss during surgery include all of the following except:

   a. Preoperative embolization

   b. **Early debulking of the tumor**

   c. Bipolar electrocautery

   d. Dividing large tumors into vascular territories

4. Which of the following statements is false?

   a. The pterygoid canal is an important landmark for the petrous ICA

   b. It is important to drill the base of pterygoid to remove all remnants of tumor

   c. **The pterygoid canal transmits the greater palatine nerve**

d. Sacrifice of the vidian nerve causes vasomotor rhinitis

5. Which of the following is most likely after surgery for JNA?

a. **Loss of ipsilateral emotional tearing**

b. Anesthesia of the palate

c. Diplopia

d. Horner syndrome

Transnasal and Transoral Approaches to the Cervical Spine

Carl H. Snyderman, and Paul A. Gardner

Introduction

The superior aspects of the cervical spine (C1 and C2) and the craniovertebral junction are difficult to access via a transcervical approach. Traditionally, a transoral/transpalatal approach has been used, but is associated with significant morbidity. With the advent of endoscopic techniques, a transnasal approach may be used with improved visualization and avoidance of the morbidity associated with a transoral approach.[1,2] For lesions that require access from the lower clivus to C3, a combined approach can be employed.

Transnasal and transoral approaches to the upper cervical spine and craniovertebral junction are most commonly performed for basilar invagination with brainstem compression. This may be the result of rheumatoid degeneration with pannus formation, or traumatic fracture and dislocation of the odontoid. A transodontoid approach also provides access to tumors at the jugular foramen and adjacent areas.

Key Operative Learning Points

- With a transnasal route, resection of the posterior nasal septum as far as the nasal floor is necessary to provide adequate lateral access.
- Resection of the nasopharyngeal mucosa and underlying muscle and fascia improves the exposure of C1 and C2.
- Removal of a thickened pannus should be performed until transmitted pulsations are evident; complete removal risks a cerebrospinal fluid (CSF) leak.

- The inferior extent of the transnasal approach is limited by the posterior edge of the hard palate.
- A palatal incision can usually be avoided by retraction of the soft palate into the nasopharynx.
- A paramedian palatal incision preserves the blood supply to the palate and minimizes scar retraction of the palate.
- Patients with preoperative pharyngeal dysfunction are at increased risk for airway problems and should have a tracheostomy performed at the time of their operation.
- Patients with cervical instability should undergo neurophysiological monitoring during positioning and throughout surgery to avoid injury to the spinal cord.
- Retropharyngeal dissection lateral to the Eustachian tube should be avoided because of the risk of injury to the internal carotid artery (ICA).

Preoperative Period

History

- Prior nasal or sinus surgery
- Cranial nerve dysfunction: hoarseness, aspiration, dysphagia, dysarthria
- Symptoms of spinal compression: long-tract signs with weakness

Physical Examination

- Nasal cavity: septal deviation, inflammatory sinus disease, prior sinus surgery
- Nasopharynx: velopharyngeal closure, retropharyngeal carotid pulsations
- Oral cavity: dentition, palate

- Larynx: laryngeal function
- Cranial nerves: X, XI, XII

Imaging

- Computed tomography (CT) scan. CT provides evidence of bone destruction from infection or neoplasm. CT angiography for navigation is preferred for the demonstration of the carotid and vertebral arteries.
- Magnetic resonance imaging (MRI) (Fig. 123.1). This is superior for soft tissue imaging, especially of the pannus and brain stem compression. Chordomas and chondrosarcomas appear bright on T2-weighted images.

Indications

- Infection
  - Localized retropharyngeal abscess
- Trauma
  - Displaced fracture of C1 and C2 with spinal cord compression

FIG. 123.1 Sagittal plane magnetic resonance imaging demonstrates basilar invagination and brainstem compression (arrow).

- Inflammation
  - Rheumatoid pannus with basilar invagination and compression of the brainstem (Fig.123.1)[3]
- Neoplasms (Fig. 123.2)
  - Chordoma
  - Chondrosarcoma
  - Meningioma
  - Nasopharyngeal carcinoma

Contraindications

- Intranasal Approach
  - Neoplastic involvement of the spine inferior to the nasopalatine line.
  - Intradural dissection should be avoided in the presence of active infection. Sinusitis should first be treated medically or surgically, if possible.
- Transoral Approach
  - Trismus
  - Fully restored teeth
  - Excessive soft tissue in the pharynx

Preoperative Preparation

- Treatment of sinusitis
- Treatment of aspiration pneumonia

Operative Period

Anesthesia

- The airway should be evaluated preoperatively for potential difficulty of intubation and consideration of airway options. Increased difficulty of intubation because of cervical instability may be encountered. There is also a risk of accidental extubation with the repositioning of the patient for posterior cervical fusion if performed during the same operative setting.

Positioning

- The patient's head is fixed in a Mayfield clamp in a neutral position. Neurophysiological monitoring is performed before and after positioning.

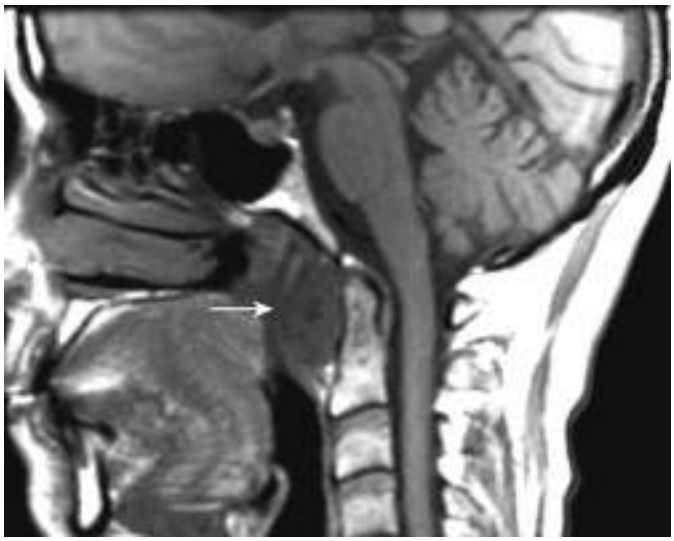

FIG. 123.2 Neoplasms at the level of the foramen magnum *(arrow)* are most commonly chordomas, chondrosarcomas, or meningiomas.

Perioperative Antibiotic Prophylaxis

- Third-generation cephalosporin with CSF penetration.

Monitoring

- Somatosensory evoked potentials (SSEP) provide an overall measure of cortical brain function. Baseline responses should be established before positioning if there is brainstem compression or cervical instability.
- Brainstem evoked responses (BSER) to monitor brain stem function also may be indicated. Cervical instability during repositioning requires continued monitoring.
- Electromyography (EMG) of lower cranial nerves can help with intraoperative identification of nerves and prevention of injury.
- Navigation system: the cervico-medullary junction is included in the imaging.

Instruments and Equipment to Have Available

- Intranasal Approach
  - Basic endoscopic sinus surgery set
  - Endoscopic surgical drill with 4 mm coarse diamond burs
  - Ultrasonic aspirator (optional)
- Transoral Approach
  - Dingman or Crockard mouth retractor
  - Red rubber tube
  - Cloward-style soft tissue retractor

Key Anatomic Landmarks

- The nasopharynx is bounded by the Eustachian tubes and parapharyngeal carotid arteries laterally. The arteries are deep to the fossa of Rosenmüller. Ectatic arteries may protrude into the retropharyngeal space.
- Passavant's ridge is a U-shaped muscular sphincter of the pharynx that forms the contact point for the soft palate with swallowing.
- The nasopalatine line is a virtual line from the inferior aspect of the

nasal bones to the posterior edge of the hard palate. Extension of this line posteriorly crosses C2 and defines the inferior limit of the endoscopic endonasal approach.

- The dominant blood supply to the palatal mucosa is derived from the greater palatine arteries. The greater palatine foramen is adjacent to the second molar.
- The dens or odontoid process is covered by the arch of C1 anteriorly.
- The vertebral bodies are covered by the paraspinal muscles anteriorly (longus capitis and longus colli).
- The bone of the clivus thins as it approaches the foramen magnum.

Prerequisite Skills

- Endoscopic sinus surgery
- Tonsillectomy

Operative Risks

- CSF leak

  With the transnasal approach, there is a greater risk of a dural opening and CSF leak if dissection is performed in the region of the occipital condyle superolaterally.

- Injury to the parapharyngeal ICA

  The extracranial parapharyngeal segment of the ICA is lateral to the fossa of Rosenmüller and deep to the Eustachian tube. On occasion, a tortuous ICA may course medially in the retropharyngeal area. This is a relative contraindication to a transoral approach, but would not preclude a transnasal approach.

- Injury to the vertebral artery

  Far lateral dissection at the level of C1 and C2 may injure the vertebral artery and should be performed only under image guidance.

Surgical Technique

Transnasal Approach

- The inferior turbinates are lateralized to improve access to the nasopharynx.
- Landmarks are identified with the aid of navigation to identify the proximity of the ICAs and the level of the arch of C1.
- Needle-tip electrocautery is used to incise the nasopharyngeal mucosa to expose the underlying paraspinal muscles (longus capitis and longus colli) (Video 123.1).
- The soft tissues and muscles are then resected to expose the underlying pharyngobasilar fascia (Video 123.2). Resection of this dense fascia is facilitated by using a drill with a 3 mm coarse diamond bur to remove the cortical bone of the clivus starting at the inferior margin of the sphenoid rostrum (and progressing inferiorly [Video 123.3]). The limits of exposure include the Eustachian tubes laterally, the floor of the sphenoid sinus superiorly, and the level of the soft palate inferiorly.
- The posterior edge of the nasal septum is resected with backbiting forceps, and the attachment of the septum to the hard palate is drilled in the midline until it is flush with the plane of the hard palate. This allows instrumentation to reach the lateral limit of the surgical field from the contralateral side.
- An image guidance system is used to identify the level of the ring of C1, and the bone is then exposed (Fig. 123.3). The inferior edge of the clivus is thinned with a drill and resected with a Kerrison rongeur. The central portion of C1 is then removed with the drill, and the defect is widened laterally with a bone rongeur (Fig. 123.4; Video 123.4).
- The location of the underlying dens is confirmed with image guidance, and the central portion of the dens is drilled (Video 123.5). When only a shell of outer cortical bone remains, the base of the dens is detached from the body of C2. Blunt and sharp dissection of the attachments of the dens to the surrounding pannus allows mobilization and removal of the remaining bone (Fig. 123.5; Video 123.6).
- Although resection of the pannus may not be necessary, we prefer to partially resect the pannus with an ultrasonic aspirator until pulsations

transmitted from the brain stem are observed (Video 123.7). No reconstruction is necessary if the dura has not been violated. The defect is covered with fibrin glue (Video 123.8).

- Silastic nasal splints are sutured to the nasal septum.
- Because of the inherent instability of the craniovertebral junction in these patients, posterior fusion of the cervical spine to the occiput is usually performed during the same operative event.

Transoral Approach

- Various retractors (Dingman, Crockard) are available and allow self-retained retraction of the mandible and tongue, as well as the lateral oral commissure (Fig. 123.6). One of the biggest challenges is finding a proper fit of the tongue blade so that the base of tongue does not bulge into the field. During lengthy cases, the retractor should be released for several minutes intermittently to prevent excessive pressure on the tongue and the potential for ischemic necrosis or edema.

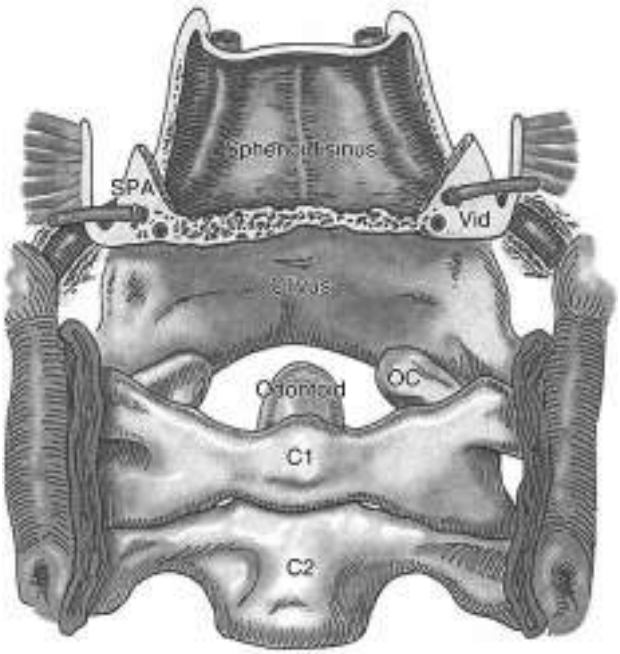

FIG. 123.3 The nasopharyngeal soft tissues are resected to expose the lower clivus and ring of C1. It is not necessary to open the sphenoid sinus in all cases. *OC*,

occipital condyle; *SPA*, sphenopalatine artery; Vid, vidian artery. Reprinted with permission from Kassam AB, Snyderman CH, Gardner PA, et al: The expanded endonasal approach: A fully endoscopic transnasal approach and resection of the odontoid process: Technical case report. Neurosurgery 2005; 57: E213, discussion E213.

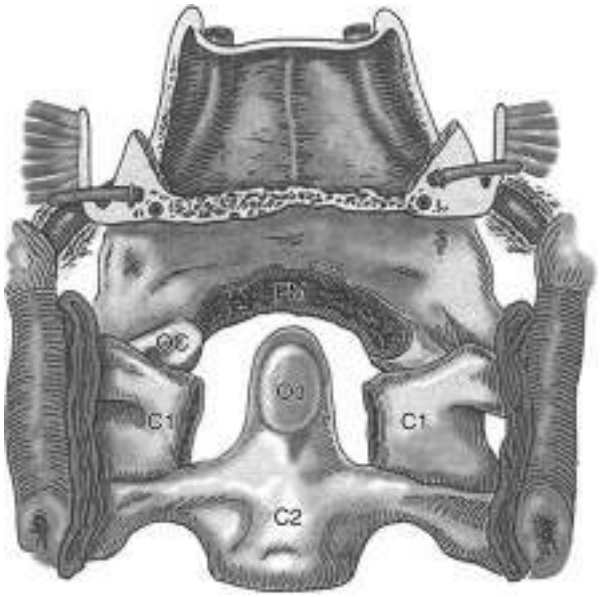

FIG. 123.4 The central ring of C1 is removed with a drill and the gap is widened with a Kerrison rongeur. *FM*, foramen magnum; OC, occipital condyle; Od, odontoid. Reprinted with permission from Kassam AB, Snyderman CH, Gardner PA, et al: The expanded endonasal approach: A fully endoscopic transnasal approach andresection of the odontoid process: Technical case report. Neurosurgery 2005; 57: E213, discussion E213.

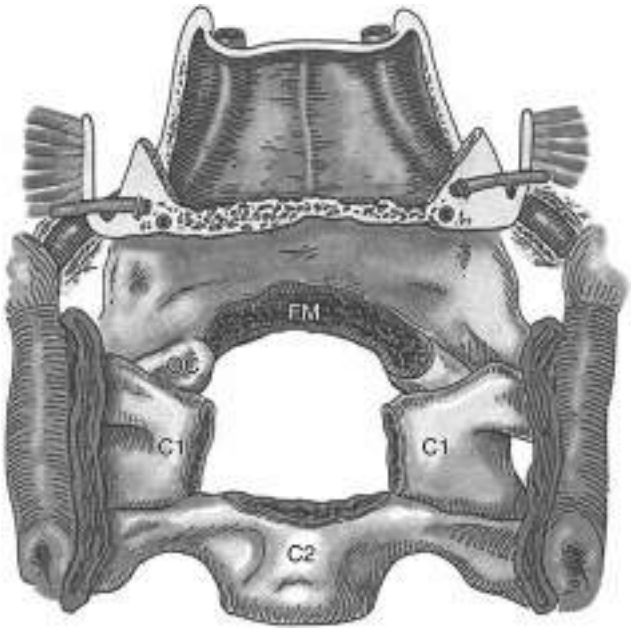

FIG. 123.5 The odontoid is removed with a drill and dissection of the ligamentous attachments. *FM*, foramen magnum; OC, occipital condyle. Reprinted with permission from Kassam AB, Snyderman CH, Gardner PA, et al: The expanded endonasal approach: A fully endoscopic transnasal approach and resection of the odontoid process: Technical case report. Neurosurgery 2005; 57: E213, discussion E213.

- If the superior extent of the resection is the odontoid, incision of the palate is not necessary. A red rubber catheter is passed transnasally and sutured to the soft palate adjacent to the uvula. It is then retracted to pull the soft palate into the nasopharynx and secured to the drapes.
- If the exposure needs to extend to the rostrum of the sphenoid, incision of the palate is generally necessary. A paramedian incision is made adjacent to the uvula and curves in a lazy "S" fashion behind the maxillary alveolus so that the majority of the palatal flap is based on one greater palatine artery.
- The mucoperiosteal flaps are elevated laterally to the edge of the greater palatine foramen with preservation of the blood supply. The posterior edge of the hard palate may be resected to provide additional exposure superiorly.
- Electrocautery is used to make a vertical midline incision in the posterior pharyngeal wall from the level of C3 to the nasopharynx. The incision continues through the soft tissues in the midline between the

longus capitis and longus colli muscles.

- The paraspinal muscles are elevated from the vertebral bodies and ring of C1. Excessive lateral dissection is avoided because of the risk of injuring the vertebral artery.
- A self-retaining retractor is placed and the bone work is then performed with a drill and Kerrison rongeurs. Visualization is enhanced with use of the operating microscope or endoscopes.
- After completion of the decompression, the pharyngeal incision is closed in two layers: a deep layer of interrupted 3-0 polyglycolic acid suture and a superficial layer of 3-0 polyglycolic acid suture placed with a vertical mattress technique. Obtaining watertight closure can be difficult at the superior and inferior limits of the incision. If a palatal incision has been made, the soft palate incision is closed in two layers: a deep intramuscular layer of interrupted 4-0 polyglycolic acid suture and a superficial layer of interrupted 4-0 polyglycolic acid suture. The mucoperiosteal flap over the hard palate is thin and is closed in a single layer with a vertical mattress technique. A paraffin nasal splint can be molded to the contour of the hard palate and secured with sutures around the teeth. This protects the palatal mucosa during mastication.

FIG. 123.6 A Dingman retractor distracts the mandible and maxilla, and displaces the endotracheal tube, the tongue, and the cheeks.

Common Errors in Technique

- Limited exposure

  The nasopharyngeal tissues, including the paraspinal muscles, should be widely resected to provide good visualization of the bone. Drilling of the bone of the hard palate in the midline improves lateral access at the level of C1. Attempts to preserve the mucosa of the nasopharynx by elevating a flap are futile as the flap is insufficient for reconstruction and interferes with visualization.

- Detachment of odontoid

  The transition from the ring of C1 to the dens is not always apparent and it is easy to prematurely drill into the dens. Detachment of the dens at its base before drilling the tip makes it difficult to dissect the tip from the ligamentous attachments.

Postoperative Period

Postoperative Management

- These patients are at increased risk for aspiration postoperatively, and reintubation can be difficult because of posterior neck fusion. Consideration should be given to leaving the patient intubated postoperatively until a safe airway can be ensured, or a temporary tracheostomy should be performed. With the transnasal approach, tracheostomy is only necessary in patients with significant preoperative pharyngeal dysfunction.
- Patients may start a full liquid diet and progress to a soft diet as soon as they are able to swallow without aspiration. Formal evaluation with a modified barium swallow may be helpful in determining swallowing capability. With the transnasal approach, patients can resume an oral diet immediately. Return of swallowing function is often delayed for several days when the transoral route is used.
- If used, nasal septal or palatal splints are removed 1 week postoperatively.

Complications

- Palatal dysfunction

  Palatal dysfunction following a transnasal approach is mild and transient since the trajectory of the approach is superior to Passavant's ridge. A transoral approach results in a greater loss of bone volume because of the trajectory with a greater separation of the palate and posterior pharyngeal wall. If a palatal incision is performed, scar contracture can shorten the soft palate, contributing further to velopharyngeal incompetence with hypernasal speech and nasal reflux. Dehiscence of the palatal closure can result in an oronasal fistula.

- CSF leak

  Aggressive resection of a rheumatoid pannus can result in a CSF leak. With a transnasal approach, this can be effectively stopped using a multilayer repair, including fascia, adipose tissue, and possibly a nasoseptal flap. With a transoral approach, it is more difficult to repair a CSF leak due to the trajectory and limited visualization. Closure of the pharyngeal incision is difficult after a transoral approach, and ongoing contamination of the wound by saliva with heavy bacterial flora can occur, increasing the risk of meningitis.

- Vascular injury

  The extracranial parapharyngeal segment of the ICA is susceptible to injury from electrocautery lateral to the fossa of Rosenmüller. A tortuous ICA that courses medially in the retropharyngeal area is a relative contraindication to a transoral approach, but it would not preclude a transnasal approach. When recognized, the nasopharyngeal soft tissues can be displaced inferiorly to protect the vessels. Far lateral dissection at the level of C1 and C2 may injure the vertebral artery and should be performed only under image guidance.

- Miscellaneous

  Other potential risks of a transoral approach include injury to the teeth, edema or necrosis of the tongue, upper airway obstruction secondary to edema, dysphagia, pain with swallowing, retropharyngeal hematoma or abscess, and temporomandibular joint syndrome

secondary to excessive opening of the mouth.

Alternative Management Plan

- Patients with a rheumatoid pannus have inherent instability of the craniovertebral junction and this contributes to the formation of the pannus. Anterior decompression is not necessary in the majority of patients, and stabilization of the spine with a posterior fusion alone will allow the pannus to resolve.
- Neoplasms that extend laterally from the lower clivus or involve the vertebral artery can be approached with a far lateral or anterior transcervical approach.

Discussion

Evidence-Based Medicine Question

What are the complication rates of transoral and transnasal odontoidectomy?

A systematic review and meta-analysis by Shriver et al.[4] reviewed the literature for rates of complications and outcomes for transoral and transnasal odontoidectomy. Twenty-six articles met the inclusion criteria. The only statistically significant difference was the incidence of postoperative tracheostomy, which was significantly higher after transoral odontoidectomy 8.4% (95% CI 4.9% to 11.9%) compared to transnasal odontoidectomy 0.8% (95% CI 1.0% to 2.9%). Due to inconsistent reporting, it was not possible to demonstrate the differences in important outcomes, such as arterial injury, CSF leak, pneumonia, velopharyngeal insufficiency (VPI), wound infection, and meningitis.

A systematic review of the literature for endoscopic endonasal approaches to the craniovertebral junction identified 71 cases.[5] Seven of 71 patients required an airway intervention (9.9%). The majority of patients (81.7%) had additional posterior decompression or fusion before or after the endonasal procedure. The authors concluded that the endonasal approach is an effective and safe alternative for most pathologies of the craniovertebral junction.

Editorial Comment

The endonasal corridor to the craniovertebral junction is another example of how enabling technology (endoscopy) has transformed surgery. Improved visualization facilitates more complete surgery with less morbidity. Endoscopic endonasal surgery is also team surgery, requiring close cooperation between surgical specialties. Each specialty benefits from the knowledge and expertise of the other. Endoscopic technology can be applied to traditional procedures (transoral approach to the cervical spine) to transform them. Modern head and neck surgeons need to be versatile in the adoption of new techniques and technologies.

Review Questions

1. Anatomical limits of the transnasal approach to the craniovertebral junction include all of the following except:

   a. Parapharyngeal internal carotid arteries

   b. Eustachian tubes

   c. Nasopalatine line

   d. **Pituitary gland**

2. Relative contraindications of the transnasal approach to the craniovertebral junction include all of the following except:

   a. **Trismus**

   b. Untreated sinusitis

   c. Tumor involving vertebral body of C3

   d. Tumor encasement of vertebral artery

3. Advantages of a transnasal approach compared to a transoral approach include all of the following except:

   a. Decreased risk of hypernasal speech

b. Earlier resumption of oral diet

c. **Stabilization of the spine**

d. Increased access to the clivus

Reconstruction After Skull Base Surgery

Patrick Colley, and Adam Zanation

Introduction

Over the past 15 years, significant improvements in surgical techniques coupled with technological advancements have led to the ability to remove complex skull base tumors using endoscopic endonasal surgery (EES).[1,2] EES is applicable for a wide variety of surgical pathology, including everything from sinonasal cancers to intradural primary brain tumors.[3] When EES was first developed, proper repair of the skull base and prevention of subsequent cerebrospinal fluid (CSF) leak was one of the primary challenges faced by the surgeon. This review describes how surgical techniques to address these issues have advanced from early free tissue grafting techniques to the current use of vascularized flaps for large skull base defects. We will focus on endoscopic techniques in this chapter.

Open transcranial anterior skull base reconstruction is usually accomplished with an anteriorly based pericranial flap (see Chapter 166).

Key Operative Learning Points

1. Measuring the size of the defect and attempting to create a smooth surface for repair are vital first steps in all skull base reconstructions.

2. A multilayered reconstruction with vascular repair is favored over a single layer whenever possible, especially in fields that have previously received or will be receiving radiation therapy.

3. Postoperative care, including bed rest, bowel regimen, elevation of the head of the bed, and maintenance of airway pressures, plays an

important role in successful reconstruction of any skull base defect.

Preoperative Period

History

1. History of present illness

   a. The location of the skull base pathology can possibly be elicited by asking if the patient has any sinonasal complaints, such as nasal obstruction, rhinorrhea, change in their sense of smell, facial pressure/pain, or epistaxis.

      Sinonasal etiologies of potential skull base defects often present with nasal obstruction, discharge, or epistaxis. Planar and perisellar etiologies are more likely to present with headache or ophthalmologic symptoms, such as visual field cuts, ophthalmoplegia, or ptosis.

   b. Postoperative CSF leaks are typically noted within a week following sinonasal or skull base surgery. The patient's history is most suggestive and often diagnostic. Primary symptoms include clear, persistent rhinorrhea with an often salty taste. Postoperative encephaloceles are also potential causes of CSF leak further out from the original surgery.

   c. A history of previous sinonasal, head, and neck or neurosurgical procedures or prior radiation therapy should be elicited.

      Vascularized flap reconstruction relies on axial blood flow and tissue planes that may have been disrupted during previous surgeries. Identifying this before the surgery allows for proper planning should the patient require an extranasal flap for reconstruction.

2. Past medical history

   a. Prior treatment: Does the patient have a known history of skull base pathology? How was this previously treated? Radiation therapy?

   b. Medical illnesses

   c. Prior surgeries: Has the patient ever had endoscopic sinus surgery, a septoplasty, craniotomy, rhytidectomy, or other head and neck

surgery?

d. Family history

e. Medications:

1) Antiplatelet drugs

2) Anticoagulants

3) Herbal products

4) Alcohol

Physical Examination

1. Nasal endoscopy

Nasal endoscopy is a key component of the physical examination. It may be limited preoperatively due to tumor or septal deviation. Identifying the size of the tumor and potential involvement of surrounding structures, particularly the septum or rostrum, can be helpful in planning the resection and reconstruction.

Postoperatively, nasal endoscopy plays a vital role in tumor surveillance and helps monitor for potential CSF leaks. In addition to nasal endoscopy, physical examination findings of a CSF leak include a positive reservoir sign and increased rhinorrhea with a Valsalva maneuver. In the early postoperative period, absorbable packing often remains in place, making visualization of the skull base defect difficult. Intermediate timed CSF leaks (2 to 6 weeks) are less common and usually present with intermittent low flow leaks from a pinpoint dural opening. Late CSF leaks (>6 weeks) are very rare and present in a similar manner to intermediate timed leaks. Both the intermediate and late CSF leaks can typically be visualized with a nasal endoscopy.

2. Orbit

A thorough ophthalmologic examination may reveal tumor involvement of the extraocular muscles, optic nerve, or cranial nerves. While involvement of these structures may not limit the surgical resection, their preoperative function should be noted.

3. Trigeminal nerve

The path of this cranial nerve and its location in the sinonasal cavity frequently lead to involvement by skull base tumors or injury during resections of these lesions. These nerves will not serve as surgical limits, but their preoperative function provides information as to the size and location of the skull base tumor.

4. Neck

Sinonasal tumors have a low rate of lymphatic metastasis, but their drainage basins are typically in the cervical lymph node chain, making examination of the neck an important preoperative assessment. Cervical vasculature could also play a role in potential skull base reconstruction depending on the size of the defect or the technique of reconstruction.

Imaging

Computed Tomography

Bony anatomy and the extent of skull base involvement are crucial information to obtain during the preoperative assessment. A CT scan can typically provide this detail as well as some information regarding soft tissue involvement (Fig. 124.1). If the planned resection will involve the use of image guidance, proper formatting is required when obtaining these scans.

Magnetic Resonance Imaging

Skull base tumors frequently abut or involve intracranial structures making soft tissue detail particularly important for proper surgical planning. Other important structures, such as the carotid arteries and optic nerves, must be identified and preserved during skull base procedures. The soft tissue detail that MRI provides is typically the most accurate means of accomplishing this task (see Fig. 124.1). The use of contrast can provide excellent detail regarding the vasculature within the skull base and should be included whenever the surgical field will involve vascular structures. Proper formatting should be applied to these scans as well if they are to be used for image guidance during the surgical resection.

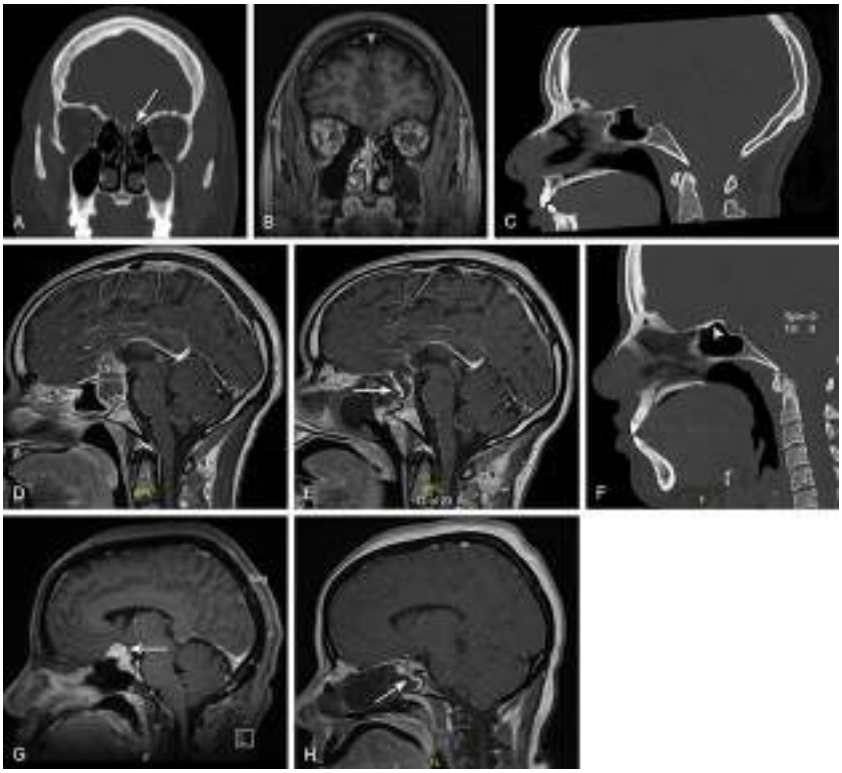

FIG. 124.1 Types of endonasal skull defects. Computed tomography (CT) demonstrates bony anatomy and allows planning of the approach corridor and sizing of the craniectomy defect for reconstruction. Magnetic resonance imaging (MRI) provides superior visualization of intracranial extent of disease and the relationship of neurovascular structures relative to the planned endoscopic corridor. **A,** Coronal CT (bone window) of a small encephalocele of the left ethmoid *(arrow)* with pooling of the cerebrospinal fluid in sinus cavities on the ipsilateral side. **B,** Coronal T1 contrasted MRI of a small encephalocele of the left ethmoid in the same patient as Fig. 124.1A. **C,** Sagittal CT (bone window) of a patient with a large pituitary adenoma. Note the expanded sella and thinning of the dorsum sellae (superior clivus). **D,** Sagittal T1 contrasted MRI of the same patient in 1C. Note the suprasellar extent and posterior expansion of the tumor. **E,** Immediate postoperative sagittal T1 contrasted MRI of the patient in 1C and 1D. Note the gross total resection of the tumor and the good placement and vascularity of the nasoseptal flap

reconstruction at the arrow. A Foley balloon catheter is in place. **F,** Sagittal CT (bone window) of a patient with a tuberculum and planar meningioma. Note the tumor-related hyperostosis of the planum extending back to the tuberculum at the arrowhead. **G,** Sagittal T1 contrasted MRI of same patient in 1F. Note the tumor extending into the sella and the anterior communicating and A2 arteries running along the superior edge of the tumor but not fully encased in the tumor at the arrow. **H,** Immediate postoperative sagittal T1 contrasted MRI of the patient in 1F and 1G. Note the good placement and vascularity of the nasoseptal flap reconstruction at the arrow.

Angiography

Preoperative angiography and intervention play an important role in the treatment of vascular tumors that can involve the skull base, such as juvenile nasopharyngeal angiofibromas. However, its routine use is not necessary in the treatment of most skull base tumors and does not aid in the skull base reconstruction.

Indications for Skull Base Reconstruction

1. Dural defect after the excision of a skull base tumor or encephalocele (Figs. 124.1 and 124.2)

Any tumor involving the anterior skull base has the potential to require reconstruction after surgical resection. The size of the defect can often be anticipated based on the preoperative imaging and should be planned for accordingly.

2. A postoperative CSF leak is identified after sinonasal surgery.

A major complication of endoscopic sinus surgery is damage to the skull base and dura with resultant CSF leak. Injury to the skull base during endoscopic sinus surgery is approached in a similar manner as that of a planned skull base resection.

3. Large extradural defects to promote healing

Many extradural tumor resections require reconstruction to promote

healing, especially in the setting of postoperative radiation therapy. In these situations, the primary reason for reconstruction is not prevention of a CSF leak but is proper healing with the reduction of potential intracranial infections and the protection of vital structures.

Contraindications

1. Medical comorbidities with unacceptable risk for general anesthesia

FIG. 124.2 Endoscopic view of a skull base defect from an endonasal approach following resection of a posterior fossa meningioma. The basilar artery and basilar tip can been seen through the transclival defect.

Patients with lesions involving their skull base who are not medically stable enough to undergo general anesthesia have a variety of treatment options, including observation, medical management of the tumor, or possibly radiation therapy.

2. Unresectable skull base tumor

Skull base tumors that are not resectable should be considered for medical management of their tumor unless surgery is the last palliative measure.

Preoperative Preparation

1. The entire surgical team must understand and agree with the plan for resection and repair.

2. If a lumbar drain is planned as part of the reconstruction, this should be included on the consent form and discussed with the patient and the surgical team.

3. Confirm that the imaging, CT and/or MRI, is compatible with the image guidance and that these scans are loaded before the surgery.

4. Discontinue all antiplatelet drugs.

Operative Period

Anesthesia

General anesthesia: This procedure often involves irrigation with the drainage of blood and potentially CSF into the oropharynx that would pose an airway risk should the airway not be secured with an endotracheal tube. The procedure itself is also intricate involving small movements in an area near many important structures, making patient movement potentially very dangerous. The anesthesiologist should be made aware when operating around or near the optic nerves or carotid arteries to ensure complete anesthesia and reduce the possibility of any patient movement.

Positioning

Supine: The patient is positioned in the supine position with access to the entire head, abdomen, and potentially upper leg from the iliac crest to the patella. This often requires turning the patient 90 or 180 degrees away from anesthesia. If an extranasal flap is part of the reconstructive plan, the patient should also be positioned appropriately in order to harvest this flap.

The patient's eyes should be protected in a manner that provides access for examination but protects from corneal abrasions.

Perioperative Antibiotic Prophylaxis

A discussion regarding preoperative medications, including antibiotics, should take place with Neurosurgery if they are involved in the procedure. Additionally, the potential need for CSF antibiotic penetration should be considered for cases with significant intra-arachnoidal dissections.

If the tumor or defect is primarily extradural or sellar without a high-flow CSF leak:

First-generation cephalosporins: These medications are typically sufficient for EES if there is no active infection identified in the preoperative evaluation.

Clindamycin: If the patient is allergic to penicillin, clindamycin is an acceptable substitute and has the advantage of a higher rate of bone penetration.

If the tumor or defect has a significant intra-arachnoidal dissection, then third-generation cephalosporin or vancomycin for the patients who are allergic to penicillin should be considered.

Monitoring

Cranial and peripheral nerve monitoring: Monitoring cranial nerves and peripheral nerves can play a role in the resection of skull base tumors but has no role in reconstruction after these surgeries.

Instruments and Equipment to Have Available

1. An endoscopic sinus surgery set

2. Guarded monopolar electrocautery: Monopolar suction electrocautery should be used with caution near the skull base due to the spread of heat and electrical current to surrounding structures. We usually prefer bipolar or advanced energy technology.

3. Bipolar electrocautery: There are many types of endoscopic bipolars

available that are all designed for use in skull base reconstruction. The use of bayonet bipolars is usually limited by the nasal aperture.

4. Endoscopic microsurgical dissection instruments: Dissection in and around neurovascular structures often requires a wide variety of instruments. Dissecting sets, such as Rhoton dissectors, provide the surgeon with a number of choices when operating at the skull base.

5. Image guidance: Using preoperative imaging for image guidance during EES supplies the surgeon with important information regarding skull base anatomy that can become distorted during the resection.

6. Allograft or collagen matrix material: This material can be used as an inlay or onlay graft during reconstruction. The size and thickness of the material should be confirmed before the start of the procedure.

7. Thrombin/Gelfoam mixture for hemostasis, fibrin or biologic glues for a potential sealant over the reconstruction

8. Endoscopic suture devices can be useful in selected cases but are difficult to use. Additionally, endoscopic carotid clips and aneurysm clips can be useful for catastrophic bleeding.

Key Anatomic Landmarks

1. The sphenopalatine artery and the sphenoid sinus natural ostium

The nasoseptal flap (Fig. 124.3) has become the flap that is most often used for skull base reconstruction and will be the primary reconstructive option discussed in this chapter. The primary blood supply is from the distal external carotid artery via the sphenopalatine artery to the posterior nasal branches that cross over the choana.[4] The sphenoid ostium is an important landmark when elevating this flap. Dissection along the anterior inferior face of the sphenoid is discouraged until the septal flap has been elevated, if it is the planned means of reconstruction.

2. Bony edge of the skull base defect

Measuring the skull base defect and identifying the bony edges is important for successful reconstruction. Inlay grafts must be placed behind these edges, and any onlay graft must cover these edges in order to properly reconstruct a skull base defect.

Prerequisite Skills

1. Endoscopic sphenoidotomy
2. Endoscopic septoplasty

Operative Risks

Damage to the flap pedicle or perforation of the flap

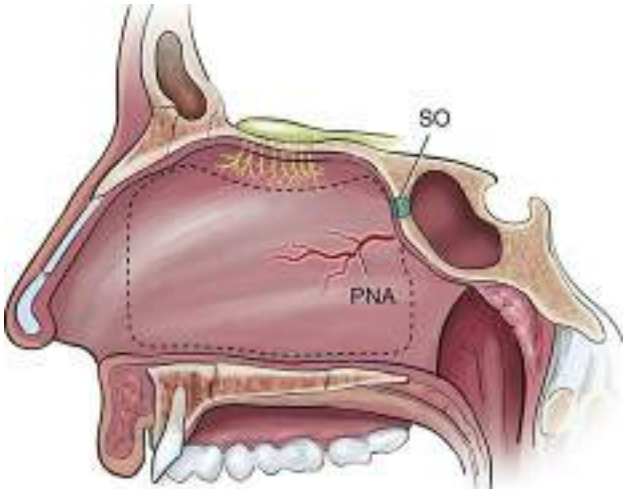

FIG. 124.3 Nasoseptal flap anatomy and standard incisions *(dotted lines)*. Note the incision is approximately 1.5 cm below the olfactory groove to preserve neural fibers. The incision can be modified to include the nasal floor or extend more anteriorly to the mucocutaneous junction. The pedicle is based on the posterior nasal artery (PNA) from the sphenopalatine artery. The arterial pedicle always runs between the free edge of the choana and the sphenoid ostium (SO).

If a pedicled flap is the planned means of reconstruction, care must be taken when incising and elevating the flap to avoid damage to the tissue. When using the nasoseptal flap, injuries to the pedicle typically occur while enlarging the sphenoid ostium, making the inferior choanal incision or dissecting the flap free from the anterior face of the sphenoid. This can be avoided by ensuring proper visualization and hemostasis

during the initial flap incisions and while elevating the flap. The position of the natural ostium of the sphenoid should be confirmed prior to making the inferior incision. Once the flap is dissected free, it should be protected from possible damage from a drill by placing it in the nasopharynx or maxillary sinus (via antrostomy).

Perforation of the flap mucosa can lead to failure of the repair due to loss of a watertight seal. Dissection in the proper sub-mucoperichondrial plane for a nasoseptal flap reduces the risk of perforation of the flap. This plane should be established at the anterior portion of the dissection, and all incisions should be made prior to proceeding posteriorly with the dissection. If the incision is not made all the way through the mucoperichondrium, sharp cutting instruments should be used to complete the incisions.

Surgical Technique

This section will provide details regarding skull base repair using free mucosal grafts and the nasoseptal flap.[1,2] Details of skull base reconstruction using particular extranasal flaps, such as the pericranial, temporalis, or temporoparietal fascia flaps, can be found in Chapters 166, 167, 168, respectively. Defects that persist despite these techniques may require the use of free tissue transfer with microvascular techniques.

- Topical vasoconstriction with oxymetazoline (0.05%)

  Topical decongestion is an important part of the procedure and should be given adequate time in the nose to maximize the effect. Decongestants provide a larger endoscopic surgical cavity by reducing mucosal congestion as well as reducing bleeding. Topical epinephrine also can be used as long as the surgeon remains aware of the risk of potential rebound bleeding after this medication stops functioning. We do not routinely inject with lidocaine ± epinephrine.

- Lateralization of the inferior and middle turbinates

  The inferior and middle turbinates are out-fractured to allow visualization of the entire height of the nasal septum from the olfactory sulcus to the nasal floor.

- Harvest of the free mucosal graft

If a free mucosal graft will be used for skull base reconstruction, it can be harvested from many sites, including (but not limited to) the nasal floor, the middle turbinate, or the nasal septum. Measurement of the skull base defect prior to collecting the graft is important in order to ensure that the graft harvested is the appropriate size. Many surgeons advise marking the mucosal side of the graft prior to removal in order to ensure that this side is positioned facing into the nasal cavity to allow vascularization.

If the middle turbinate is chosen as the donor site for a mucosal graft, the entire turbinate should be adequately visualized up to the axilla prior to beginning the harvest. Using a cutting instrument, such as a septal scissor or thru-cut, the middle turbinate should be cut in an anterior to posterior fashion just below the axilla. Care must be taken to avoid extending this incision superiorly and injuring the skull base. Once this incision has been made, the horizontal portion of the basal lamella should be transected as well taking care to cauterize the middle turbinate branch of the sphenopalatine artery without injuring the main trunk of the sphenopalatine artery in case it is needed in the future. The mucosa can then be harvested on the back table by separating it from the underlying middle turbinate bone using a Freer or Cottle elevator. This bone should be kept for possible use later in the reconstruction.

Nasal floor grafts can be harvested from the nasal floor between the septum and the inferior meatus. These grafts can encompass a large area when they are extended into the inferior meatus, along the lateral nasal wall, and can even be extended onto the nasal septum. Posteriorly, the graft should not extend past the hard palate in order to avoid damage to the musculature of the soft palate. Anteriorly, care should be taken around Hasner's valve and the mucocutaneous junction. Once all incisions have been made, the graft should be raised in a submucoperiosteal plane. All mucosal grafts should be kept in saline or saline-soaked gauze.

- If a nasoseptal flap (see Fig. 124.3) will be used for reconstruction, the sphenoid ostium is identified and entered on the side of the flap harvest.

The side of the flap is determined by several factors. First, if the skull base lesion requires dissection of the lateral pterygoid recess or the

pterygomaxillary fossa, then the vascular supply of the flap will be compromised; thus, a flap from the opposite side is used. Similarly, lesions that invade the rostrum of the sphenoid or the septal mucosa will mandate harvesting a flap on the contralateral side. If the skull base lesion is in the midline, and no significant lateral dissection is required, then sharp or large septal spurs that place the flap at risk for perforation during dissection may dictate the side from which the flap is harvested. The patient's right side is usually an easier dissection for the right-handed surgeon.

- The inferior incision begins inferolateral to the sphenoid ostium below the floor of the sphenoid sinus and is extended medially to cross the posterior choana.

  These incisions are typically made with needle-tip electrocautery and are ideally made in one smooth motion to stay in the same incision line. Suction should be placed at the edge of the nose in order to remove the smoke generated by the cautery.

- This inferior incision should be continued over the posterior aspect of the nasal septum curving inferiorly toward the floor of the nose to the level of the hard palate.

- The inferior incision should be continued anteriorly in a straight line along the junction of the septum and floor of the nose.

  The incision should be continued anteriorly as far as needed in order to create a flap that is large enough to cover the anticipated skull base defect. The entire ipsilateral mucoperiosteum and mucoperichondrium may be harvested to cover anterior skull base defects as large as from the posterior wall of the frontal sinus to the sella turcica and from orbit to orbit. Additionally, a wider flap may be harvested by extending the incision to include the mucoperiosteum of the floor of the nose.

- The superior incision begins at the sphenoid ostium and proceeds across the face of the sphenoid sinus medially with an upward slant over the rostrum.

- The incision should be carried anteriorly along the nasal septum approximately 10 to 15 mm below the most superior aspect of the septum.

  Preserving this mucosa is designed to leave olfactory epithelium in

place, in order to preserve olfaction.

- The two parallel incisions are joined anteriorly by a vertical incision at a level that is anterior to the plane of the anterior head of the inferior turbinate.

  If the defect is larger or a longer flap is required, this incision can be made as far forward as the mucocutaneous junction; and wider flaps can be extended onto the nasal floor. The flap is designed according to the size and shape of the anticipated defect, although it is best to slightly overestimate the size, and trim the flap if needed.

- Flap elevation starts anteriorly with a Cottle elevator or a small suction dissector.

  It is advantageous to complete all incisions before elevating the flap as it is difficult to orient the tissue and maintain tension once it has been elevated. Septal incisions may be completed with scissors or other sharp instruments as necessary. Elevation of the flap from the anterior face of the sphenoid sinus is completed with preservation of its posterolateral neurovascular pedicle.

- The flap is then placed in the nasopharynx or maxillary sinus (middle meatal antrostomy) until it is needed for reconstruction at the end of the procedure.

- Once the ablative portion of the procedure is complete, all mucosa is removed from around the defect, and attempts are made to create a planar surface for reconstruction.

  A planar surface results in better adhesion by the flap and makes placement of the inlay graft somewhat easier. Occasionally, creation of a planar surface requires obliteration of dead space with an adipose tissue graft. The mucosa surrounding the defect is removed before the flap is placed to prevent nonhealing or mucocele formation.

- Allogenic material or collage matrix is then placed as a subdural inlay graft.

  This inlay graft helps to obliterate the intradural dead space. The pliability and texture of cellular matrix often work well here and allow for safe manipulation around neurovascular structures. Ideally, this subdural graft should extend 5 to 10 mm beyond the dural margins in

all directions.

- A subsequent inlay graft of allogeneic material (either acellar dermis or collagen matrix) is then placed in the epidural space between the bone and dura edges if needed. Occasionally, the bony ledges are not adequate to support an inlay graft.
- The free mucosal graft or nasoseptal flap is placed as an onlay graft over the bony edges of the skull base defect (Fig. 124.4).

  Sealants are never used between the grafts or under the flap as this prevents direct tissue contact and proper healing.
- The edges of the flap are bolstered intranasally with oxidized cellulose absorbable packing.

  It is critical to separate the grafts from the nasal packing using some type of nonadherent material, such as absorbable gelatin sponge or film, as this will prevent traction on the grafts when the packing is removed. In addition, shifting of the underlying inlay/onlay grafts may occur during the placement of the packing; thus, the surgeon must be vigilant and perform placement of the packing under direct visualization with the endoscope.
- Placement of a 12-French Foley catheter balloon or 10-cm expandable tampon-type packing sponges is performed under direct endoscopic visualization.

  This packing is used to stabilize and bolster the inlay/onlay grafts and counteract intracranial pressure. Placement and inflation of the balloon catheter using 7 to 10 mL of saline are performed under direct endoscopic visualization. Care is taken to avoid over-inflation as this may result in excessive compression of intracranial structures.

Common Errors in Technique

- Graft or flap placed over a nonplanar defect or dead space (Fig. 124.5)

  Planar defects are particularly important when using a free mucosal graft, but an irregular surface can affect the success of the repair regardless of the technique. Closure of dead space with an adipose tissue graft can be used to create a planar defect and facilitate placement of the onlay graft. We are using dermal adipose tissue grafts

more often since they have a smoother dermal surface that can face outward.

- Mucosa left around the skull base defect

  Mucosa trapped under an onlay graft can lead to poor healing and mucocele formation.

- Flap or graft not adequately covering the bony edges of the skull base defect

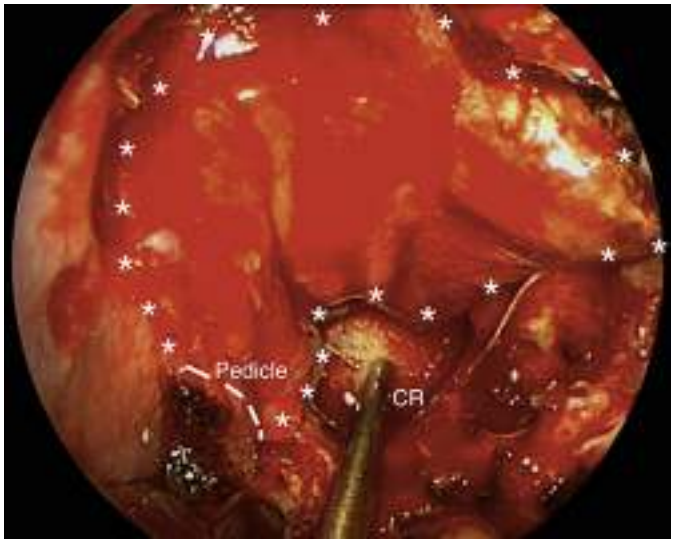

FIG. 124.4 Intraoperative photo of a right-sided nasoseptal flap onlay over a sellar and planar defect (astericks mark outline of flap). The pedicle was rotated, and the flap was placed above the clival recess (CR) to provide a flatter surface for reconstruction. Without a planar defect, the flap is usually transposed through the clival recess and sits more upright.

Grafts or flaps should be placed in a manner to provide complete coverage of the defect ensuring that all edges rest on skull base bone. This leads to a watertight seal and encourages healing with direct tissue contact. If there is a tear or perforation in the flap, we try to not place that over the dural defect. If this is unavoidable, then we may plug the flap defect with dermal grafts.

- Movement of the flap with packing placement (see Fig. 124.4)

Placement of packing materials, such as a Foley catheter or Merocel tampon, can cause significant movement of the onlay graft and should be performed only under direct visualization, taking care to place the catheter tip in the nasopharynx prior to inflating the balloon.

Postoperative Period

Postoperative Management

1. Forty-eight hours of bed rest if there is a high-flow intraoperative CSF leak

2. We do not routinely use lumbar drains in the postoperative period.

3. Elevation of the head of the bed to 30 to 45 degrees

4. A stool softener to prevent elevations of CSF pressure during bowel movements is important for proper graft healing.

5. Nasal packing or balloon is removed 3 to 5 days after the skull base repair.

6. Saline irrigations are started after removal of the packing or balloon.

7. The first débridement takes place 2 weeks after the surgery and consists of gentle removal of packing that is not adherent to the repair.

8. The second débridement takes place 4 weeks after surgery and consists of near complete removal of all remaining absorbable packing.

FIG. 124.5 Displacement of reconstruction into a craniofacial defect following the resection of a sinonasal cancer. Note that this patient was not leaking but was re-explored, and the reconstruction was revised to place the flap at the level of the anterior skull base.

9. Activity restrictions and cessation of continuous positive airway pressure (CPAP) use are maintained until 6 weeks after surgery.

Complications

1. CSF leak

Clear rhinorrhea in the postoperative period should be concerning for a CSF leak. The presence of a leak can be confirmed with endoscopic examination, beta-2-transferrin, topical placement of fluorescein-soaked pledgets into the nose, or by the use of intrathecal fluorescein.

2. Pneumocephalus

Some degree of postoperative pneumocephalus is expected after surgery. Asymptomatic patients can be managed expectantly and monitored closely. Increasing pneumocephalus on serial CT scans is indicative of a CSF leak and requires early exploration and repair.

Tension pneumocephalus is most often seen when positive pressure ventilation is used after the surgery. Patients with symptomatic tension pneumocephalus can be managed by returning to the operating room for take down of the skull base reconstruction and release of the pneumocephalus.

3. Hemorrhage

Injury to a major blood vessel, such as the carotid artery, can result in life-threatening hemorrhage and requires prompt control. Packing the nasal cavity can temporarily control bleeding until hemostasis can be achieved. Reconstruction with a nasal septal flap provides coverage of an injured vessel. Delayed reconstruction may be necessary after angiographic treatment and removal of nasal packing.

4. Mucocele

Repair of a skull base defect by a graft or flap that covers sinonasal mucosa or obstructs the outflow tract of a sinus can lead to mucocele formation.[5] All attempts should be made during the surgery to remove mucosa surrounding the skull base repair prior to placement of the graft or flap. Depending on the location of the defect, the surrounding sinuses should be opened widely to allow for drainage around the repair site. This may require that a wide sphenoidotomy, posterior septectomy, or modified Lothrop procedure be performed prior to the skull base repair. If a mucocele develops, it can be addressed via endoscopic drainage and marsupialization once the skull base repair has had adequate time to heal.

Alternative Management Plan

1. Extranasal flaps

If the defect is large or the nasoseptal flap is not available, the use of flaps from outside of the sinonasal cavity may be required.[2] Scalp flaps, such as the pericranial, temporalis, or temporoparietal flap, are other vascularized flaps that can be used and brought into the nasal cavity for skull base repair. Free tissue from elsewhere in the body, such as the radial forearm flap, also can be used in the sinonasal cavity to repair cranial vault defects. Placement of these flaps typically requires an open approach to the skull base to allow the pedicle to be brought out to the

donor vessels and in order for the large tissue bulk to be placed into the sinonasal cavity.

2. Lumbar drain and medical management

The removal of CSF via a lumbar drain can help remove pressure from the intracranial side of the skull base and aid in the repair of cranial vault defects. However, complications from these drains can be severe should they not be managed properly. As surgical technique for skull base repair has improved, there has been a shift away from using lumbar drains on small defects with low flow leaks.

Discussion

Evidence-Based Medicine Question

1. Should CSF diversion techniques, such as lumbar drains, be used routinely on high-flow CSF leaks?

High-flow CSF leaks are typically the result of entry into a basal cistern or the third ventricle. These leaks present an increased risk for a postoperative CSF leak and previously prompted many surgeons to place a lumbar drain for CSF diversion in the hopes of relieving stress from the reconstructed site. However, lumbar drains carry with them a 5% rate of minor complications and a 3% rate of major complications. This has prompted some surgeons to move away from the routine use of these drains as evidenced by multiple case series of high-flow leak repairs without the use of CSF diversion. A recent review by Tien et al. revealed that data on lumbar drain use are limited to nonrandomized, prospective, or retrospective data.[6]

However, recent data suggest no significant difference in the CSF leak rate after skull base repair when lumbar drains are used in addition to a multilayer skull base repair with vascularized tissue. This review suggests that the decision to use a lumbar drain should be made on a case-by-case basis and not used routinely even in the presence of a high-flow CSF leak. There are factors that would prompt a surgeon to consider the use of CSF diversion in a high-flow CSF leak. The presence of intracranial hypertension, an early postoperative CSF leak, previous radiation therapy, or the need for intrathecal fluorescein (which is

delivered much more uniformly into the cranial CSF by a drain compared with a puncture) is a factor that should push a surgeon to consider placing a lumbar drain.

2. Does the use of a vascularized mucosal flap improve the rate of postoperative CSF leak after skull base repair when compared to a free mucosal graft?

When EES was first developed, skull base repair was primarily performed using free mucosal grafts or exogenous grafting materials. Early postoperative CSF leak rates ranged from 5% to 35%. Through improved surgical techniques, the leak rate has decreased to 8.5% in recent reviews of skull base repair after EEA. This is believed to be due, in large part, to the increased use of vascularized mucosal flaps. Large systematic reviews performed by Harvey et al. and Soundry et al. demonstrate an improvement in postoperative CSF leak rates with the use of vascularized mucosal flaps.[5,7] Harvey et al. reported a statistically significant difference in the CSF leak rate between vascularized reconstruction (6.7%) and free graft reconstruction (15.6%).[7] Soundry et al. showed that in high-flow CSF leaks, an 82% success rate was found with free graft use while vascularized repairs were associated with a 94% success rate.[5] These reviews, and many others, demonstrate that skull base reconstruction after EES can be accomplished in multiple ways. However, the use of vascularized, multilayer closures is the mainstay for the repair of complex skull base defects and high-flow CSF leaks.

Editorial Comment

Historically, reconstruction of dural defects was one of the greatest challenges of EES. As surgical techniques and technology continue to improve, the rate of postoperative CSF leaks has declined. This chapter describes the key techniques of skull base reconstruction using free grafts and nasoseptal flaps, the two most commonly used techniques. Other local flaps include the middle and inferior turbinate (lateral nasal wall) flaps, which have limited applications. High success rates are observed using a wide variety of materials and techniques. The use of lumbar drains remains controversial but is generally reserved for large high-flow leaks or patients with risk factors for postoperative CSF leak. Our experience demonstrates that large defects of the anterior and posterior

cranial fossae benefit from CSF diversion, whereas sellar/suprasellar defects do not.

Other chapters in the Cranial Base Section describe the rationale for choosing a reconstructive method based on the site of the defect as well as regional flaps when local flaps are not available. The endoscopic skull base surgeon needs to be able to choose the best reconstruction based on the defect and the needs of the patient. Familiarity with both endoscopic and open techniques is necessary, especially when the first reconstruction fails.

Review Questions

1. Postoperative management after skull base reconstruction includes all the following, except

   a. Head of bed elevation to 30 to 45 degrees

   b. **Bed rest**

   c. Avoiding CPAP for at least 2 to 4 weeks

   d. Stool softeners

2. An ipsilateral nasoseptal flap may not be possible if tumor involves the following area(s):

   a. Rostrum

   b. Ethmoid sinus

   c. Pterygopalatine fossa

   d. **a and c**

   e. All of the above

3. Factors that may prompt a surgeon to use a lumbar drain after EES with skull base reconstruction include:

   a. Prior radiation therapy to the skull base

   b. Intracranial hypertension

c. Postoperative CSF leak

d. **All of the above**

Office-Based Procedures in Otology

Mark Whitaker

Introduction

In the practice of otology, the various surgical procedures extend along a spectrum from the clinic to the operating room. The procedures performed in the clinic recapitulate the same surgical techniques used in the operating room. For this reason, the process of refining one's surgical techniques begins in the clinic. The methodology, preparation, and calming bedside manner while performing procedures in the clinic can lead to a trusting patient-physician relationship.

In an era of medicine that is highly focused on cost-containment, the ability to perform procedures in an outpatient setting is encouraged. There are, however, situations where an office-based approach is not suitable. Sedation-based or general anesthesia will likely be required for children, anxious or uncooperative adults, the patient with a narrow ear canal, and for complex or time-consuming procedures. A thorough discussion with the patient regarding expectations regarding the duration of the procedure, levels of pain, noise involved, and the possibility of vertigo will have a positive impact on overall satisfaction.

Anesthesia

Prescient planning for an office procedure includes thorough attention to anesthesia considerations. A properly anesthetized surgical site will help maintain a calm patient and in turn, steady the surgeon's hands. As the surgical site expands in size, the options for anesthesia advance from topical agents and local anesthesia to regional blocks.

Topical Anesthesia of the Tympanic

Membrane

A number of topical agents have been studied for use on the intact tympanic membrane (TM). There are several considerations when choosing a topical agent. The ear must be meticulously cleaned in order for a topical agent to be effective. A thickened TM related to acute otitis media may require an extended treatment time or make a topical anesthetic ineffective. A perforated TM will allow the anesthetic agent to contact the middle ear structures, which may contribute to temporary facial nerve paralysis or vertigo.

Phenol

Phenol works as an effective topical anesthetic by creating a chemical burn that both anesthetizes the TM and provides hemostasis. This is the preferred topical anesthetic used for the TM. Excess use may contribute to scarring or irritation. It is used sparingly in a linear focal region for myringotomy and small focal regions for intratympanic injections. There are three options for application. A phenol applicator acts like a quill pen to deliver a precise amount of phenol. Other options include use of a small wisp of cotton on a metal applicator or via a disposable phenol kit with a sponge tipped applicator (Fig. 125.1). Care must be taken to ensure that the TM is dry in order to maintain a focal application. The patient must be informed that this method will cause a temporary burning sensation lasting seconds. Blanching of the TM is noted as immediately indicating the expected effect.

Tetracaine or Lidocaine

There are no standard concentrations of topical lidocaine or tetracaine. However, solutions of 4% to 10% lidocaine (amide) in saline or 8% to 10% tetracaine (ester) in isopropyl alcohol are the most commonly described preparations.

With the patient positioned supine with the head turned away, the medial half of the ear canal is filled with the predetermined anesthetic agent. The tympanic membrane must be treated for approximately 15 minutes for lidocaine and 60 minutes for tetracaine. Use of a cotton

pledget or an oto-wick placed in the ear will allow the patient to ambulate while allowing the allotted time to lapse. Before commencing with the surgical procedure, the solution should be removed completely from the canal and the site should be tested to ensure proper anesthesia.

Eutectic Mixture of Local Anesthesia Cream

Eutectic mixture of local anesthesia (EMLA) cream is an emulsion containing lidocaine 2.5% and prilocaine 2.5%, which is pH buffered to 9. This is easily applied to the TM with minimal risk of entry to the middle ear; however, it does not always provide adequate anesthesia. Furthermore, at least 1 hour is required for EMLA to be absorbed and take effect.

Anesthetic Options for the External Ear and Canal

Procedures involving the external ear generally can be performed in the outpatient setting. Depending on the site and extent of the procedure, topical, local, or regional anesthetics could be considered.

Topical Anesthesia

The benefit of providing an anesthetic without the need of a needle stick is favorable in children and in certain adults. EMLA or lidocaine-epinephrine-tetracaine (LET) can be used on intact or broken skin. LET is a combination of lidocaine (4%), epinephrine (0.1%), and tetracaine (0.5%) in an aqueous solution or gel.

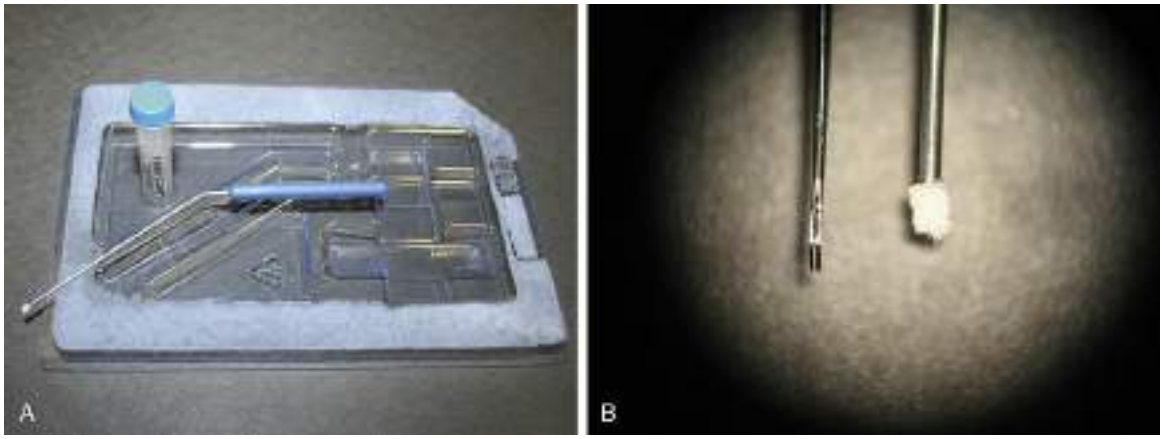

FIG. 125.1 Options for application of phenol to the tympanic membrane.

A, Prepackaged kit with sponge tip. **B,** Cotton on a metal applicator and Phenol applicator.

These agents are applied directly to the surgical field and are covered with an occlusive dressing for a minimum of 30 minutes for LET and 60 minutes for EMLA. The site is then tested with a pinprick in order to ensure that an appropriate level of anesthesia has been achieved.

Local Injection of Lidocaine With Epinephrine

The hemostatic benefits of added epinephrine in injected local anesthetic agents are well recognized. Several studies have demonstrated the safe use of injectable lidocaine with epinephrine in the external ear. Diluting the solution with a 1:10 ratio of bicarbonate to lidocaine will reduce burning at the injection site.

The injection site is swabbed with an alcohol swab. A smaller syringe (1 to 3 mL) will facilitate ease of injection, and a 25-gauge needle or smaller is recommended. The pain associated with injection will be minimized by injecting slowly, through use of distracting measures, and by minimizing the total number of skin punctures. The maximum dose of 1% lidocaine with epinephrine is 7 mg/kg up to 500 mg or 50 mL. The maximum dose of lidocaine without epinephrine is 4.5 mg/kg. The desired effect is generally noted in 2 minutes and should last for 4 to 6 hours.

Regional Anesthesia

Regional anesthesia can be employed for procedures involving the TM, the external auditory canal (EAC), and the pinna. The pinna and meatus of the EAC receive their sensory innervation from the third cervical nerve and from the trigeminal, facial, and vagal nerves (Fig. 125.2). The great auricular nerve and the lesser occipital nerves are branches of the third cervical nerve and cervical plexus. The great auricular nerve provides sensory innervation to the skin overlying the mastoid process and the inferior pinna. The lesser occipital nerve provides sensation to the middle section of the pinna. The auriculotemporal nerve, which is a branch of the mandibular branch of the trigeminal nerve, innervates the superior portion of the pinna. The auditory branch of the vagus supplies the concha and EAC. The EAC also receives innervation from the trigeminal and facial nerves and from the cervical plexus.

There are two regional blocks that are frequently used in order to facilitate procedures of the pinna, EAC, and TM. A four-quadrant EAC block will provide anesthesia to the canal and TM but not the pinna. An outer ear block will provide anesthesia to the pinna but not the EAC or TM.

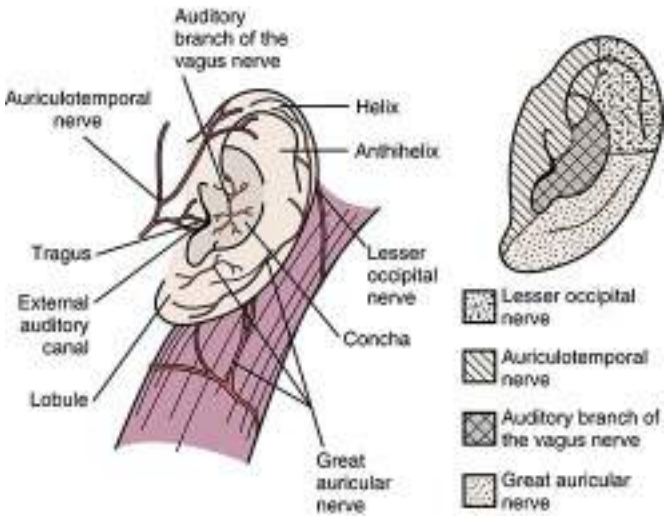

FIG. 125.2 Innervation of the auricle. Adapted from Roberts R, Hedges JR, editors. Clinical Procedures in Emergency Medicine, 4th ed. Philadelphia, PA: WB Saunders; 2004.

External Ear Block

Providing anesthesia to the entire pinna may be helpful for treatment of large auricular hematomas, laceration repairs, or excisions. This may be performed with only two injection entry sites, one each at the superior and inferior junction of the attachment of the pinna to the head (Fig. 125.3). A 10-mL syringe is filled with 1% lidocaine with epinephrine, and a 25-gauge needle is attached. The injection sites are swabbed with alcohol. The needle is advanced fully in a subcuticular plane while drawing back on the syringe in order to ensure that the injection is not administered intravascularly. While the needle is withdrawn, approximately 2 to 3 mL is injected. Without removing the needle completely from the injection site, the direction of the needle is altered to treat the posterior aspect of the pinna. Again, 2 to 3 mL is injected. This same procedure is repeated for the inferior pole of the pinna.

FIG. 125.3 Regional block of the pinna and external ear. Adapted from Roberts R, Hedges JR, editors. Clinical Procedures in Emergency Medicine, 4th ed. Philadelphia: WB Saunders; 2004.

Four Quadrant Canal Block

This technique again uses 1% lidocaine with 1:100,000 epinephrine. A smaller syringe, 1 to 3 mL, is used in order to provide greater dexterity and visibility with a 27-gauge needle. The needle is inserted at the bony cartilaginous junction with the needle advanced a few millimeters along the bone. An aural speculum is held with slight pressure applied to the canal wall lateral to the injection site in order to encourage medial diffusion of the anesthesia. The injection is performed with direct visualization of the medial canal in order to watch for blanching. Careful observation is employed to detect early signs of bleb formation, which is to be avoided.

Disimpaction of Cerumen

Obstruction of the ear canal with cerumen is the most likely cause of a conductive hearing loss in adults. The ear canal is naturally self-cleaning. Excess cerumen, dirt, dust, hair, and exfoliated squamous cells are expelled through gradual outward migration of the epithelium of the TM and external auditory canal. This process of self-cleaning can be interrupted by a narrow ear canal, use of a hearing aid, use of cotton swabs, and a prior history of radiation therapy to this region. If the self-cleaning process is not effective, physical débridement of cerumen by a clinician may be required. The task of removing cerumen generally falls on primary care physicians; however, there are instances where these techniques may not be effective or appropriate. Flushing the ear canal in the face of a perforated, retracted, or atrophic TM is not recommended.

Technique

Under microscopic vision, cerumen is removed with suction, wax curettes, Hartman forceps, or picks. In a large canal with a favorable shape, cerumen may be grasped easily with Hartman or small alligator forceps. In a narrow canal or if the canal is occluded by cerumen, the interface between the cerumen and canal wall should be identified. The contour of the canal is followed to the medial aspect of the cerumen or TM. The consistency of the cerumen will dictate the choice of suction,

picks, alligator forceps, or curettes. A small right angle pick is helpful in identifying the interface between the canal and the cerumen and for removal of cerumen impacted against the TM. For wet or soft cerumen, aspiration of cerumen is generally the most efficient method of removal. Generally, 5F suction is employed. The size of suction device should be reduced to 3F when working adjacent to the TM. A 7F suction device should be limited to the onset of the procedure if the canal is completely obstructed and should be quickly replaced with a 5F device in order to minimize noise exposure. Treating the cerumen with Colace may facilitate removal. To do this, the lateral canal is filled with Colace solution (docusate sodium liquid, 100 mg/10 mL) and should remain for 15 minutes prior to proceeding with removal.

Mastoid cavity débridement employs similar principles. Review of the prior operative note is helpful in order to determine the status of the TM, middle ear structures, horizontal semicircular canal, facial nerve, and tegmen. The degree of difficulty noted with mastoid cavity care is greatly dependent on the postoperative anatomy of the meatus and mastoid. It is important to remove all squamous and ceruminous debris. Some moisture medial to the debris may be revealed, which may be dusted with Boric acid powder in order to prevent infection. Excessive moisture may be cleared with suctioning; however, this commonly leads to complaints of dizziness. Swabbing the mastoid cavity with cotton held by an alligator forceps or metal applicator may limit the need for suction. The use of a smaller diameter suction device will minimize dizziness.

Drainage of a Hematoma of the Auricle

Hematoma of the auricle is most commonly noted in wrestlers but is also seen in other sports such as boxing and rugby. Hematoma of the auricle is formed by a shearing force, which separates the skin and perichondrium from the underlying cartilage. Wrestling headgear and rugby scrum caps help reduce the incidence of auricular hematomas.

Cartilage receives its blood supply from the overlying perichondrium. A shearing injury will cause a collection of blood separating the vascular supply from the cartilage, which will result in cartilage necrosis. “Cauliflower ear” is the term used to describe the altered appearance of the pinna related to subsequent fibrosis, contracture, and formation of

reactive or calcified perichondrium. The urgent treatment of auricular hematoma is encouraged in order to reestablish the blood supply to the cartilage and avoid this sequela. The resulting deformity of the pinna is primarily a cosmetic concern; however, thickening of cartilage in the conchal region may lead to a collapsing ear canal and hearing loss.

Preoperative Period

A careful history is obtained in order to determine the mechanism of injury as well as the duration of time that has lapsed since the injury. Athletes may be unwilling to miss practice or competition during the healing process. In this instance, bulky dressings and simple needle aspiration should be avoided. Open exploration may be required in recurring hematomas.

Surgical Technique

Incision and drainage is the preferred method of treatment, as this technique provides a lower risk of recurrence compared to needle aspiration. All hematomas, including those that are multiloculated and intracartilaginous, can be successfully treated with this technique. The pinna is treated with surgical preparation solution. Anesthesia of the pinna is obtained by using a regional nerve block. An incision is created in the helical or antihelical fold to conceal the scar. Blood and serous fluid are expressed from the incision facilitated by digital compression. A fine hemostat may be introduced into the incision in order to ensure that any loculations are incorporated into the pocket. Once the hematoma is completely evacuated, a small sterile rubber band or a Penrose drain may be placed. The success of this procedure relies on proper placement of a compression dressing. A bolster dressing has been demonstrated to be effective against recurrence despite immediate return to contact sports. A dental roll is cut to the size of the hematoma with a similar or slightly smaller size used on the medial surface of the pinna. This can also be supported using Silastic sheeting (0.04-inch thickness). 3-0 nylon or silk suture on a Keith needle is inserted through the dental roll and passed through the pinna in a lateral to medial fashion. It is then passed through the medial dental roll and back through the medial roll again. The suture is then passed through the pinna in a medial to lateral fashion and then

through the lateral dental roll. The dental rolls and incision site are coated liberally with an antibiotic ointment. This creates a mattress suture, which is then tied to secure the bolster (Fig. 125.4).

FIG. 125.4 Penrose drain and Silastic bolsters in place for treatment of auricular hematoma.

Postoperative Period

After draining the hematoma, the patient is monitored for signs of recurrence or infection. Oral antibiotics are used while the bolster is in place. The bolster is removed in 5 to 7 days. Patients are instructed to watch for evidence of recurrence of the hematoma.

Incision and Drainage of an Ear Abscess

The external ear is a common site of local infections that require incision and drainage of a fluctuant collection of purulent exudate and necrotic tissue. These infections can be as small as a furuncle in the canal or as extensive as a subperiosteal abscess. They will sometimes drain spontaneously or after treatment with warm compresses and manual manipulation. Antibiotics are seldom necessary but should be considered in cases with significant concomitant cellulitis.

Perichondritis, or inflammation of the perichondrium, and chondritis, or inflammation of the cartilage, may lead to true abscess formation and

require incision and drainage. Débridement may be necessary to contain or resolve the infection. The auricular cartilage is relatively avascular, with a consequent diminished capacity to clear an infection and limited delivery of systemic antibiotics at adequate minimal inhibitory concentrations.

All patients with an acute formation of a painful fluctuant mass in the ear require drainage. Although some furuncles can be managed with warm compresses and manual expression, incision and drainage may be required. In the early stages of infection of the ear, a true abscess may not have formed. High-dose systemic antibiotics can sometimes prevent abscess formation. These patients will require close monitoring in order to determine if the infection resolves or if an abscess requiring drainage has developed.

Preoperative Period

Antibiotic prophylaxis should be considered in transplant or other immunocompromised patients, diabetics, alcoholics, and patients receiving chemotherapy or steroids.

The size and cause of the abscess will determine what type of drainage procedure is appropriate. A small abscess may require only a small drain for a few days, while a larger abscess will likely require a more elaborately planned procedure and postsurgical plan. The incision should be planned so that it does not hinder future reconstructive procedures when treating infections that are likely to cause destruction of cartilage.

Surgical Technique

Injection of local anesthetic at several points lateral to the abscess generally suffices for incision and drainage of furuncles. An abscess involving the pinna may be incised with a no. 11 blade. An abscess situated in the EAC may be accessed more readily with a myringotomy blade.

For a larger abscess, a regional ear block may be required. The abscess is incised with a no. 15 blade along the natural contour of either the helical or antihelical fold. The purulent exudate is collected and sent for

culture. The abscess cavity must be completely evacuated with all loculations incorporated into the main abscess cavity. The cartilage is examined and any necrotic cartilage is débrided. It is possible that the cartilage may need to be débrided again, but staged débridement helps to minimize the size of the helical rim deformity. If extensive necrosis of the cartilage is noted, performing the procedure in the operating room may be advised. Once the cavity is adequately débrided, it is flushed with saline. The incision is not closed and use of a drain should be considered.

Postoperative Management

Furuncles do not generally require follow-up, but the patient should return if the pain or swelling worsens, recurs, or if the infection has not resolved in 1 week. Patients with an abscess of the auricle should be instructed that it may take several weeks for the infection to clear completely and that they are at risk for recurrence during this time. If the infection recurs, it should again be drained immediately with débridement of necrotic tissue. If a defect in the auricular rim develops, the patient should be offered consultation for reconstruction of the rim.

BOX 125.1 Masses in the External Ear Canal

Benign

Cholesteatoma

- Eosinophilic granuloma
- Exostosis
- Fibrous dysplasia
- Keratosis obturans
- Neurofibroma
- Osteoma
- Paraganglioma/schwannoma

Stenosis

Temporomandibular joint herniation

Vascular lesions

Malignant

Adenocystic carcinoma

Basal cell carcinoma

Cerumen gland tumor

Malignant melanoma

Metastatic cancer

Soft tissue sarcoma

Squamous cell carcinoma

Biopsy of a Mass in the External Auditory Canal

Detection of a mass in the EAC may occur during routine otologic examination. A mass may also be associated with hearing loss, otalgia, otorrhea, or bleeding. Masses in the EAC may be benign or malignant (Box 125.1). Certain lesions may be diagnosed by otologic examination alone. For example, osteomas and exostosis can be diagnosed based on their classic appearance and by gentle palpation. Patients presenting with recent onset of pain and drainage may have lesions best treated with topical drops containing both an antibiotic as well as a steroid prior to considering biopsy.

Polyps may arise from a tympanic membrane perforation or related to cholesteatoma. Caution should be used with polyps arising from the posterior canal wall or if the site of origin is not easily identified. Approximately 13% of facial nerve schwannomas present as a mass in the ear canal.[1] If the site of origin cannot be identified, CT imaging is recommended in order to evaluate the facial nerve prior to removing a polyp. When safe to proceed, removing a polyp should be followed by treatment with steroid/antibiotic drops. Treatment in this fashion will reduce inflammation, which will facilitate a definitive surgical procedure.

Removal of an inflammatory polyp can typically be performed without anesthesia. Cupped forceps are used to remove the polyp.

Malignant otitis externa must be considered in the differential diagnosis regarding a mass in the ear canal, particularly in patients with diabetes. Granulation tissue noted at the bony-cartilaginous junction is characteristic of malignant otitis externa; however, biopsy of the granulation tissue is recommended in order to rule out a malignancy. Of special consideration is the pulsatile mass as seen in large glomus tumors. Biopsy of these lesions in the office is strongly discouraged, due to the high vascularity of this tumor, resulting in bleeding that is difficult to control in the office setting.

Instruments and Equipment to Have Available

The surgeon should have the following readily available: appropriate sized speculums, 5F suction devices, fine cupped forceps, Belucci scissors, epinephrine diluted to 1:10,000 or silver nitrate for topical application, specimen collection container, and bacitracin for topical application after the procedure.

Postoperative Management

Topical therapy with antibiotic and steroid drops is recommended for inflammatory processes. Follow-up in one week should be arranged for evaluation of the biopsy site and in order to discuss the results of the biopsy.

Intratympanic Injections

Intratympanic injections of gentamicin and corticosteroids have become very popular outpatient treatments for conditions such as Meniere disease (MD) and sudden idiopathic sensorineural hearing loss (SSNHL). This treatment is very well tolerated, is not time consuming, does not require an extended time of convalescence, and is repeatable. The puncture site typically closes in a few weeks. There is a low risk of

associated infection or persistent perforation.

The round window is the main site of chemical diffusion to the inner ear. Obstruction of the round window membrane reduces absorption of the medication.[2] There are various delivery techniques described in the literature. Intratympanic injection is the method preferred by the author.

Intratympanic Gentamicin

The treatment of MD-related vertigo generally proceeds in a stepwise approach. When patients fail to respond to conservative measures with dietary changes and diuretics, more aggressive measures are employed. Intratympanic gentamicin (IT- GENT) is a favored treatment. It can be used as a standard (high-dose regimen) or a low-dose regimen for partial or total chemical vestibular ablation. This treatment is a repeatable, low cost ablative therapy, which selects the involved ear, and may eliminate the need for surgical intervention.

Gentamicin is the most commonly used aminoglycoside due to the fact that it has a relatively greater vestibular toxicity compared to its cochlear toxicity. It causes a partial destruction of the vestibular hair cells and of the dark cells. Streptomycin is not generally used because it has been demonstrated to cause a poorer hearing outcome and lower rate of control of vertigo.[3] This treatment affords a 90% rate of control of MD-related vertigo. The incidence of hearing loss has been listed between 30% and 17%.[4] The higher incidence of hearing loss was noted with an ablative high-dose treatment regimen as opposed to the currently favored conservative low-dose regimen.

Intratympanic Corticosteroids

Intratympanic steroid injection has been advocated for treatment of both SSNHL and MD. It has been demonstrated that intratympanic administration provides a higher steroid concentration compared to systemic therapy.[5] It has been described as a salvage therapy for SSNHL; however, some clinicians are offering this as first-line treatment.

Indications

Intratympanic Gentamicin

As an ablative procedure, conservative therapies should have been tried and failed prior to considering IT-GENT. Furthermore, the diagnosis of MD should be confirmed with careful discussion and review of the characteristics of the vertigo episodes. Other potentially similar causes of vertigo, such as vestibular migraine, benign paroxysmal positional vertigo, and superior semicircular canal dehiscence, should be ruled out by history, physical, audiometric and vestibular testing, and imaging. Other nonablative options should be reviewed, including subcutaneous histamine injections and use of a Meniett device (Medtronic), as well as surgical options such as endolymphatic sac decompression, labyrinthectomy, and vestibular nerve section. The risks of IT-GENT need to be discussed, including persisting TM perforation, permanent hearing loss, increased tinnitus, and chronic disequilibrium and their associated implications. The risk of MD affecting the contralateral ear should be reviewed. Patients should be counseled to expect the possibility of disequilibrium for several days after treatment. Vestibular physical therapy could be initiated prior to the IT-GENT if possible. Caution should be used prior to treating elderly patients, visually impaired individuals, and patients with peripheral neuropathy due to the increased difficulty compensating for the unilateral weakness. Gentamicin should not be used in patients who have MD affecting the only hearing ear.

Intratympanic Dexamethasone

A recent multicenter trial has demonstrated similar hearing responses with use of oral and intratympanic steroids.[6,7] Intratympanic dexamethasone (IT-DEX) may be used in combination with prednisone, as a salvage therapy for those with persisting sudden sensorineural hearing loss,[8] or in patients who may not tolerate systemic steroid therapy.

Preoperative Preparation

Pure tone audiometry should be performed before each injection of either gentamicin or dexamethasone. Vestibular testing should be performed

prior to treatment with IT-GENT in order to ensure that the contralateral ear does not demonstrate hypofunction, which would be a contraindication to ablative therapy. In MD, elevated thresholds are often noted on vestibular evoked myogenic potentials. Patients with SSNHL should undergo contrast-enhanced magnetic resonance imaging (MRI) in order to rule out a retrocochlear process such as a vestibular schwannoma. The first treatment with IT-DEX should not be delayed until after the MRI is obtained, as prompt initiation of treatment is associated with a better prognosis for hearing recovery.

Surgical Technique

The patient is positioned supine with his or her head turned 45 degrees away with the treatment ear up (Fig. 125.5). The tympanic membrane is anesthetized with topical phenol applied to focal regions anterior superiorly and posterior inferiorly. A tuberculin syringe with a 1.5-inch 25-gauge needle is filled with 0.6 mL. A fully filled tuberculin syringe is difficult to handle due to the position of the plunger being beyond the reach of the thumb of the injecting hand. The needle is gently bent in order to provide adequate visualization of the TM and the rising air fluid level (Fig. 125.6). A puncture is made in the anterior superior TM, which provides a means for air to escape from the mesotympanum during the injection. Through the posterior inferior puncture, roughly 0.4 mL of solution is injected into the middle ear space. The gentamicin solution is buffered with sodium bicarbonate at a final concentration of 30 mg/mL. Depending on the availability of a compounding pharmacy for preparation, the concentration of dexamethasone solution is from 10 mg/mL to 24 mg/mL. Methylprednisolone has been used but is associated with a greater sense of discomfort during the injection. The medication is slowly injected into the middle ear space, while the air fluid level is followed to the level of the anterior superior puncture site. The injection is completed once the middle ear is filled and a small efflux of medication is noted in the ear canal. The needle is withdrawn and the patient remains supine for 25 minutes. A basin and tissues are provided to the patient, who is instructed to spit secretions and to avoid swallowing in order to minimize rapid clearance of the medication from the middle ear space.

FIG. 125.5 The injection is performed with the patient's head turned 45 degrees away from the affected ear. He remains in this position for 25 minutes and is provided with tissues to handle saliva to avoid swallowing.

FIG. 125.6 Bending the needle slightly allows better visualization during the injection.

Postoperative Management

Intratympanic Gentamicin

Dry ear precautions are recommended until follow-up in 4 weeks. At the follow-up visit, if the patient continues to complain of episodes of vertigo, the injection can be repeated. Audiometry is repeated before each injection and 2 months after the last injection. Diuretic therapy and

dietary recommendations are maintained during the course of treatment.

Intratympanic Dexamethasone

Dry ear precautions are recommended and follow-up in 1 week is arranged for repeat audiometric testing. If an improvement is noted without return to baseline, repeat injection is performed. Injections are performed on a weekly basis for 3 weeks until the hearing returns to baseline or improvement plateaus.

Myringotomy and Insertion of Tubes

Myringotomy with or without tube insertion is commonly performed in the outpatient setting for management of chronic otitis media with effusion, complicated acute otitis media, and for eustachian tube dysfunction. Other less common indications are for access of the middle ear for medication delivery and to provide ventilation for hyperbaric oxygen therapy in patients who are unable to clear their ears. Most adults and many older children are able to tolerate myringotomy and tube insertion in the clinic with use of local anesthesia. The choice of tube style is generally determined by physician preference; however, smaller tubes are chosen for short-term therapy, midsize tubes are used for chronic otitis media with effusion, and larger lumen tubes are considered for patients with mucoid effusions. Longer lasting Goode T-tubes may be placed in the clinic setting with local anesthesia in a cooperative patient with a favorably sized ear canal; however, placement of the T-tube may require sedation in an operative setting due to its size and the relative technical difficulty associated with proper placement.

Preoperative Preparation

All patients are examined using an operating microscope. Pneumatic otoscopy should be included, as this will occasionally reveal evidence of an effusion that may not otherwise be noted. Tuning fork testing will help confirm a conductive hearing loss; however, formal audiometric testing is recommended for diagnostic and medico-legal purposes. Any adult with a unilateral effusion should undergo examination of the nasopharynx in order to evaluate for possible adenoid hypertrophy or

mass lesion. The need for water precautions is discussed prior to tube placement, and avid swimmers may prefer either to be fit with custom earplugs or to continue nonsurgical treatments.

A myringotomy without tube insertion will generally close spontaneously in days and is therefore not recommended for chronic otitis media with effusion. Acute serous effusions in the setting of allergies or upper respiratory tract infections usually resolve spontaneously, and therefore, tube insertion is not recommended. Treatment of allergy symptoms, frequent autoinsufflation, and use of decongestants are recommended. Myringotomy is not recommended for initial treatment of acute otitis media; however, it may be considered for pain relief. Myringotomy and tube insertion are recommended when acute otitis media does not respond to antibiotic therapy. It is also recommended for acute otitis media complicated by facial nerve paralysis, vertigo, sensorineural hearing loss, mastoiditis, or intracranial complications. Vascular anomalies (aberrant carotid artery or dehiscent jugular bulb) and glomus tumors may be mistaken for effusion and may need to be ruled out with imaging prior to myringotomy in order to avoid the risks of bleeding and neurovascular complications.

Instruments and Equipment to Have Available

The surgeon should have the following readily available: appropriate sized ear speculums, cerumen curettes, phenol, phenol applicator, myringotomy knife, 3F and 5F suction devices, fine alligator forceps, a fine right-angled or gently curved pick, and an assortment of different style tubes, depending on the indication for placement. Topical epinephrine should also be accessible for bleeding related to an inflamed tympanic membrane.

Surgical Technique

Positioning the patient from a sitting to a fully recumbent position is based on clinician preference. The procedure is performed with use of lower magnification on the operating microscope in order to provide greater ease of instrument handling. It is important to be mindful of the walls of the ear canal in order to avoid bleeding or discomfort. Myringotomies are performed either in an anterior inferior or a posterior

inferior location. The posterior superior quadrant is avoided in order to avoid trauma to the ossicles. The anterior superior quadrant may be difficult to access if there is a prominent anterior canal wall overhang. Phenol is applied directly to the planned myringotomy site, and a radial myringotomy is performed. The type of tube used will dictate tube handling for placement. Generally, bobbin style tubes are grasped on their lateral flange and are positioned partially in the myringotomy. A fine pick is used to gently insert the medial flange through the TM. Some tubes may be placed with one fluid motion; however, a stepped technique will allow less tension to be applied to the TM and therefore less discomfort for the patient.

Postoperative Management

Serous effusions do not require treatment with antibiotic drops. However, if bleeding is encountered, with evidence of infection, or if a thick mucoid effusion is identified, use of antibiotic drops with or without steroids for 5 to 7 days may help resolve the infection more rapidly and prevent obstruction of the tube. Follow-up in 1 month followed by every 6 months is recommended until the tube extrudes. Very close monitoring is recommended in patients with complications of acute otitis media requiring tube insertion.

Editorial Comment

As reviewed by the author, a significant varied list of otologic procedures can be performed in the office or clinic. In order to avoid complications or anxiety and pain to the patient, it is important for the surgeon to realize the limitations imposed by the procedure and tolerance of the patient. The operative skills of the surgeon can be more critical and demanding in this setting. Training and experience in this regard comes from procedures performed in the operating room, where techniques can be mastered in a controlled environment.

Intratympanic therapies have transformed the delivery and outcomes of previously limited treatment options. Gentamicin instilled into the middle ear has provided an excellent means of controlling vertigo attacks from Meniere disease, avoiding more complicated operative interventions.

Since the patient is fully awake, it is important to have the office equipped with anticipated medications, dressings, and instruments needed to complete these procedures. The physician should have a reassuring demeanor to put the patient at ease in this potentially challenging setting.

Review Questions

1. Which of the following agents can be used for topical anesthesia for office-based procedures in otology?

   a. Phenol

   b. LET

   c. EMLA

   d. **All of the above**

2. Which of the following lesions of the ear canal does not require biopsy for diagnosis?

   a. Paraganglioma

   b. **Exostosis**

   c. Adenocystic carcinoma

   d. Squamous cell carcinoma

3. What is the incidence of hearing loss with low-dose intratympanic gentamicin treatment for Meniere disease?

   a. 90%

   b. 50%

   c. 30%

   d. **17%**

Foreign Bodies of the External Auditory Canal

Douglas M. Hildrew, and Barry Hirsch

Introduction

The acute event resulting from entrapment of a foreign body in the ear canal will bring most patients to the attention of a physician, physician's assistant, or nurse practitioner. Patients may be treated in a variety of settings including an emergency room, clinic, or office. It is important to note that different age- and gender-specific patterns emerge in describing the specific types of foreign bodies found within the external auditory canal.[1] A recent review of the National Electronic Injury Surveillance System (NEISS), a database that tracks injuries caused by consumer products, revealed that children between the ages of 2 and 8 were the most common age group affected. Jewelry was by far the most common foreign body seen in the young population, with beads and earrings being the most frequently identified types.[1] Among adults and senior citizens, the most common offenders were cotton swabs and first aid supplies.[1] After ear cleaning, a person may realize that the cotton tip is no longer attached to the end of the applicator. Senior citizens are also uniquely vulnerable to the accidental insertion of disk batteries owing to altered cognition, reduced tactile sensation, and the more frequent use of hearing aids.[1]

Adolescents and/or adults may become immediately aware that an object that they were using to clean or manipulate the ear has become dislodged and remains in the external auditory canal. The most common inorganic object creating this problem, as already stated, is the end of a cotton-tipped applicator. Similarly, other materials (e.g., facial tissue and paper) can be rolled in an elongated fashion and used to either probe, clean, or pack the ear. Institutionalized adults and children may use these

materials instead of cotton-tipped applicators, medical packing, or earplugs. In this population, if drainage, infection, or odor has not developed, such material may be found only on routine physical examination.

Along with using instrumentation to clean their ears, adults also place objects in the ear canal for protection, including devices to minimize water exposure because of recurrent otitis externa or perforation of the tympanic membrane. Materials used for hearing protection can become lodged or break off and remain in the external canal. Examples of such products include silicone putty used for sound or water protection and Silastic occlusive plugs or foam inserts for sound protection. Again, patients become acutely aware of broken off materials remaining in the ear canal.

The list of objects that children put in their ears is endless. Unless a witness observes a child placing a foreign body in the canal, its presence may not be discovered until routine physical examination detects the object or problems arise because of its presence. Objects that occlude the ear canal can produce hearing loss. This is a common chief complaint in an aware child or adult. Inflammation caused by the foreign object may result in infection and drainage. Localized aural discharge, cellulitis of the concha and external meatus, or serosanguineous otorrhea would prompt further evaluation. Some materials are more difficult to extract from the ear canal. Once water enters the external canal, vegetable materials such as beans and peas can swell and cause obstruction, pain, and maceration. Other materials that have been found in the ear canal include small toys, beads, erasers, crayons, pits from fruit, disk batteries, nuts, and stones. Disk batteries should be removed as soon as possible to avoid the liquefaction necrosis that results when moisture and secretions permit the flow of electrons.[2] Irrigation of the ear canal should be avoided to minimize the risk of generating an electric current. Similarly, unsuccessful attempts at removal of the battery that result in trauma and bleeding in the ear canal would also allow flow of current and thus lead to further tissue destruction.

Insects occasionally find their way into the ear canals of children and adults alike. These are usually flying insects, but crawling insects may also enter the canal, especially when a person is sleeping. Patients become acutely aware of such a situation because of the noise generated

by the insect and the associated pain. Management in this situation becomes more urgent than that called for by inanimate objects.

Key Operative Learning Points

1. Aural irrigation to remove foreign bodies (other than insects) in the external auditory canal should be avoided because the object is rarely flushed out and skin maceration often results.

2. Firm, rounded objects are notoriously difficult to grasp and remove.

3. Live insects should be drowned with alcohol, mineral oil, or topical anesthetics (Pontocaine, Xylocaine).

4. A large nasal suction (10-12 French) device may make sufficient contact with the object to remove it from the canal.

5. Passing a right-angled hook parallel to the object and then beyond it allows optimal placement of instruments for extraction.

6. Injection of a local anesthetic followed by canal dilatation with progressively larger specula may facilitate removal of the foreign body.

7. Ease of extraction is directly proportional to the number of previous failed attempts.

Preoperative Period

History

1. History of present illness
   a. Risk factors: Infants and children
   b. Onset: Was the foreign body insertion observed?
   c. Location: What items were around the infant/child at the time of insertion?
   d. Duration: Approximately how long has the foreign body been in place?
   e. Other: Are there any disk batteries and/or hearing aids in the house?

f. Pain

g. Drainage/odor

h. Bleeding

i. Hearing loss

j. How many times has extraction been attempted and by whom?

2. Past medical history

a. Prior treatment

1) If there is a history of previous foreign bodies and infection (Beware of canal stenosis.)

2) If there is a history of recurrent infection and drainage, the foreign body may have been present for weeks or months.

3) If there is a history of recurrent infection, the ear canal skin may be friable and hypervascular.

b. Medical illness

1) Diabetes mellitus

c. Surgery

1) If there has been previous otologic surgery, determine its extent and type.

a) Canal wall down can put the facial nerve at risk.

b) Congenital anomalies can cause canal stenosis.

d. Family history

1) Clotting disorders can be inherited.

e. Medications

1) Antiplatelet/anticoagulant drugs

Physical Examination

1. Binocular microscopic otoscopy

a. Evaluation of both ears

2. Anteroposterior rhinoscopy

a. Evaluation for coexisting foreign body

3. Larynx

a. Specifically listen to and observe breathing patterns.

1) If concern arises for a coexisting foreign body, consider flexible fiberoptic laryngoscopy.

4. Pulmonary

a. Auscultate for evidence of a coexisting aspirated foreign body.

1) If concern arises for a foreign body, consider chest radiography.

Imaging

1. Chest radiograph

a. Not routinely necessary

b. Consider if there is concern for a coexisting foreign body in the tracheobronchial tree

2. Computed tomography (CT) scan

a. Not routinely necessary

b. Consider if patient has a history of extensive otologic surgery, disease, or the medial extent of the foreign body is in question

3. Magnetic resonance imaging (MRI)

a. Not routinely necessary

b. Consider if patient has a history of extensive otologic surgery or disease and there is concern for meningoencephalocele or cerebrospinal fluid (CSF) otorrhea

4. Audiogram

a. A baseline audiogram should be obtained if it is anticipated that removal of the foreign body requires monitored anesthesia care (MAC) or general anesthesia.

Indications

1. Painful or draining ear

2. Concern for a foreign body

3. Hearing loss

Contraindications

1. An uncooperative patient may require MAC or general anesthesia.

Preoperative Preparation

1. In most situations, removal of a foreign body is an elective event.

   a. Permits planning in terms of the appropriate instrumentation, lighting, the type of anesthesia (if needed), and the method of extraction

2. The patient should be relaxed and calm.

   a. Facial grimacing contracts and moves the external auditory canal.

   b. Uncooperative patients may suffer iatrogenic trauma.

3. Exploration of the ear under intravenous sedation or general anesthesia should be considered for patients who may have damage to the ossicular chain or inner ear.

   a. General anesthesia will probably be necessary for most children and anxious, uncooperative adults.

   b. Patients with acute hearing loss and dizziness should be suspected of injury transmitted to the inner ear.

      1) An audiogram and CT scan should be obtained for suspicion of violation of the tympanic membrane.

Operative Period

Anesthesia

- Extraction of a foreign body is most frequently performed in the clinic without anesthesia.

- A particularly anxious, difficult, or mentally challenged patient may require MAC anesthesia.
- If there is severe acute infection from prolonged exposure to a foreign body, general anesthesia may be required.

Positioning

- Position the patient so that a head rest is seated comfortably, stabilizing the head.
- A papoose may be necessary for uncooperative infant/children, but this inevitably exacerbates patient anxiety and should be avoided if possible.
- Extraction can be accomplished with the patient in either a supine or upright position.

Preoperative Antibiotic Prophylaxis

- Clean contaminated procedure
- Preoperative antibiotics are generally not required.
  - Consider if the patient shows signs of cellulitis
- Postoperative antibiotics may be needed.
  - Traumatized external auditory canal
  - Otitis externa or surrounding cellulitis
- Antibiotic choices
  - Systemic: Amoxicillin, amoxicillin-clavulanate, clindamycin, cepahlosporin
  - Ototopical: Ofloxacin, ciprofloxacin/dexamethasone, neomycin/polymyxin-B/hydrcortisone

Monitoring

- Routine anesthesia monitoring only if patient required MAC or general anesthesia

Instruments and Equipment to Have Available

- Binocular otologic microscope
- Hydrogen peroxide, isopropyl alcohol, mineral oil
- Injectable lidocaine with epinephrine, syringe, and 25-gauge needle
- Otologic specula
  - Size: 3, 4, 5, and 6 mm
- Suction and suction tips
  - Size: 3, 5, 7, 10, and 12 French
- Forceps
  - Small alligator and Hartman-style forceps
- Right-angled hook
- Cerumen curette
- Wire cerumen loop
- Silver nitrate
- Cotton-tipped applicator
- Ear wick
- Ear irrigation kit (rarely used)

Key Anatomic Landmarks

1. Pinna, conchal bowl, and external auditory canal

2. Tympanic membrane and ossicles

3. If previous otologic canal wall down surgery or congenital anomalies, one must ensure they are oriented to the facial nerve, lateral canal, oval window and round window

Prerequisite Skills

1. Binocular microscopic otoscopy and fine motor skills
2. Thorough understanding of the anatomy of the ear

Operative Risks

1. Laceration to the skin of the external auditory canal
    a. Cellulitis
    b. Bleeding
2. Perforation of the tympanic membrane
3. Ossicular trauma
    a. Ossicular dislocation
    b. Conductive hearing loss
    c. Fractured stapes
    d. Perilymphatic fistula
    e. Sensorineural hearing loss
    f. Vertigo
4. Postoperative canal stenosis
5. Infection
    a. Adult or pediatric patients with otorrhea, hearing loss, and obstruction or occlusion of the ear canal who fail to respond to topical and systemic therapy may have pathology of the middle ear and mastoid or foreign bodies causing their symptoms and findings.
    b. If medical therapy fails to reduce the inflammation that limits visualization of the medial canal and tympanic membrane, a CT scan would be appropriate to assess the status of the external canal, middle ear, and mastoid.

Surgical Technique

Foreign bodies can be categorized not only by their chemical composition but also by their shape and consistency. Understanding the physical

properties of a foreign body facilitates the choice of method for removal. Soft and wet objects similar to cerumen can be suctioned or flushed from the canal. Firm or hard foreign bodies require specific instruments for extraction. Round objects may become wedged at the bony isthmus or the junction of cartilage and bone. Small foreign bodies may shift to the medial canal and become caught in the anteroinferior sulcus between the tympanic membrane and the bony canal.

The success and/or difficulty of foreign body extraction from the external auditory meatus is strongly influenced by the number of previous failed attempts.[3] Since removal of a foreign body may be attempted first by emergency department personal and pediatricians, the otolaryngologist may encounter significant edema of the canal skin.[3] One may also find that the foreign body is located medial to the bony cartilaginous junction as a result of previous failed attempts—a situation that can be particularly challenging.

FIG. 126.1 A large-gauge suction is usually successful in removing most objects from the external auditory canal. Care must be taken to not push the foreign body more medially.

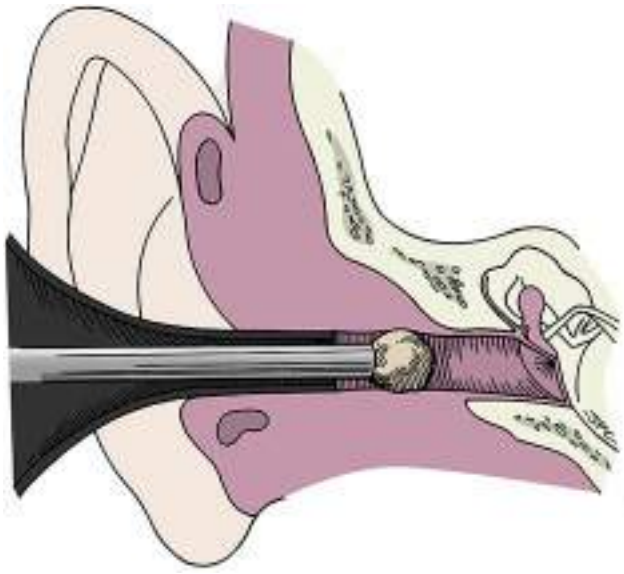

FIG. 126.2 A right-angled hook is passed beyond the object, which is then extracted laterally.

- *Removal of jewelry*
  - Removal should not be unnecessarily delayed.
    - Timely treatment reduces the opportunity for resultant edema of the external auditory canal and otitis externa
  - Beads can be hard and smooth, making them difficult to remove because they cannot be readily grasped.
  - A large nasal suction (10-12 French) device can be most useful if it is possible to create a seal between the suction tip and the foreign body (Fig. 126.1).
  - A right-angled hook placed behind the foreign body can be a well-suited method of extraction (Fig. 126.2).
- *Removal of disk batteries*
  - Do not irrigate, as this will cause a flow of current, leading to further tissue destruction.
  - Do not lacerate the external auditory canal skin, as blood will allow a flow of current, thus leading to further tissue destruction.
  - The orientation of the battery in the external auditory canal can make it difficult to grasp.

- The combined use of a forceps or right-angled hook is often successful.
- Most disk batteries are magnetic, and access to a strong magnet can assist greatly in atraumatic extraction.

- *Removal of insects*

Management of insects in the ear canal requires additional material. A live insect can be difficult and painful to extract. Various solutions, including ether, isopropyl alcohol, and mineral oil, are effective in drowning the insect before flushing or extraction. Topical tetracaine (Pontocaine) or lidocaine (Xylocaine) solution can also be used to submerge and paralyze the insect in the ear canal.[3] These are readily available in all emergency room settings.

- A live, moving insect can cause pain, irritation, and potential trauma to the tympanic membrane.
- Thorough inspection should help to identify the insect and evaluate for potential trauma.
- Place patient in the supine position with the involved ear facing up.
- Drown and/or paralyze insect by filling the ear canal with ether, isopropyl alcohol, mineral oil, tetracaine, or lidocaine.
  - This may lead to a flurry of activity as the insect drowns.
  - Should the patient have severe pain, the skin of the external canal can be infiltrated with a local anesthetic.
- The insect is extracted from the canal with suction, which also removes the excess solution.
- Once the insect has been removed, the canal is carefully inspected.
  - Loose appendages such as wings or legs should be carefully removed with forceps or a fine cotton-tipped applicator.
  - The integrity of the skin of the ear canal and the tympanic membrane is verified.

- *Any vegetable material is removed.*
  - If the object is relatively dry and intact, extraction with suctioning may remove it.

- It may be necessary to place a small, right-angled hook medial to the object to manipulate it into the lateral canal.
- Irrigation should be avoided so as to minimize swelling, maceration, and disruption of the integrity of the foreign object.
  - Peas, beans, nuts, and corn have the potential to swell owing to exposure to sebaceous secretions from the canal, water from swimming or showering, or attempts at irrigating the ear canal.
- If the object is soft, crumbling, and friable and cannot be extracted with suction, irrigation may be necessary.
  - Mixing hydrogen peroxide with an equal volume of warm tap water mechanically facilitates aural irrigation.
  - An irrigating system is most effective.
  - Other systems would include a large-gauge angiocatheter attached to a syringe.
    - Large metal ear syringes are also available for this purpose.
  - Care is taken to avoid directing excessive hydraulic pressure at the tympanic membrane.

- Surgical Removal
  - A wedged foreign object may completely occlude the canal, prohibiting instrumentation and extraction. Access can be afforded through a relaxing 12-o'clock incision at the incisura, which widens the meatus (Fig. 126.3). First local anesthetic must be injected into the ear canal. This may best be done in the operating room. On rare occasions, a postauricular approach will be necessary if the object is wedged at the bony isthmus of the canal. A prominent spine of Henle or tympanomastoid suture may have to be removed or recontoured (Fig. 126.4). This is done under intravenous (IV) sedation or general anesthesia.

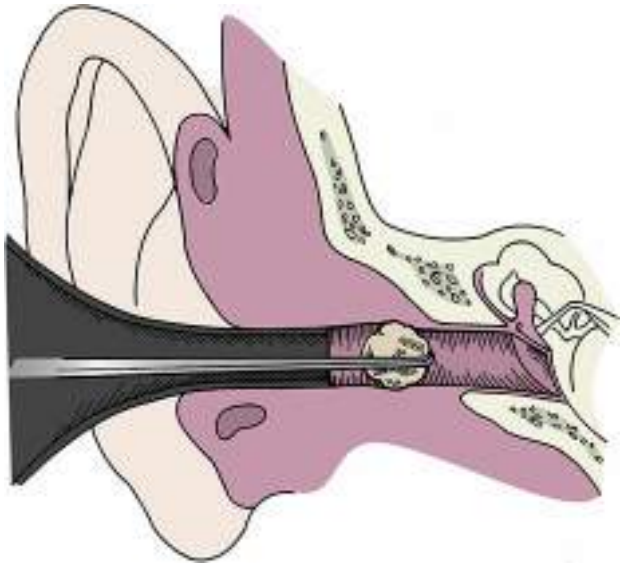

FIG. 126.3 An incision is made in the incisura (12-o'clock position) of the external auditory meatus to widen the meatus and permit an instrument to be passed medial to the foreign body.

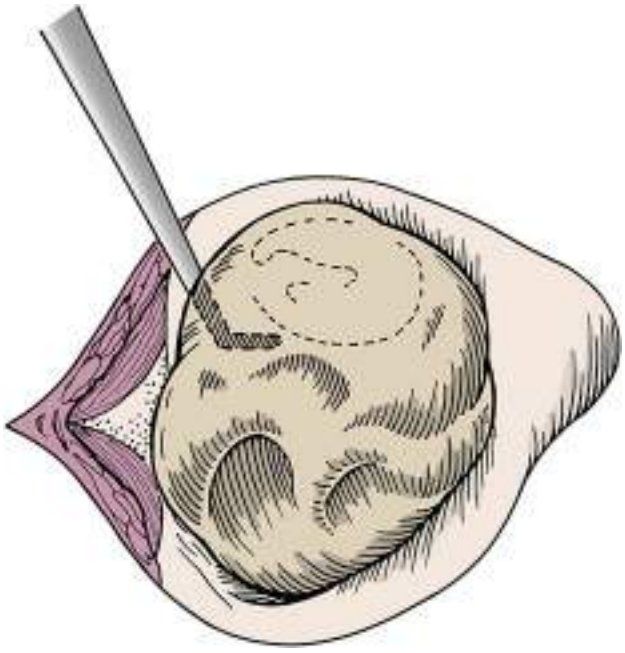

FIG. 126.4 The ear has been reflected anteriorly to expose the lodged foreign object medially.

Common Errors in Technique

1. Instrumented removal of a live insect without first drowning it can intensify the pain and stimulation experienced by the patient.

2. Instrumentation directed medially along the posterior ear canal may contact and traumatize the tympanic membrane.

3. Aggressive manipulation may result in more medial impaction and possible injury to the tympanic membrane and ossicular chain.

4. Failure to recognize and properly reapproximate lacerated canal skin may lead to trapped epithelium and the development of a cholesteatoma in the canal.

5. Repeated unsuccessful attempts at removing the foreign body will result in canal trauma, further obstruction, and an uncooperative, irritable patient.

Postoperative Period

Postoperative Management

- Atraumatic extraction
  - Atraumatic extraction of a foreign body with no associated inflammation requires no further treatment.
- Traumatic extraction
  - Should maceration or cellulitis preexist or laceration and inflammation occur during extraction, topical eardrops are advised.
  - Should there be moderate edema and concern for laceration of the canal, a wick may have to be placed.
    - Wicks, such as a Pope otowick, are meant to be placed for a short time and are generally removed after 3 days.
      - The patient may be instructed to remove the wick and continue applying topical drops.
    - If there is severe inflammation or laceration of the ear canal skin, the wick should remain for 1 week.
    - Topical drops are then continued for a few more days.

- Topical otic antibiotics, usually containing steroids, are instilled twice daily, depending on the severity of inflammation.
- The patient is instructed to avoid further water contamination by keeping the ear dry (free of swimming-pool or shower water) for 1 to 2 weeks.
- Vaseline applied to a cotton ball is usually effective in keeping the ear canal dry while showering.
- Traumatic injury to the tympanic membrane or middle ear requires early follow-up and intervention for repair, based on the nature and degree of damage.
    - Patients experiencing infection, complicated extraction, or complications related to the foreign body or its removal should be seen in follow-up within the week.

Complications

1. Infection
    a. If significant cellulitis has developed or the patient is diabetic, systemic antibiotics may be required.
    b. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the organisms most likely to be involved.
    c. Oral ciprofloxacin should be effective in treating cellulitis of the external canal.
2. Edema of the external auditory canal
    a. Patients who require stenting or packing of the external canal are also treated with topical antibiotic drops.

Alternative Management Plan

A foreign object should not be left in the canal. Successful extraction of a foreign body in the external auditory canal frequently requires a combined approach. Unless contraindicated, irrigation, suction, forceps, and a right-angled hook may be used in combination. Also, a strong magnet may assist in the extraction of a disk battery.

Discussion

Evidence-Based Medicine Question

- *Question:* When should a patient with a foreign body in the ear canal be immediately referred to an otolaryngologist instead of having removal first attempted by a primary care physician, pediatrician, urgent care facility, and/or emergency room physician?
- *Answer:* In a series of 698 pediatric patients with foreign bodies in the external auditory canal, Schulze and colleagues proposed indications for referral for otomicroscopy-guided removal. These indications were categorized by the type of foreign body (spherical or sharp-edged shape, disk batteries, and vegetable matter), location of the foreign body (adjacent to the tympanic membrane), time in the ear (>24 hours), patient description (<4 years of age, with difficulty visualizing the foreign object, agitation, or both), and a history of previous attempts at removal.[4]

Editorial Comment

Most often a foreign body in the ear canal becomes manifest by pain, otorrhea, or hearing loss. Children are much more likely to place objects in their ears. This may go unnoticed until there is a routine physical examination or sequelae develop. Adults are not excluded from this problem. Cotton buds from applicators can break off. Domes from hearing aid receivers may become lodged in the canal. Like children, adults may not be aware of the problem, thinking that the dome may simply have fallen off.

There may only be a single opportunity to remove the object, especially in the case of a child. Repeated attempts will cause the patient to become uncooperative. If the child can be restrained quickly and efficiently, extraction may be done in the office, clinic, or emergency room. Otherwise brief sedation or general anesthesia will be necessary.

Irrigation is rarely needed unless the material is friable and pasty. Use of a wider-diameter suction can be successful in extracting larger objects. This may result in excessive noise and, rarely, trauma to the tympanic

membrane or inner ear.

As with all minor medical procedures, the physician or surgeon must be experienced and know his or her skill set as well as the instruments needed. It is also important to be able to gauge the patient's tolerance of the procedure.
